ON THE SPECTRUM OF THE MORE VOLATILE GASES OF ATMOSPHERIC AIR, WHICH ARE NOT CONDENSED AT THE TEMPERATURE OF LIQUID HYDROGEN.*

(PRELIMINARY NOTICE).

By Professor G. D. LIVEING, M.A., D.Sc.,
Professor of Chemistry, University of Cambridge,
and
Professor DEWAR, M.A., LL.D.,
Fullerian Professor of Chemistry, Royal Institution, London.

In August last some tubes were filled at low pressure by an improved process with the more volatile gases of the atmosphere.† The air was liquefied directly from that above the roof of the Royal Institution by contact at atmospheric pressure with the walls of a vessel cooled below -200° C. When about 200 c.c. of liquid had condensed, communication with the outer air was closed by a stop-cock. Subsequently, communication was opened, through another stop-cock, with a second vessel cooled by immersion in liquid hydrogen, and a part of the liquid from the first vessel, maintained at -210°, was allowed to distil into the second still colder vessel. When about 10 c.c. had condensed in the solid form in the second vessel, communication with the first vessel was cut off, and a manometer showed a pressure of gas of about 10 to 15 m.m. of mercury.

This mixture of gases was passed into tubes previously exhausted by a mercury pump, but before reaching the tubes it had to pass through a U-tube immersed in liquid hydrogen so as to condense less volatile gases, such as argon, nitrogen, oxygen, or carbonic oxide, which might be carried along by those more volatile. Previous trials with tubes filled in the same way, except that the U-tube in liquid hydrogen was omitted, showed that these tubes contained traces of nitrogen, argon, and compounds of carbon. The tubes filled with gas which had passed through the U-tube showed on sparking no spectrum of any of these last-mentioned gases, but showed the spectra of hydrogen, helium, and neon brilliantly, as well as a great many less brilliant rays of unknown origin. In addition, they showed at first the brightest rays of mercury, derived, no doubt, from the mercury pump by which they had been exhausted before the admission of the gases from the liquefied air. After some sparking the mercury rays disappeared, probably in consequence of absorption of the mercury by the electrodes, which were of aluminium.

In one experiment the mixture of gases in the second vessel, into which a fraction of the liquefied air was distilled as above described, was pumped out without being passed through the U-tube in liquid hydrogen and examined. This mixture was found to contain 43 per cent of hydrogen, 6 per cent of oxygen, and 51 per cent of other gases—nitrogen, argon, neon, helium, &c.—and it was explosive when mixed with more oxygen. This shows conclusively that hydrogen in sensible proportion exists in the earth's atmosphere, and if the earth cannot retain hydrogen or originate it, then there must be a continued accession of hydrogen to the atmosphere (from interplanetary space), and we can hardly resist the conclusion that a similar transfer of other gases also must take place. The tubes containing the residue of atmospheric gases uncondensed at the temperature of liquid hydrogen we have examined spectroscopically.

On passing electric discharges through them, without any condenser in the circuit, they glow with a bright orange light, not only in the capillary part, but also at the poles, and at the negative pole in particular. The spectroscope shows that this light consists in the visible part of the spectrum chiefly of a succession of strong rays in the red, orange, and yellow, attributed to hydrogen, helium, and neon. Besides these, a vast number of rays, generally less brilliant, are distributed through the whole length of the visible spectrum. They are obscured in the spectrum of the capillary part of the tube by the greater strength of the second spectrum of hydrogen, but are easily seen in the spectrum of the negative pole, which does not include the second spectrum of hydrogen, or only faint traces of it. Putting a Leyden jar in the circuit, while it more or less completely obliterates the second spectrum of hydrogen, also has a similar effect on the greater part of these other rays of, as yet, unknown origin. The violet and ultra-violet part of the spectrum seems to rival in strength that of the red and yellow rays, if we may judge of it by the intensity of its impressions on photographic plates. We were surprised to find how vivid these impressions are up to a wave-length 314, notwithstanding the opacity of glass for rays in that part of the spectrum. The photographs were taken with a quartz calcite train, but the rays had to pass through the glass of the tube containing the gases.

We have made approximate measurements of the wave-lengths of all the rays which are sufficiently strong to be seen easily or photographed with an exposure of thirty minutes, and give a list of them below. These wave-lengths are computed to Rowland's scale, and were deduced from the deviations produced by two prisms of white flint glass for the visible, and of calcite for the in-

* A Paper read before the Royal Society, December 13, 1900.

† In this paper we describe researches in continuation of those previously communicated to the Society by one of us, in a paper entitled "Application of Liquid Hydrogen to the Production of High Vacua, together with their Spectroscopic Examination," *Roy. Soc. Proc.*, vol. lxiv., p. 231.

visible, rays. The wave-lengths assigned to the helium lines are those given by Runge and Paschen, and some of these lines were used as lines of reference. In general, the iron spark spectrum was the standard of reference.

The tubes when first examined showed the lines of the first spectrum of hydrogen vividly, and the earlier photographs of the spectrum of the negative pole contained not only the violet lines of hydrogen, but also the ultra-violet series as far up as λ 337. In order to get impressions of the fainter rays, exposures of half-an-hour or more were required, and a succession of photographs had to be taken so as to get different sections of the spectrum into the middle of the field, where measurement of the deviations would not be impeded by the double refraction of the calc spar. As the light of the negative pole only was required, the electric discharge was made continuously in one direction only, with the result that the hydrogen lines grew fainter in each successive photograph, and soon disappeared altogether. Along with the ultra-violet rays the less refrangible rays of hydrogen also disappeared, so that no trace of the C or F line could be seen, nor yet of the second spectrum, so long as the current passed in the same direction as before. Reversal of the current soon made the F line show again, so that it seems that the whole of the hydrogen was driven by the current to the positive pole. The conditions under which this ultra-violet series shows itself are a matter of interest. It appears here in the midst of a brilliant spectrum due to gases other than hydrogen, and yet it is very difficult to obtain a photograph of it when no gas but hydrogen is known to be present, or, at least, to become luminous in the electric discharge.

We have had an opportunity of comparing the spectrum of the volatile residue of air with that of the more volatile part of gas from the Bath spring. The tube did not admit of the separate examination of the light from the negative pole, but was examined end on, so that the radiation probably included rays emitted from the neighbourhood of the negative pole. The whole of the hydrogen had been removed from the Bath gas, but not all the argon. In the spectrum of this gas the rays of helium are dominant, decidedly stronger than those of neon, although the latter are very bright. In the spectrum of the residue of atmospheric air, the proportion of helium to neon seems reversed, for in this the yellow neon line is as much more brilliant than the yellow helium line as the latter is more brilliant in the spectrum of Bath gas. All the prominent lines in the spectrum of the volatile residue of Bath gas were also in that of the residue of atmospheric air except the argon lines. There were, on the other hand, many lines in the latter not traceable in the former, some of them rather conspicuous, such as the ray at about λ 4664. It is, of course, probable that such rays are the outcome of some material not contained in the Bath gas. A very conspicuous pair of lines appears in photographs of the spectrum of the air residue, at about λ 3587, which is not traceable in the spectrum of Bath gas. The helium line, λ 3587·4, is seen in the latter spectrum, but is quite obscured in the former spectrum by the great intensity of the new pair. This helium ray is really a close double, with the less refrangible component much the weaker of the two, but the new pair are wider apart, and of nearly equal intensities; this character also distinguishes them from the strong argon line at λ 3588·6. They are, however, very much more intense at the negative pole than in the capillary, and it will require a good deal more study to determine whether these rays, and many others which we have not tabulated, are due to the peculiarity of the stimulus at the negative pole, or to the presence of a previously unrecognised material.

As our mixture of gases probably includes some of all such gases as pervade interplanetary and interstellar space, we early looked in their spectra for the prominent nebular, coronal, and auroral rays. Searching the spectrum about λ 5007 no indication of any ray of about that wave-length was visible in the spectrum of any one of the three tubes which had been filled as above described. Turning to the other green nebular line at about λ 4959 we found a weak rather diffuse line to which our first measure assigned a wave-length 4958. The correctness of this wave-length was subsequently verified by measuring with a micrometer eye-piece the distances of the line from the helium lines λ 4922·1 and λ 5015·7 which were in the field of view at the same time. The position of the line was almost identical with that of the iron spark line λ 4957·8, and the conclusion arrived at was that the wave-length was a little less than 4958, and that it could not be the nebular line. There remained the ultra-violet line λ 3727. Our photographs showed a rather strong line very close to the iron spark line λ 3727·8, but slightly more refrangible. As the line is a tolerably strong one it could be photographed with a grating spectrograph along with the iron lines. This was done, and the wave-length deduced from measuring the photograph was 3727·4. This is too large by an amount which considerably exceeds the probable errors of observation, and we are forced to conclude that the nebular material is either absent from our tubes, or does not show itself under the treatment to which it has been subjected.

Although the residual gases of the atmosphere uncondensed at the temperature of liquid hydrogen do not show the nebular lines, we found that another tube gave a ray very close indeed to the principal green nebular ray. This tube had been filled with gas prepared in the same way as the others, with the exception that, in passing from the vessel into which the first fraction of liquid air was distilled, it was not passed through a U-tube immersed in liquid hydrogen on its way to the exhausted tube. In consequence it contained traces of nitrogen and argon, and when sparked showed the spectra of these elements as well as those of hydrogen, helium, &c. The nitrogen spectrum disappeared after some sparking, but the tube still shows rays of argon as well as those of the gases in the other tubes. On examining the spectrum of the negative pole in the neighbourhood of the principal nebular green ray, a weak ray was seen in addition to those given by the other tubes. It was found by comparison with the nitrogen rays λ 5002·7 and λ 5005·7 to be a little less refrangible than the latter of these rays, and by measuring its distance from the nitrogen rays and from the two helium rays λ 4922·1 and λ 5015·7 with a micrometer eye-piece, the wave-length λ 5007·7 for the new ray was deduced. This looks as if we might find the substance which is luminous in nebulæ to be really present in the earth's atmosphere, and we hope shortly to be able to verify the observation of it.

(To be continued).

DETECTION OF ARSENIC IN THE PRESENCE OF SULPHITES, &c.

By JAS. F. SMITH.

WHEN sulphuretted hydrogen and arseniuretted hydrogen are heated together a mutual reaction occurs; the products so obtained are sulphide of arsenic, sulphur, and free hydrogen.

This takes place when the gases are passed slowly through a tube heated to redness, as in Marsh's test for arsenic; it is also deposited from the flame when the mixed gases are burnt, and a piece of cold porcelain is brought into it.

The above reaction therefore forms a convenient method for the detection of arsenic in the presence of compounds of sulphur that give off sulphuretted hydrogen when treated with zinc and acid, not only in inorganic solutions, but extracts similar to beer, without previous treatment. The experiment is conducted in Marsh's apparatus, and in the same way, the only difference being in the results

obtained in the heated tube, or on cold porcelain, as above stated.

The following precautions, however, are necessary to obtain all the arsenic as sulphide in the heated tube. To add the solution under examination slowly and in small quantities of about 1 to 2 c.c. at a time to the acid and zinc, in the generating flask, and to keep the heated tube at red heat for about 1 inch in the centre, otherwise some loss may take place.

When cold the deposit is washed with a little carbon bisulphide to remove the free sulphur, and afterwards with a little sodium, potassium, or ammonium hydrate to dissolve out the sulphide of arsenic, and the tube washed with a few drops of water, two or three times, adding the washings to the solution containing the sulphide of arsenic; neutralise with hydrochloric acid, and if the quantity of precipitate is large it can be filtered off and tested by the usual methods, but if the solution is only slightly coloured yellow it must be evaporated and a few drops of strong nitric acid added and again evaporated to dryness on a water-bath, the residue taken up with a few drops of hot water, and tested by Marsh's method in the usual way.

By this, 15 parts of arsenic in 1,000,000 were detected in the presence of a large quantity of bisulphite in 5 c.c. of beer without previous treatment.

When the amount of sulphuretted hydrogen evolved is too small to effect the precipitation of all the arsenic, the sulphide is first precipitated nearest the heated part, and after the yellow sulphide a metallic deposit of arsenic, or if the gas is burnt at the end of the tube—which, of course, must not be heated—and a piece of cold porcelain is brought into the flame, there will be a yellow deposit of sulphur and sulphide of arsenic with a metallic ring round the edge of it; this can easily be tested after the removal of the sulphur and sulphide of arsenic.

The above has also been applied to antimony, which undergoes the same mutual decomposition under the same conditions; its detection and separation from arsenic can easily be carried out, as the antimony sulphide is deposited nearer the flame than that of arsenic, and sometimes a distinct line separates the two sulphides.

The antimony sulphide can easily be removed by means of dry hydrochloric acid gas after the removal of the free sulphur, and the remaining sulphide of arsenic treated as above, or the separation can be effected by any of the well known methods.

ON THE DIVISION OF NITROGEN IN CHEMICAL MANURE COMPOUNDS.

By J. OSTERSETZER, F.I.C., F.C.S.

In an article on "Nitrogen in Artificial Manures" published in 1884 (CHEMICAL NEWS, vol. l., p. 291), I have shown, by a series of laboratory experiments, how far organic nitrogen can be made soluble by the action of sulphuric acid. In the manufacture of chemical manure compounds, it is neither possible nor would it appear desirable to carry the point for dissociating nitrogenous matter to its theoretical limit. There is, however, no doubt that more or less considerable quantities of ammonium sulphate can be detected in dissolved manure compounds which derive their nitrogen from organic sources only. I have recently examined several samples of such manures and obtained the following results, viz.:—

No.	Percentage of the N made soluble.	Percentage of the N left insoluble.
I.	23·16	76·84
II.	38·30	61·70
III.	25·15	74·85
IV.	36·91	63·09
V.	28·80	71·20
VI.	29·89	70·11

It will be seen from the foregoing that, in addition to organic nitrogen homogeneously divided, a certain percentage of ammonium sulphate is thus introduced, but in a state of molecular division; that is to say, more minute than can be obtained by mechanical means, and certainly more intimate than by the rough and ready addition of commercial ammoniacal salts to superphosphate, as is frequently practised by agriculturalists when compounding their own formulæ.

This question of division has of late attracted an increased amount of attention from a theoretical as well as a practical point of view. It has frequently been found that some of the misleading—if not negative—results obtained on experimental plots could be traced to the want of homogeneous division of fertilisers; when, for instance, a thin layer of superphosphate or that of other ingredients was proved to retard the action of ammonium sulphate (J. M. Pomorski, *Zeit. Landw. Versuchs. w. Oesterr.*, 1900, iii., 649).

The chemical composition will, of course, remain the most important factor in estimating the relative value of manures, but, judging from the present current of opinion, such valuations on the one hand, and the actual methods for practical experiments on the other, will have to be supplemented by the careful investigation of the *state of division* in all its aspects.

Goulding's Manure Works, North Wall, Dublin,
December 21, 1900.

THE EFFECT OF SMALL AMOUNTS OF ARSENIC ON COPPER.

By ERNEST A. LEWIS.

The following experiments on the influence of small amounts of arsenic on the strength of copper were made by the writer, as the metallurgical and chemical text-books and journals do not appear to give any information on this subject. In Hiorn's "Metallic Alloys" it is stated that "Copper and arsenic readily combine when metallic arsenic is dropped into molten copper. When a very small quantity is thus added, the metal may be cast into a sound ingot, which contracts during solidification like phosphorised copper, and may be rolled cold and afterwards drawn into fine wire. Much arsenic is highly injurious, making the metal hard and brittle." The copper used contained—

Copper	99·843	per cent.
Oxygen	0·05	,,
Arsenic	0·007	,,

The arsenic used was commercial arsenic, containing 99½ per cent arsenic.

Six experiments were made as follows:—

Eight lbs. of copper were melted in a crucible, and to it was added enough arsenic to give the following percentages of arsenic. The copper was then cast into a test-piece, and rolled down to ¼th inch thick.

The sheets were put in cold water whilst still red-hot to scale them.

Photomicrographs were made of each of the samples of cast-metal before rolling.

	Arsenic added. Per cent.	Arsenic found in copper. Per cent.
1.	2	1·80
2.	1½	1·37
3.	1	0·94
4.	¾	0·75
5.	½	0·53
6	¼	0·24

No 1 was found to contain 1·75 per cent arsenic after rolling; this shows that the re-heating of the metal before

rolling does not affect the amount of arsenic present to any extent.

1. Rolled well.
2. Rolled very well.
3. " "
4. Rolled well.
5. " "
6. " "

Pieces of the six rolled samples were bent over and hammered up closely, both hot and cold; there was not the sign of a crack in either of them.

Tensile Tests.

	Arsenic. Per cent.	Break, in tons per square inch.	Limit of elasticity. Tons per square inch.	Elongation. Per cent.
1.	2	17·83	11·52	20
2.	1½	18·83	10·09	28
3.	1	18·02	9·01	25
4.	¾	18·31	8·91	21
5.	½	18·38	9·52	29·5
6.	¼	16·92	10·25	27·5
Ordinary sheet copper .		13·4	7	25

From the above experiments, it appears that the presence of a small amount of arsenic in copper intended for rolling is an advantage, except the copper is intended for electrical purposes. The tensile strength is from 3 to 5 tons higher than ordinary sheet copper treated in the same way, and the limit of elasticity is about 3 tons per square inch higher, and the elongation is not reduced.

From the micrographical examination of arsenical copper, it appears to consist of crystals of copper surrounded by an eutectic, which is probably arsenide of copper or a solution of arsenide of copper in copper.

There is no advantage in having more than 0·5 per cent arsenic present.

310, Dudley Road, Birmingham,
December 17, 1900.

ON THE CAUSE OF ERROR IN THE SEARCH FOR SALICYLIC ACID IN WINES.

By A. Y. FERREIRA DA SILVA.

Several Portuguese wines recently, in Brazil, have been declared to be salicylised from the fact that analysis showed traces of salicylic acid.

In this connection the author has made some experiments on wines from this and other localities (de Bastao, de Monsao, &c.), with regard to which no suspicion could be entertained as to their genuineness.

They were treated by the German method (*Zeits. für Analytische Chemie de Fresenius*, xxxv., 1896), by operating on 50 c.c. (not more), of acidulated wine, which was shaken up with a mixture of equal volumes of ether and petroleum ether, or on 200 c.c. of wine which was shaken up with ether, adopting the method of Pellet, Grobert, and Baudrimont, which has been used in the laboratories of Brazil since 1888.

The German method has in no case given a violet colouration with perchloride of iron; that is to say, the results were always negative; at the same time the method is exact and delicate.

By the Pellet-Grobert method a pale rose, or a violet-red colour was obtained from several samples, which an unsuspecting analyst would certainly take as an indication of traces of salicylic acid.

This latter method is therefore one which may cause perfectly natural wines to be returned as salicylised, and is thus erroneous.

It is thus undeniable that in certain Portuguese wines a small quantity of a substance may be met with closely resembling salicylic acid, which can be extracted by means of ether in sufficient quantity to give a colouration with perchloride of iron, resembling that of salicylic acid, when a considerable volume of wine is used for the operation. This fact, which is new as regards Portuguese wines, will account for the results obtained in Brazil, and is in fact the true explanation.

They are not salicylised wines, but they naturally contain a small proportion of a substance resembling salicylic acid in its reactions.

At the meeting of German chemists at Erlangen, in 1890, Professor L. Medicus mentioned an exactly similar occurrence in the case of some Austrian and German wines. He was of the opinion, from experiments made, that the principle analogous to salicylic acid came from the grape stalks.

Whatever it may be, the fact is of great analytical importance.

If in the search for salicylic acid, in cases of supposed falsification, we make use of the Pellet, Grobert, Baudrimont, or other method, in which we have to use a considerable volume of wine, we run the risk of obtaining a coloured reaction, falsely resembling that of salicylic acid, and therefore of declaring as salicylised wines which do not merit that description.

We are thus in accord with Professor Medicus in recommending that in the search for salicylic acid, no more than 50 c.c. of wine should be taken, which is the volume indicated when using the official Austrian and German methods.

The sensitiveness of this process being greater than 1 per 200,000, we are perfectly able to detect 5 m.grms. of salicylic acid per litre, or 0·5 grm. per hectolitre, a quantity which is much less than that required for the conservation of wine (3 to 8 grms. per hectolitre). We may therefore rest assured that fraud will be detected by this process, and at the same time no errors will be committed.—*Bull. Soc. Chim.*, Series 3, xxiii., 795.

THE ESTIMATION OF MANGANIC ACID IN THE PRESENCE OF MANGANOUS SALTS BY MEANS OF ARSENIOUS ACID IN ALKALINE SOLUTION.

By T. REICHARD.

It often happens in making an analysis, that we have to estimate the manganous salts as well as those of manganic acid. In such a case as this, very good results can be obtained by making use of the arsenious acid process, previously described but slightly modified. If the solution contains manganates or permanganates, we add a certain quantity of soda-lye, so that the manganous salt will be completely precipitated in the form of manganous hydrate or manganoso-manganic hydrate. It is then only that we add the titrated solution of arsenious acid in excess. The residue, collected on a filter, is weighed. The difference between the total amount of manganese found by the gravimetric method, and that given by the volumetric method, represents the quantity of the metal which exists in the state of manganous salt, in the substance under examination.

We may also proceed in another different manner, subject, however, to starting with solutions as neutral as possible, and working in the absence of iron and chromium. This second method depends on the fact that the manganous salts are completely precipitated at about 80°, by permanganate of potash. Finally, a third method is founded on the precipitation of the manganous salts, in the form of arsenites, by alkaline solutions of arsenious acid, at the same time that the permanganate is decomposed. The products of decomposition, manganous hydrate and arsenite of manganese, are thrown on a filter,

and, in the filtered solution, the quantity of arsenious acid which has not taken part in the solution is estimated by means of a solution of iodine.

The contents of the filter are dissolved in sulphuric acid, and the amount of arsenious acid, existing in the form of arsenite of manganese, is estimated by means of a titrated solution of permanganate of potassium. The different figures thus obtained enable the proportion between the two compounds of manganese to be established.—*Chemiker Zeitung*, xxiii., p. 867.

ON AN EUCALYPTUS OIL CONTAINING SIXTY PER CENT OF GERANYL ACETATE.*

By HENRY G. SMITH, F.C.S.,
Assistant Curator, Technological Museum, Sydney.

IN this paper the author shows that the oil of *Eucalyptus macarthuri*, known locally as Paddy's River Box, is very rich in geraniol, it containing 60 per cent of geranyl acetate, and 10·64 per cent of free alcohol, calculated as geraniol. The oil is somewhat analogous with that obtained from *Darwinia fascicularis*, brought under the notice of this Society by Mr. R. T. Baker and the author in December, 1899. Both *Darwinia* and *Eucalyptus* belong to the natural order Myrtaceæ. The oil of *E. macarthuri* contains eudesmol (the stearoptene of Eucalyptus oil), the fraction distilling between 266—282° C., crystallising quite solid in the bottle. This substance is absent in the oil of *Darwinia*. The yield of oil from this Eucalypt, collected in October from near Wingello, in this colony, and obtained by steam distillation from fresh leaves and branchlets, was 0·112 per cent. The whole of the ester was saponified in the cold by alcoholic potash in one and a half hours. As no heat was applied, the separated oil was excellent, the geraniol not being interfered with. This fact of cold saponification of geranyl acetate might be used for quantitative determination of this ester, when it and other esters are present in essential oils. Citral was obtained by oxidation, and the pure geraniol prepared from the calcium chloride compound; this was a colourless oil boiling at 224—225° C. (uncor.), and had a specific gravity of 0·885 at 20° C. The acid of the ester was shown to be acetic acid. The crude oil contained neither eucalyptol nor phellandrene, it was entirely different in appearance and constituents from ordinary Eucalyptus oil. It formed a clear solution with two volumes of 70 per cent alcohol, it had an optical rotation of +3·6° in a 100 m.m. tube, and specific gravity at 15° C. of 0·9245, the comparatively high specific gravity being due to the presence of the stearoptene.

The Separation of Dithionic Acid from the other Acids of Sulphur.—A. Lingi and L. Bonavia.—The method proposed is based on the fact that all the lower acids, with the exception of dithionic acid, are oxidised in alkaline solution by permanganate or hypobromite of potassium. After oxidation the solution is acidulated with acetic acid, and the sulphuric acid precipitated by a very slight excess of acetate of baryta; let stand for some hours at 40° and filter. The filtrate is treated with aqua regia, or hydrochloric acid and potassic chlorate, and chloride of barium. After prolonged heating on the water-bath this fresh precipitate of sulphate of barium, formed from the dithionic sulphur, is collected.—*Gazz. Chim. Ital.*, p. 341.

* A Paper read before the Royal Society of New South Wales, November 7, 1900.

THE SEPARATION OF TUNGSTEN TRIOXIDE FROM MOLYBDENUM TRIOXIDE.*

By MAX J. RUEGENBERG and EDGAR F. SMITH.

THE separation of tungsten from molybdenum is always of interest to those who are brought in contact with analytical methods. It has been the subject of numerous investigations and much discussion, and while comparatively good methods exist for this purpose, the analyst continues to seek for others, hoping that eventually he shall find a procedure which will be satisfactory in all respects and under nearly all conditions.

The writers have not discovered the method *par excellence*, but desire to offer briefly, in the following lines, their experience in pursuing a suggestion made in an article emanating from this laboratory; viz., "tungstic acid is . . . . insoluble in concentrated or dilute sulphuric acid, hot or cold, whereas molybdenum trioxide is very easily and rapidly dissolved, so that we have in this deportment a very simple and exact method for the separation of the two metals" (En. D. Desi, *Journ. Amer. Chem. Soc.*, xix., 242).

No analytical data accompanied this declaration; therefore it seemed not improper to attempt to learn the conditions most favourable for the separation. Upon trial it was found that sulphuric acid of specific gravity 1·378, dissolved molybdenum trioxide very readily and apparently did not affect the tungsten trioxide. Acid of this concentration was therefore used with the following mixture of the two oxides:—

1. 0·7355 grm. of tungsten trioxide and 0·0185 grm. of molybdenum trioxide were digested for a few minutes with 25 c.c. of warm sulphuric acid. The insoluble portion was filtered out, and washed with water containing sulphuric acid. After drying, it was ignited and weighed. It equalled 0·7350 grm.

The other trials, conducted in precisely the same manner, were as follows:—

	II. Grms.	III. Grms.	IV. Grms.	V. Grms.	VI. Grms.
Tungsten trioxide taken	1·0638	0·0871	0·3588	0·8868	0·5996
Molybdenum trioxide taken	2·2712	0·6871	1·1836	1 1986	1·0770
Tungsten trioxide found	1·0630	0·0870	0·3587	0·8866	0·5996

The filtrate containing the dissolved molybdic acid showed no tungstic acid upon examination.

These results indicate that where the two oxides are present together this mode of separation is apparently of value and merits consideration.

A weighed quantity of a ferric salt equivalent to 5 grms. of ferric hydroxide was precipitated with ammonia water, and the resulting precipitate, after being washed, was mixed in a beaker with different amounts of tungsten trioxide, and the resulting mixture was then digested with sulphuric acid of the strength of that used in the preceding experiments. The residual oxide was treated as before:—

	I. Grms.	II. Grms.	III. Grms.	IV. Grms.	V. Grms.	VI. Grms.
Tungsten trioxide taken	0·5282	0·2087	1·3270	0·2004	0·9091	0·2263
Ferric hydroxide taken	5·0000	5·0000	5·0000	5·0000	5·0000	5·0000
Tungsten trioxide found	0·5278	0·2086	1·3265	0·2003	0·0988	0·2262

We may conclude from these trials that the solubility of the trioxide in the sulphuric acid is in no wise affected by the presence of the iron.

THE ALLOTROPIC FORMS OF SELENIUM.*

By A. P. SAUNDERS.

(Continued from vol. lxxxii., p. 310).

5. *Metallic Selenium.*

SOME of the methods by which this modification can be obtained from the other have been already indicated. It is in the mass a steel-grey metallic substance; when powdered, it gives a black powder, but if the grinding be made finer still, the substance is seen to be red. Thus, if a little of the powder be rubbed upon a soft porcelain plate, it becomes so red that it cannot be distinguished from the other forms in the same state of division. There are in the literature many conflicting statements regarding the powder and streak of this modification. Thus, Rathke (1869), states that it is black, even in the finest powder; and the streak is almost always given as black. Mitscherlich, on the other hand, observed that the streak was red. In my experiments on the changes of the amorphous form in liquids, I observed that the powder which results in quinoline and some of the other compounds used, while it appears black to the eye, always shows a purplish colour under the microscope; and it is easy to rub this into a red powder in the way indicated.

In view of the possibility of a reverse transformation from the metallic form back to the vitreous at lower temperatures, I made some experiments upon the red powder obtained from metallic selenium in order to show that it really retained the properties of that form. The first of such experiments was made with some of the powder out of quinoline, and was far from reassuring. I found that when this is rubbed up very fine, so that it is quite red, and then treated with carbon disulphide, it gives a coloured solution, indicating the presence of one of the soluble forms of selenium. The powder obtained from some grey metallic selenium, which had been prepared by heating the vitreous form for some time to 150°, gave the same result, although in this case the resulting colour was less intense. When selenium is dissolved in hot sulphuric acid to purify it, there is often a separation of crystals about the upper surface of the liquid. They are in the form of grey metallic scales, and as they separate at a high temperature, it was to be assumed that they would be quite free from the amorphous modification. When finely powdered, they also give a red powder, and this when brought into contact with carbon disulphide colours it, though only very slightly. Plainly, then, the purer the metallic modification is, the less soluble is its powder, in carbon disulphide; and I presume therefore, that if one could prepare the metallic modification in quite pure condition, it would no longer show this property at all. With regard to the presence of soluble selenium in the metallic form which was prepared from the vitreous substance, Petersen (1891), has observed the same thing. He found that the purest metallic selenium he could prepare always contained about 1 per cent of a form soluble in carbon disulphide.

The quantity of material used in the above tests was small, but it has been mentioned in speaking of soluble selenium that one part of that material in 10,000 parts of water imparted a distinct colour to the solution; hence the quantity of the soluble form which would be required to colour 1 or 2 c.c. of carbon disulphide would, without doubt, be extremely small.

In making some experiments upon the effect of heat on these red powders, I found it impossible to prepare one which did not turn grey on heating to about 200° in an air-bath; but on rubbing up again, even at that temperature, the red colour always reappears. This observation I am somewhat at a loss to explain. It is due, perhaps, to an alteration in the state of aggregation, but how this is brought about with a substance which melts sharply at 217° without previous softening, and in a powder which is a mixture of selenium and foreign matter, it would be difficult to say.

In addition to the method of preparation by direct transformation of the other forms, metallic selenium may be obtained by the spontaneous decomposition of solutions of the alkali selenides in contact with the air; it then forms a crust consisting of very small crystals, which were considered by Berzelius to be tetragonal.

Fabre (1887), mentions that selenium separates in the metallic form when hydrogen selenide is decomposed by moist oxygen. It is soluble in many organic liquids at high temperatures; in the dilatometer experiments recorded above, beautiful, leaf-like crystals were obtained on heating to 230° with quinoline, and cooling down. Ethyl benzoate, aniline, naphthalene, and other organic substances also dissolve it at high temperatures.

Fröbel (1840), made a microscopic study of the crystals which separate from a solution of ammonium selenide, and pronounced them to be orthorhombic.

The crystal form of metallic selenium has been studied by Muthmann (1890), who prepared the crystals by sublimation. Earlier observers had in most cases studied those crystals which separate from solutions of selenides of the alkalis, and in this way none were obtained of sufficient size to make measurements possible. Muthmann finds them hexagonal, rhombohedral, and fully isomorphous with tellurium. The observed faces were ∞R and R.

6. *Heat Conductivity.*

Bellati and Lussana (1887), observed that the heat conductivity of selenium was increased by illumination. They covered a circular plate of crystalline selenium with a double salt HgI_2CuI_2, and heated it at a point by means of a hot platinum wire. The double iodide is red at ordinary temperatures, brown above 70°, and hence the area of change of colour is a measure of the heat conductivity. They guarded against heating effects from the source of light, and found that direct sunlight increased the heat conductivity 8—25 per cent. Even the light of a gas flame had a perceptible effect.

7. *Heat of Transformation of Liquid Selenium into the Metallic Modification.*

The first determination of this heat value was made by Regnault (1856). The figures obtained by him have scarcely more than a qualitative value, but are quoted here for the sake of comparison with the later results of Petersen (1891).

Regnault's method was to place a mass of about 200 grms. of vitreous selenium in an oven at 100°. A thermometer standing in the selenium was then read every minute. When the temperature reached about 98° the substance began to go over to the metallic form, and the temperature rose to about 214°, subsequently dropping to 100°. The main corrections are (1) for the heat absorbed in the containing vessel, and (2) for the loss by radiation; the first of these is made on the basis of a previous determination of the water-equivalent of the vessel, the second by noting the normal rate of change per minute in the temperature of the selenium when no transformation was going on in the mass. Regnault reached the conclusion that the reaction set free enough heat to raise the temperature of the selenium from 98° to about 329°, *i.e.*, through 231°. A second determination was made by another method, which is even less exact, and the results so obtained indicated that the heat of reaction would raise the mass of selenium from 0° to 180°.

Regnault concludes that vitreous selenium in passing over to the metallic form sets free enough heat to raise its own temperature about 200°. In other words, taking the specific heat of vitreous selenium as 0·1, we have the value about 15 K for 1 grm.-equivalent of selenium.

Before passing on to consider the determination of Petersen we must mention the researches of J. Thomsen (*Thermochem. Unters.*, ii., 269, 313), which bear indirectly

* From the *Journal of Physical Chemistry*, vol. iv., No. 6.

upon this point, and are of especial interest in connection with a possible difference between the vitreous and amorphous forms of selenium. Thomsen determined firstly the heat involved in the reaction :—

$$SeO_2Aq + 2HClAq + 2NaSHAq = = 2NaClAq + 2H_2O + Se + S_2.$$

The solutions used had the molecular composition :—

A.. .. .. $NaSH + 616{\cdot}7\ H_2O$.
B.. .. .. $SeO_2 + 2HCl + 1500\ H_2O$.

In each experiment 1/30 of the corresponding weight of A and 1/60 of that of B was used.

The total heat value is made up as follows :—

$$R = \begin{cases} 2(NaOHAq, HClAq) - 2(NaOHAq, SH_2) \\ + 2(H_2,O) - 2(H_2,S) - (Se,O_2,Aq). \end{cases}$$

R is found experimentally to be 733·98 K; introducing this along with previously known values, we get—

$$733{\cdot}98 = 274{\cdot}80 - 249{\cdot}80 + 1367{\cdot}14 - 94{\cdot}80 - (Se,O_2,Aq).$$

whence $(Se,O_2,Aq) = 563{\cdot}36$. It will be seen from the nature of this reaction that the heat value here found refers to amorphous selenium.

Thomsen determined, secondly, the heat of formation of the chloride Se_2Cl_2 from "ordinary amorphous selenium, prepared by cooling the melted substance," *i.e.*, from the vitreous form.

Three separate determinations gave 221·29—219·85—223·35, the mean being 221·5. From the chloride Se_2Cl_2 he determined the heat of formation of the chloride $SeCl_4$, and finally, by finding the heat of reaction of this substance with water, obtained as an independent result for the reaction (Se,O_2,Aq), 559·86. Thomsen considers these two results in satisfactory agreement, although he suggests that a slight difference in the physical state of the selenium in the two cases may explain the variation. It is of interest to note that the difference is in the direction of greater heat of reaction for selenium in the amorphous state. This falls into line with what is said below in the chapter on specific gravities, regarding a possible difference between the two forms.

Fabre (1887), measured the heat of transformation of liquid selenium into crystalline, by placing the material in the calorimeter, and warming it by adding sulphuric acid to water in a larger tube, which surrounded the one containing the selenium; after the reaction was over, these tubes were broken, and a correction then introduced for the heat of dilution of the sulphuric acid in the total water-content of the calorimeter.

By this ingenious device, he was able to measure directly the heat of reaction. His results are as follows :—

For 1 grm.-equivalent of vitreous selenium—

52·2 57·2 58·2 Mean, 55·8 K.

For red precipitated selenium—

55·8 51·2 Mean, 53·4.

These results are practically identical within the limit of experimental error. They indicate that Regnault's value is far too low, a conclusion that is only confirmed by later results. The material used by Fabre was afterwards tested as to its specific gravity, and found to give as a result 4·78 for the first, and 4·79 for the second; hence the transformation was probably complete.

Fabre used an indirect method to confirm these conclusions, namely, the action of bromine in bromine water, upon selenium. For the metallic modification he found the values 431·6—432·4—421·0; mean, 429. Unfortunately, we are not told how the material was prepared.

The crystals which separate from solutions of selenides of the alkalies gave 432—434; mean, 433. Vitreous selenium prepared by rapid cooling, on a porcelain plate, from the fused state, gave 480—495·6—485·2; mean, 486·8. The difference in the two cases may be taken at about 57 K, a result which agrees fairly well with that obtained by direct measurement.

Finally, Petersen (1891), re-determined by indirect methods the heat of transformation from the amorphous to the metallic and to the red crystalline form.

For the heat of formation of the chloride Se_2Cl_2 from vitreous selenium prepared by pouring the melted element into water, he obtained values which vary in four experiments from 240° to 250° K. Thomsen's value obtained from essentially the same material was 221·5. Petersen finds in this difference ground for the assumption that there are two different soluble vitreous forms of selenium. It is much more likely that these variations are experimental, especially since Petersen has himself shown that vitreous selenium always contains more or less of the metallic modification.

From the monoclinic red crystals which separate out of carbon disulphide, Petersen finds the heat of formation of the chloride Se_2Cl_2 to be 207·5 K. From Thomsen's data, using this value, we obtain for the heat of formation of the oxide SeO_2 from the monoclinic form, 562·0 K. Deducting this from 572·5, Thomsen's result for the oxidation of amorphous selenium, we get 10·5 K as the heat of transformation of that form into the red crystalline. By a direct comparison of the results for the heat of formation of the chloride from monoclinic and vitreous selenium we find quite a different value; but they both point at least in the same direction, that the heat value in the change from liquid selenium to monoclinic red, is positive.

Metallic selenium was prepared by Petersen by heating the element to 250°, then cooling to 180°, maintaining this temperature for a long time, and then slowly cooling. So prepared, it contains about 1 per cent of soluble selenium. The value for the heat of formation of the chloride Se_2Cl_2 from this form is 200·0 K, and for the crystals from selenide solutions 199·8 K. This gives, by calculation, for the heat of formation of the oxide SeO_2 from metallic selenium 558·2 K, a value which differs by 14·3 from Thomsen's result for the amorphous form. It should be mentioned that Petersen, in quoting Thomsen's data, makes a correction of 9 K in them for the heat of solution of SeO_2, as Thomsen's results refer to reaction in solution. Summing up the results thus far obtained, we have for the heat of transformation of liquid into metallic selenium :—

Regnault (direct)	15 K
Fabre (direct)	55
,, (indirect)	57
Petersen (indirect)	14·3

For the change from the amorphous to the vitreous form we have the very doubtful value deducible from Thomsen's results, 3·5; and for the transformation from that form to the red monoclinic, 10·5.

8. *The Specific Heat of Selenium.*

Determinations of the specific heat of liquid selenium at any temperatures above 60° necessarily give uncertain values because of the danger of some of the element going over to the crystalline form. The heat set free in this transformation has so large a value that the change of even a very small quantity would utterly falsify the results. The determinations of the specific heat of the crystalline form are not open to this objection, provided the transformation into this form has been effected completely.

The data regarding the specific heat of the different modifications of selenium are to be found in the papers of Regnault (1840 and 1856), Neumann (1865), and Bettendorf and Wüllner (1868). Regnault's first determination was undertaken with some material which showed no appreciable sulphur content, but which was not tested for tellurium; nor are any particulars given as to how the material was treated before the determinations were made. The values, when compared with later results, show that he had in hand here, in all probability, the grey metallic modification. The two forms were not well differentiated at that time. Regnault made three determinations, and

found for a range of temperature from 98° to 12°, the values :—

0·08349 0·08396 0·08368 Mean, 0·08371

Sixteen years later he returned to the subject. This time he made himself familiar with the change from the vitreous to the metallic form. An analysis of the material gave Se 97·75 per cent, Te 2·25 per cent. Here again we have no information concerning the preparation of the material, but are told merely that it was metallic selenium. The results for a range from 98° to 20° are 0·07517, 0·07563, 0·07675, 0·07709; mean, 0·07616. The method used by Regnault in both of these investigations was the ordinary calorimetric one, by heating the substance to a higher temperature, dropping it into a large mass of water, noting the rise in temperature, and correcting for the alteration in this rise due to radiation, and to the cooling effect of the surrounding atmosphere.

A determination with vitreous selenium between 87° and 19° gave the results :—

0·1036 0·1026 Mean, 0·1031.

At lower temperatures the values were as follows :—

Vitreous form	−27 to +8°	0·07461
	−20 to +7°	0·07476
	Mean,	0·07468
Metallic form	−20 to +7°	0·07323
	−16 to +7°	0·07570
	Mean,	0·07446

Thus at low temperatures the specific heat appears the same whichever form we have in hand. These results show a large variation from the earlier ones of the same author; it is unfortunate that no information is given regarding the preparation of the material; there are not even sufficient data to make possible a re-calculation of the results.

In the light of his earlier values, and of the later work which we shall have to consider below, there can be little doubt that the specific heat of metallic selenium is about 0·084, a value which varies widely from the above. It is difficult to imagine that Regnault by any error used vitreous in place of metallic selenium in the later determination; on the other hand, it is possible that he was here dealing with the red crystalline form; true, the direct production of this modification from the vitreous has never been observed with certainty, but it is not in the nature of the case impossible; and there are other isolated instances on record where the assumption of such a change is at least a convenience.

The next specific heat determinations are those made by Neumann, in Göttingen, in 1865. The method used was Regnault's. His experiments were confined to the metallic form which, it is to be inferred, was prepared by heating vitreous selenium in the water-bath. As a mean of thirteen determinations, varying from 0·0847 to 0·0872, he finds the value 0·0860. Neumann used an arbitrary thermometer, but the range over which he worked was from the temperature of boiling water down to about 21°.

Finally, in 1868, Bettendorf and Wüllner published the results of their determinations. They followed essentially the same method as Regnault, simplified in certain details according to the procedure of Kopp. Their statement that Regnault prepared his material by heating the red powder obtained from selenious acid solutions finds no support in Regnault's original papers. Furthermore, their conjecture that Neumann worked with a mixture of two forms is unnecessary. It is based on the abnormally low value for the specific gravity of Neumann's material, but this is shown elsewhere to have been most probably due to experimental error.

Metallic Selenium.—Bettendorf and Wüllner prepared their material by heating amorphous selenium in an air-bath at 100° for a week. The substance was then grey in colour, and had the specific gravity 4·797. Their values are :—

0·0840, 0·0839, 0·0846, 0·0841, 0·0828, 0·0850, 0·0870, 0·0829, 0·0825; Mean, 0·0840.

The range of temperature being from 60° down to 25°.

A second specimen prepared in an entirely different way gave the same result :—The material in this case was the crystals which separate from solutions of selenides of the alkalis on standing in contact with the air. The following values were obtained: 0·0842, 0·0838, 0·0836, 0·0847, 0·0835: or in the mean, 0·08399, the range of temperature being the same as before.

Vitreous Selenium.—The material was prepared by dropping melted selenium into cold water; since vitreous selenium softens at 40° to 50° the determinations were restricted to temperatures below 38°. The results are as follows :—0·0952, 0·0958, 0·0950; mean, 0·0953, the range of temperature being from 38° to 20°. For higher temperatures, the following results were obtained :—

Temperature.	Specific heat.
53—22°	0·1104
62—20°	0·1147

There is a possibility that these large values may be due to a certain amount of the selenium having gone over to the metallic form. They could be checked by making a determination in the reverse way, *i.e.*, by introducing the cold substance into a hot bath; here, if any such change went on, the values would come out too low.

The above results are, in summary as follows :—

Vitreous Selenium.

Temperature.	Specific heat.	Observer.
87 to 19°	0·1031	Regnault II.
−25 to + 8°	0·0747	—
38 to 20°	0·0955	B. and W.
53 to 22°	0·1104	—
62 to 20°	0·1147	—

Metallic Selenium.

98 to 12°	0·0837	Regnault I.
98 to 20°	0·0762	Regnault II.
−20 to + 7°	0·0745	—
100 to 20°	0·0860	Neumann
60 to 25°	0·0840	B. and W.

Person (*Ann.*, 1849, [3], xxvii., 263), determined the specific heat of ordinary bees' wax, a substance which, like vitreous selenium, gradually softens on being warmed. His results are :—

Temperature.	Specific heat.
−21 to 3°	0·4287
6 to 26°	0·504
26 to 42°	0·82
42 to 58°	1·72

(To be continued).

"Knowledge" Diary and Scientific Handbook for 1901.—The scope of this book is principally astronomical, though it also includes a historical summary of the advance of science in the nineteenth century. Among the principal contents may be noted tables of the most important astronomical phenomena of the year, and twelve star maps showing the night-sky for every month of the year, with a full descriptive account of the visible constellations and principal stars. The calendar of notable scientific events is very complete and full of interest. The diary portion of the book allows of a whole page to a day, besides the usual pages for cash, &c.

THE ACTION OF REDUCING AGENTS UPON NITROGEN IODIDE.*

By F. D. CHATTAWAY and H. P. STEVENS.

All ordinary reducing agents when brought into contact with nitrogen iodide, suspended in water, rapidly decompose it. In these reactions the different reducing agents are invariably oxidised while hydriodic acid and ammonia are produced. The quantity of reducing agent oxidised is found in every case to be exactly double the amount equivalent to the hydriodic acid produced, using nitrogen iodide obtained by any method. The action of sodium sulphite, sulphurous acid, arsenious oxide, antimonious oxide, stannous chloride, and hydrogen sulphide has been investigated with the following results:—

Amount of reducing agent oxidised—

Na_2SO_3 H_2SO_3 As_2S_3 Sb_2O_3 $SnCl_2$ H_2S

Amount of hydriodic acid simultaneously produced—

HI HI 2HI 2HI HI HI

All the iodine contained in nitrogen iodide therefore behaves towards reducing agents like the chlorine contained in a hypochlorite, and exerts twice its normal oxidising action.

Action of Sodium Sulphite on Nitrogen Iodide.

When a solution of sodium sulphite in excess is added to nitrogen iodide suspended in water, rapid interaction ensues, and a colourless solution, somewhat acid from the presence of hydriodic acid, results.

If the sulphite be added slowly from a burette a liquid coloured brown by free iodine is obtained when the solid has entirely disappeared; the end-point of the reaction is then easily seen by the disappearance of the colour, or starch paste may be used as an indicator. The hydriodic acid produced can afterwards be estimated in one of several ways; the most convenient, and the one usually adopted, is to titrate the clear solution with standard silver nitrate, using the blue so-called "iodide of starch" as indicator (Pisani, *Annal. d. Min.*, x., 83). The actual operation is carried out as follows:—Nitrogen iodide prepared in any one of the ways previously described (Chem. News, lxxxii., p. 63), is rapidly filtered off through asbestos by the aid of a pump, and thoroughly washed with decinormal ammonia, and finally, once with water. A number of 250 c.c. flasks having been prepared, about 0·2—0·5 grm. of the moist iodide is placed in each with about 25 c.c. of water, and titrated as rapidly as possible with decinormal sodium sulphite, shaking gently the while. The estimation of hydriodic acid by silver nitrate is then carried out in the ordinary way. Light must be rigorously excluded while washing and transferring the nitrogen iodide to the flask, and during the titration until all solid particles have disappeared.

In the tables where the results are recorded the amount of reducing agent oxidised is stated in the second line, that of the hydriodic acid produced in the third, while in the fourth is the ratio between the reducing agent oxidised and the hydriodic acid produced, calculated to the third decimal place.

The Roman numerals in the first column refer to the mode in which the nitrogen iodide used was prepared. The experiments numbered I. were made with amorphous nitrogen iodide prepared by adding a decinormal solution of iodine in potassium iodide to a strong solution of ammonia; those marked II. with material prepared similarly but using a normal solution of iodine. In those numbered III. the nitrogen iodide was made by treating finely powdered iodine with a strong solution of ammonia; in those numbered IV. iodine, precipitated by diluting a saturated solution of iodine in potassium iodide, was used. In preparing the material for those numbered V. an alcoholic solution of iodine,* and for those marked VI. a solution of iodine monochloride was added to a saturated solution of ammonia. In experiments VII. and VIII. crystalline nitrogen iodide was employed, prepared respectively by adding ammonium hydroxide to a solution of potassium hypoiodite, and by heating amorphous nitrogen iodide with ammonia, and rapidly cooling. In those numbered IX. the nitrogen iodide was prepared by adding an excess of a solution of bleaching-powder to a solution of ammonium iodide.

Although in the tables one result only with each specimen of nitrogen iodide is given, this has in every case been confirmed by from 22 to 30 concordant experiments:

Number of experiment.	N/10 $\frac{Na_2SO_3}{2}$ oxidised.	N/10 HI produced.	Ratio.
	C.c.	C.c.	
I.	87·1	43·6	2 : 1·001
II.	68·2	34·1	2 : 1
III.	47·1	23·6	2 : 1·002
IV.	70·5	35·3	2 : 1·001
V.	86·2	43·2	2 : 1·002
VI.	138·2	69·1	2 : 1
VII.	60·8	30·4	2 : 1
VIII.	98·1	49·1	2 : 1·001
IX.	80·7	40·3	2 : 0·999

In order to establish beyond question this ratio between the sodium sulphite oxidised and the hydriodic acid produced, series of experiments have been made in which the latter was estimated by other methods.

In the following series, after the decomposition of sodium sulphite, the hydriodic acid was oxidised by iron-alum and sulphuric acid, and the liberated iodine distilled off and titrated by the same sulphite solution. The distillation was carried out in a special form of apparatus (Chem. News, lxxix., 85), in which only ground glass joints are employed, and to prevent bumping, a very slow stream of carbon dioxide is led in by a capillary tube to the bottom of the boiling liquid:—

Number of expt.	N/10 $\frac{Na_2SO_3}{2}$ oxidised by nitrogen iodide used.	N/10 $\frac{Na_2SO_3}{2}$ oxidised by iodine liberated from hydriodic acid produced.	Ratio.
	C.c.	C.c.	
I.	46·0	23·0	2 : 1
II.	42·1	21 1	2 : 1·002
III.	52·7	26·3	2 : 0·998
IV.	65·6	32·7	2 : 0·997
V.	45·0	22·5	2 : 1
VI.	48·6	24·3	2 : 1

Exactly similar results were obtained when the hydriodic acid formed was estimated by adding an excess of silver nitrate, and then determining the excess by a standard solution of potassium thiocyanate.

In connection with the action of reducing agents a number of experiments were made to show the necessity for the exclusion even of the diffused light of a laboratory when working with nitrogen iodide. Some amorphous nitrogen iodide prepared by adding a solution of iodine monochloride to ammonia was taken, and carefully washed with decinormal ammonia. Approximately equal quantities were then placed in four flasks; that in flask A was titrated immediately with sodium sulphite; that in flask B was exposed to the diffused light of the laboratory on a dull winter afternoon for five minutes, and then titrated; that in C was similarly exposed for ten minutes; that in D for twenty minutes. The hydriodic acid formed in each case was afterwards estimated by silver nitrate,

* From the *American Chemical Journal*, xxiii., No. 5.

* In these cases a small residue of iodoform was left in the flask after titration.

and the ratio calculated between this and the sulphite oxidised.

	$N/10 \frac{Na_2SO_3}{2}$ oxidised.	N/10 HI present.	Ratio.
	C.c.	C.c.	
A	74·8	37·4	2 : 1
B	71·5	39·2	2 : 1·100
C	65	38·2	2 : 1·17
D	73·2	49·1	2 : 1·34

It is seen that the ratio diminishes as the time of exposure increases. This is due to a decomposition of some of the nitrogen iodide into nitrogen and hydriodic acid, a change which occurs whenever the substance is exposed to light.

A solution of sulphurous acid behaves toward nitrogen iodide as sodium sulphite does; a further action, however, accompanies this, similar to the one occurring when nitrogen iodide is exposed to light, whereby a small portion breaks up into nitrogen and hydriodic acid. This latter, as it is estimated, with that produced by the reducing agent, causes the ratio to appear too low. If, however, the amount due to the reaction with the sulphurous acid be calculated from the ammonia formed, as can easily be done when the composition of the substance is known, the quantity of sulphurous acid oxidised is found to be exactly double that equivalent to the hydriodic acid produced.

(To be continued).

CORRESPONDENCE.

MARSH'S TEST FOR ARSENIC.

To the Editor of the Chemical News.

Sir,—As considerable difficulty has been experienced when testing by Marsh's test for arsenic in the presence of sulphites, I have had occasion to thoroughly investigate the influence of these compounds upon Marsh's test, and after successfully employing for the last few weeks a filter-paper moistened with a solution of lead acetate in the first part of the chloride of calcium tube, as suggested by Mr. Estcourt (Chem. News, lxxxii., p. 295), I am happy to confirm the value of this addition to the Marsh's test for counteracting the effect of the above-mentioned sulphites.

I take the liberty of expressing the opinion (judging from the reports as published in many of the papers as to the presence of arsenic in beer and other materials) that in many instances the results obtained are based upon an erroneous interpretation of the deposits in the tube, which has been contaminated by the above-mentioned sulphites. In many instances I have found that, although the deposit in the tube very closely resembled that of arsenic, on further investigation it was found not to be so, but to consist principally of sulphur compounds.

In my own opinion no time should be lost in putting the method for the detection of arsenic on a thoroughly reliable basis, as the present unsatisfactory conditions have undoubtedly in many instances been the cause of considerable unrest and suspicion in many minds.—I am, &c.,

A. E. Berry.

DETECTION OF ARSENIC.

To the Editor of the Chemical News.

Sir,—For microscopical examinations of arsenical sublimates I use a thin sheet of mica in place of porcelain; according to the quantity present, the deposit appears as a white film or cloud, more or less distinct, and can be mounted as an ordinary transparent object, and is admirably adapted for viewing with polarised light, liquid reagents, solubility, &c.

The mica, with the deposit, is cut the size of an ordinary glass slip, and held in position by strips of gummed paper; it thus serves as a permanent record which can be photographed and enlarged.

The strips of copper from Reinsch's test can be heated between strips of mica.

The mica is about the thickness of ordinary cover glass, and should be cleaned and free from scratches, and previously examined with the same magnifying power used, both before and after heating, and with polarised light.

Sulphur polarises well, arsenious oxide does not; compounds of sulphur and arsenic are in hand, and if any marked feature presents itself I will send account of the same.

One great advantage is that the mount lies perfectly flat on the stage, and the position of any special feature can be registered by an ordinary finder; if any doubt arises from colour, Nelson's method of illumination with pure white light should be tried.

If the deposit is dissolved, it can be transferred to an ordinary glass slip, if required, by a fine platinum wire.—I am, &c.,

Thos. T. P. Bruce Warren.

88, Earlham Grove,
Forest Gate, E.

NOTICES OF BOOKS.

The Inventors' Adviser, or Every Man's Own Patent Agent. By Reginald Haddan. Fifth Edition. London: Harrison and Sons. 1900. Pp. 458.

Patent Law is no simpler than any other law; in fact, owing to its peculiar combination of law, trade, and science, it is generally admitted to be a branch of law of rather exceptional difficulty; misapprehension therefore easily arises, and serious mistakes are often made by those not well-versed in the law; under such circumstances there can be no doubt that a convenient guide to the patent system, such as the present volume, would be of great assistance.

The main object of this book is not only to explain the Patent Law, and also the Patent Office practice, but to guide the applicant for a patent so that it may be obtained in the best possible way. Part I. deals with the commercial aspect of the Patent Law. Part II. is confined to the consideration and explanation of the legal questions in British law, which will arise in carrying out the policy outlined in the first part. Part III. contains a full synopsis of the Patent Laws of all foreign and Colonial States, with methods of patenting, fees, &c. To the above is added Part IV., containing chapters upon the nature and registration of trade marks in Great Britain, and details of the requirements for registration abroad.

The Art of Dispensing: A Treatise on the Methods and Processes involved in Compounding Medical Prescriptions. Sixth Edition. Revised and Enlarged. By Peter MacEwan, F.C.S. London, Melbourne and Sydney: *The Chemist and Druggist.* 1900. Pp. 490.

The first edition of this book was published in September, 1888, and was rapidly followed by two more editions in the same year; others quickly followed, and the fifth edition, published in 1890, has been reprinted six times. In this, the Sixth Edition, the book has been again entirely re-cast, and has been expanded from 288 pages to 490 pages,

The former style and most of the material have been retained, but at least two-thirds of the book is new; for instance, the chapters on Capsules, Tablets, Incompatibles, and New Remedies are practically new, and the extent of the revision is evident throughout, in the great increase in the number of pages.

This volume is a valuable addition to pharmaceutical literature, and should be in the hands of all dispensing chemists.

A Text-Book of Paper-making. By C. F. Cross and E. J. Bevan. Second Edition. London: E. and F. N. Spon, Limited. New York: Spon and Chamberlain. 1900.

In preparing this edition the authors have adhered strictly to the original plan and scope of the work, but have introduced a good deal of new matter. Certain sections, notably those dealing with the chemistry of cellulose and the operations of sizing, loading, and colouring, have been entirely re-written; many other chapters have also been re-arranged and revised with additions.

The book is fully illustrated and well printed, and will furnish a useful guide to the student or apprentice to the art of paper-making.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Note.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. cxxxi., No. 24, December 10, 1900.

Molecular Specific Heat of Dissociable Gaseous Compounds.—M. Ponsot.—The author discusses mathematically the subject of the molecular specific heat of dissociable gaseous compounds, and comes to the conclusions that for the extreme limit of rarefaction (1) the molecular specific heat of a gaseous compound, whether under constant volume or under constant pressure, is less than that of the mixture of the elements with which this compound is resolved by dissociation; (2) the hypothesis, $C_m - C_a = O$, may perhaps be adopted as an approximate law.

The Concentration at the Electrodes in a Solution, with regard specially to the Liberation of Hydrogen by Electrolysis of a Mixture of Copper Sulphate and Sulphurous Acid.—H. J. S. Sand.—The author made the researches described in this paper with the object of finding a formula which will express the concentration at the electrodes in the solution of a single salt or a mixture. In the case of the solution of a single salt, in which Hittorff's transport values are constant, in which the diffusion obeys Fick's law, in which the metal from the salt is uniformly deposited on the electrodes, and where there are no convection currents, this can be theoretically calculated. The author uses the formula thus obtained as the base of a method for determining the diffusion coefficient of copper sulphate.

The Spectra of Samarium and Gadolinium.—Eug. Demarçay.—The author attributes the non-agreement between his list of wave-lengths of the spectrum lines of gadolinium (comprised between $\lambda = 5000$ and $\lambda = 3500$), as given by himself and by Exner, as due to the impurity of the materials used by M. Exner. He believes his own samarium to have but mere traces of gadolinium left in it, and his gadolinium the merest trace of samarium. The line spectrum of samarium is very ill-defined, and the use of the absorption spectrum, discovered by Lecoq de Boisbaudran, is better, or, better still, though more difficult in practice, is Crookes's phosphorescent spectrum. The material which furnished the test given in the paper contained, in its visible spectrum, mere traces of the lines of λ, $\Sigma - Z\varepsilon$ and Gd. $\Sigma - Z\varepsilon$ is especially difficult to eliminate. Its spectrum is very sensitive, and this body is, of all the rare earths, the nearest chemically to samarium.

Action of Water-vapour and Mixtures of Hydrogen and Water-vapour on Molybdenum and its Oxides.—Marcel Guichard.—It is possible to obtain the total reduction of molybdenum oxides at a temperature below 600°. The oxidation of molybdenum by water-vapour starts at a temperature above 600° and near to 700°. By the progressive oxidation of molybdenum in water-vapour, or in mixtures of hydrogen and water-vapour, the only anhydrous oxides which are obtained are the dioxide MnO_2 and the trioxide MoO_3. Towards 800° metallic molybdenum can be obtained by total reduction of these oxides by means of a mixture of hydrogen and water-vapour of total pressure equal to the atmospheric pressure, in all cases, when the tension of the aqueous vapour in the mixture is below 350 m.m.

Remarks on M. Lemoult's Paper entitled "Relations between the Chemical Constitution of Colouring-matters of Triphenylmethane and the Absorption Spectra of their Aqueous Solutions."—Charles Camichel.—In the paper mentioned above M. Lemoult announces a relation between the position of the luminous bands of the absorption spectra of these substances and their constitution. The author states that this fact was known since the researches of M. Bayrac and himself in 1896 (*Comptes Rendus*, cxxii., p. 193, &c.), and was announced in the following law:—"If weights of each substance (of the series of the indophenol derivatives) proportional to their molecular weight are dissolved in the same weight of the solvent, the different spectra obtained show a red band of invariable position." M. Lemoult's researches are therefore merely a verification of this law.

Bulletin de la Société Chimique de Paris. Series 3, Vol. xxiii., No. 14.

The Impossibility of the Primary Formation of Chlorate of Potassium by Electrolytic Means.—A. Brochet.—Already noticed.

Thermic Examination of Gallic Acid (Trioxybenzoic Acid.—G. Massol.—Crystallised commercial gallic acid contains 1 molecule of water; the heat of solution of this hydrate is $-7{\cdot}1$ cal. The author has prepared the anhydrous acid by prolonged desiccation in an oven at 120° (it is not decomposed at this temperature), and has determined its heat of solution, which is $-4{\cdot}48$ cal. The total heat of neutralisation, measured by M. Berthelot, is $+30{\cdot}07$ cal.; in spite of this somewhat high figure gallic acid is monoacid to litmus, the same as protocatechic and salicylic acids. The aqueous solution of gallic acid, treated with 1 molecule of soda, easily gives, on evaporation in vacuo, crystallised monosodic gallate in fine needles containing 3 molecules of water. This hydrate dissolves in water with great absorption of heat $-8{\cdot}40$ cal. It completely loses its 3 molecules of water at 115°; the heat of solution of the anhydrous salt is 1·01 cal. The heat of formation of the anhydrous monosodic gallate, calculated from the above results, is—

$$C_7H_6O_5 \text{ sol.} + NaOH \text{ sol.} = C_6H_5O_5Na \text{ sol.} + H_2O \text{ sol.} \ldots 20{\cdot}86 \text{ cal.}$$

a figure higher by 3·46 cal. than the heat of formation of benzoate of soda, and which shows the influence of the three phenolic oxhydriles.

Thermic Examination of Pyrogallol-carbonic Acid (Trioxybenzoic Acid).—G. Massol.—The acid used by the author for these experiments was in the form of fine, white crystalline needles, melting at 220°; they contained

1 molecule of water of crystallisation, which they lost slowly by desiccation at 110°. Its heat of solution is −6·3 cal. The total heat of neutralisation was found to be +23·65 cal., which is much lower than that of its isomer gallic acid (+30·07 cal.). The heat of formation of the anhydrous monosodic pyrogallol carbonate was found to be—

$C_7H_6O_5$ sol. + NaOH sol. = $= C_6H_5O_5Na$ sol. + H_2O sol. . . . +19·62 cal.

This heat of formation is lower than that of the monosodic gallate by 1·24 cal., and only 0·5 cal. higher than that of the monosodic salicylate.

On Citral, and its Isomeric Forms.—Ph. Barbier.—A controversial paper replying to MM. Tiemann and Kerschbaum.—Not suitable for abstraction.

Composition of Compounds of Fuchsine with Colouring-matters, Acid by Constitution.—A. Seyewetz.—Already noticed.

MISCELLANEOUS.

Analysis of White Metal.—H. Nissenson.—White metal is an alloy of lead, antimony, tin, and a small quantity of copper. For the separation and estimation of these metals, we proceed in the following manner:—1 grm. of alloy is treated with 2 to 4 grms. of tartaric acid and 12 c.c. of water; 4 c.c. of nitric acid, of 1·4 density, are added to the solution obtained. This is heated moderately, to assist complete solution. The lead is then precipitated with 4 c.c. of concentrated sulphuric acid. It is necessary to drive off the whole of the nitric acid; a little cold water is then added, the sulphate of lead allowed to settle, and weighed in the usual manner. The solution, free from lead, is made alkaline by means of caustic soda, and then treated with 50 c.c. of a cold saturated solution of sulphide of sodium. The precipitate of sulphide of copper formed is thrown on a filter, the filtrate is collected in a platinum crucible, heated to about 80°, and subjected to the action of an electric current of about 3 volts and 1·5 ampères. When the antimony is thus entirely deposited, the liquid is quickly poured into a beaker and the precipitated antimony dried. The solution is treated with 25 grms. of pure sulphate of ammonium, to transform the sulphide of sodium into sulphide of ammonium. There then only remains to electrolyse the warm liquid with the same strength of current, to estimate the tin.—*Chemiker Zeitung*, xxiii., 868.

Estimation of Phosphoric Acid by Molybdate.—J. Hannamann.—To prevent the simultaneous precipitation of the silica with the phosphoric acid by the acid molybdic solution, it is necessary to operate in a solution containing a good deal of nitric acid and nitrate of ammonium, or else the operation should be carried out in the cold. The author has observed that the precipitation takes place more rapidly at 40°, by using a molybdic solution strong in nitric acid. The operation can be completed in ten minutes, even in solutions containing a considerable quantity of iron, and the precipitate obtained, which filters easily, can be washed rapidly, and does not adhere to the sides of the glass. By gently calcining the yellow phosphomolybdate of ammonium, we can obtain a deep-blue coloured compound of constant composition, containing, according to Meinecke, 3·94495 P_2O_5. There is no loss of molybdic acid if the whole is uniformly heated and a certain temperature not surpassed. If, after calcination, the precipitate has not the characteristic deep-blue colour, it must be moistened with ammonia, dried, and calcined again. The molybdic reagent is prepared in the following manner:—100 grms. of molybdate of ammonia are dissolved in 150 c.c. of ammonia of 0·91 density, in the presence of 100 grms. of nitrate of ammonium. The solution is poured into a litre of nitric acid ($d = 1·2$), boiled, filtered into a flask of brown glass, and kept in a cool place.—*Zeitschr. landw. Vers-Wes. Oesterr.*, 1900, iii., 53.

Determination of the Value of Basic Slags.—F. W. Daffert and O. Reitmair.—The quantity of grain harvested depends generally on the proportion of phosphoric acid in the slag, the rapidity of its action is in direct proportion with the fineness of the grinding and its chemical nature. The solubility of the phosphoric acid in slightly acid liquids enables us to judge, within certain limits, of the quality and fineness of the slag. The solubility in citrate and citric acid is not a very sure method for determining the fertilising value. The author proposes, for determining the agricultural value of a slag, to depend on the solubility of the total phosphoric acid in formic acid. A good slag yields 90 per cent of its phosphoric acid to this reagent. The total phosphoric acid is determined by precipitating an aliquot part of the nitric solution of the slag by the molybdic reagent (870 c.c. of nitric acid $d = 1·3$, 200 grms. of nitrate of ammonium, 400 grms. of molybdate of ammonium, make up to 2000 c.c.) Shake for a minute, and filter after half-an-hour. For the determination of the soluble phosphoric acid, shake up 5 grms. of slag with 5 per cent formic acid for half-an-hour. The phosphoric acid is precipitated with molybdate; the precipitate, after standing for two hours, is shaken up for fifteen minutes in a graduated cylinder. The volume it occupies is noted, and its weight is arrived at by means of a factor.—*Zeitschr. landw. Vers-Wes. Oesterr.*, 1900, iii., 75.

MEETINGS FOR THE WEEK.

MONDAY, 7th.—Society of Chemical Industry, 8. "The Early Manufacture of Sulphuric and Nitric Acids," by Oscar Guttmann. "Note on the so-called 'Heat Test' for Explosives," by W. Cullen.

TUESDAY, 8th.—Royal Institution, 3. (Christmas Lectures to Young People). "On Great Chapters from the Book of Nature," by Sir Robert Stawell Ball, D.Sc., LL.D., F.R.S.

CITY OF LONDON COLLEGE,
WHITE STREET, MOORFIELDS, E.C.

LENT TERM Commenced JANUARY 2nd.

EVENING CLASSES in CHEMISTRY, BOTANY, GEOLOGY, BIOLOGY, and all Science subjects. Well equipped Laboratories for Practical work. Low fees.

THE CHEMICAL NEWS.

Vol. LXXXIII., No. 2146.

THE GOLD USED BY THE ANCIENT EGYPTIANS.

By J. H. GLADSTONE, D.Sc., F.R.S.

M. Berthelot has recently made a communication to the French Academy on the subject of Egyptian gold (*Comptes Rendus*, 1900, vol. cxxxi., [9], p. 461). He gives an analysis of specimens of gold leaf from mummies of the VI. and XII. Dynasties and another specimen belonging to the Persian era. I have recently had the advantage of examining gold-foil from the Royal tombs of the First Dynasty, discovered in the early part of this year (1900) by Professor Flinders Petrie; the analyses have not yet been published. I had previously examined a specimen of gold of Adu I. of the VI. Dynasty, and another from a casket of Amenhotep II. of the XVIII. Dynasty (Dendireh, Petrie, p. 61; and *Proc. of Soc. of Antiquaries of Scotland*, vol. xxx., p. 33).

I have placed the results of all these observations in the following table, adopting Berthelot's arrangement, in which all the other substances besides the gold and silver have been classified under the heading of "Organic Matter, &c."

King.	Dynasty.	Gold.	Silver.	Organic matter, &c.	Observer.
Zet..	I.	79·7	13·4	6·9	Gladstone
Mersekha ..	,,	84·2	14·3	1·5	,,
Qa..	,,	84·0	13·0	3·0	,,
Adu I.	VI.	77·9	18·0	4·1	
		81·7	16·1	2·2	,,
—	,,	92·3	3·2	4·5	Berthelot
		92·2	3·9	3·9	
—	XII.	90·5 / 90·0	4·5	5·0	,,
Amenhotep II.	XVIII.	81·1	11·4	7·5	Gladstone
		83·5	11·7	4·8	,,
Persian Era ..	—	99·8	—	—	Berthelot

The specimens analysed by me contained little, if any, copper. M. Berthelot found no other metal present in his specimens. It is evident, on comparing these figures, that there is no similarity of composition between these different specimens of gold, except that the three kings of the First Dynasty probably drew their supplies from the same source. It is evident from the case of Amenhotep II. that, down to the sixteenth century B.C., the Egyptians continued to use the native alloy, some specimens of which almost approached that which would be designated electrum.

Some of the foil is much tarnished, and this I found to be due to the formation of chloride of silver, which of course turns dark in colour when exposed to the light. As this appears as a superficial crust, we seem here to have an instance of the slow diffusion of one part of the alloy—the silver—till it reaches the outside surface, where it meets with the chlorides that exist in the sands of the desert.

It is well known that Seti I., of the XIX. Dynasty, and his son Rameses II., worked very extensive gold-mines in the Nubian desert. It is stated by Arthur Phillips that "the gold of Nubia is of a deep yellow colour and remarkably pure." This difference could not fail to be noticed by the Egyptians; and in the great Harris papyrus, containing the annals of Rameses III., about B.C. 1200, it is perfectly evident that they distinguished different qualities of gold. Mention is made of gold, pure gold, good gold, and white gold; of best gold, and gold of the second quality; of fine gold of the land, and gold of the land of Koebti, and of Kush (see "Records of the Past," vol. vi.).

ON THE SPECTRUM OF THE MORE VOLATILE GASES OF ATMOSPHERIC AIR, WHICH ARE NOT CONDENSED AT THE TEMPERATURE OF LIQUID HYDROGEN.*

(Preliminary Notice).

By Professor G. D. LIVEING, M.A., D.Sc., Professor of Chemistry, University of Cambridge, and Professor DEWAR, M.A., LL.D., Fullerian Professor of Chemistry, Royal Institution, London.

(Concluded from p. 2).

Turning to the coronal rays, our tubes emit a weak ray at about λ 5304. This is not far from the wave-length λ 5303·7 assigned by Sir N. Lockyer to the green coronal ray. It is, however, greater than that assigned by Campbell, namely, 5303·26 (*Astroph. J.*, vol. x., p. 190). Other lines observed by us near the places of coronal lines are at wave-lengths about 4687, 4570, 4358, 4323, 4232, 4220, 3985, 3800. These are all weak lines, except that at λ 4232, which is of tolerable strength, and that at λ 4220, which is rather a strong line. The wave-lengths 4323, 4232, 4220, and 3800, come very close to those assigned to coronal rays, but the others hardly come within the limits of probable error. The ray 4220 seems too strong in proportion to the others, but the strength of that at 4232 seems to accord with the strength of the corresponding ray in the corona. It will be seen that the rays we enumerate above correspond approximately to the stronger rays in Sir N. Lockyer's list (*Roy. Soc. Proc.*, vol. lxvi., p. 191). Further measures of the wave-lengths of the faint lines are needed before we can say definitely whether or no we have in our tubes a substance producing the coronal rays, or some of them.

As to the auroral rays, we have not seen any ray in the spectrum of our tubes near λ 5571·5, the green auroral ray. We have observed two weak rays at λ 4206 and λ 4198, which may possibly, one or both, represent the auroral ray λ 420. The very strong ray of argon, λ 4200·8, would make it probable that argon was the origin of this auroral ray, if the other, equally strong, argon rays in the same region of the spectrum were not absent from the aurora. Nor have we found in the spectrum of our tubes any line with the wave-length 3915, which is that of another strong auroral line. On the other hand, it seems probable that the strong auroral line λ 358 may be due to the material which gives us the very remarkable pair of lines at about the place of N of the solar spectrum, λ 3587, which are very strong in the spectrum of the negative pole, but only faint in that of the capillary part of our tubes. It may well be that the auroral discharge is analogous to that about the negative pole. We have also a fairly strong ray at λ 3700, which may be compared to the remaining strong ray observed in the aurora λ 3700. This, however, is a ray which is emitted from the capillary part of our tubes as well as from the negative pole, and is, moreover, emitted by Bath gas, and may very likely be a neon ray.

We hope to pursue the investigation of this interesting spectrum, and if possible to sort out the rays which may be ascribed to substances such as neon and those which are due to one or more other substances. The gas from Bath, even if primarily derived from the atmosphere—which is by no means sure—seems to have undergone some sifting which has affected the relative proportions of

* A Paper read before the Royal Society, December 13, 1900.

helium and neon, and a more thorough comparison of its spectrum with that of the residual atmospheric gases may probably lead to some disentanglement of the rays which originate from different materials. The arrangement of the rays in series, if that could be done, would be a step in the same direction.

We are indebted to Mr. Robert Lennox, F.C.S., for the great help he gave us in the complicated manipulation with liquid hydrogen required to fill the spectral tubes, and to Mr. J. W. Heath, F.C.S., for kind assistance.

List of Approximate Wave-lengths of the Rays, Visible and Ultra-violet, observed about the Negative Pole.

The rays of hydrogen and helium, and those attributed to neon by other observers, are indicated by the chemical symbols of those substances:—

A "b" prefixed to the number expressing the wave-length indicates that the ray is emitted by gas from the Bath spring as well as by that obtained from the atmosphere.

A "c" similarly prefixed indicates that the ray has been observed to be emitted from the capillary part of the tube as well as from about the negative pole.

A "w" indicates a weak line; "s" strong one; "d" a diffuse one; "vw" a very weak; and "vs" a very strong one.

THE IODOMETRIC ESTIMATION OF ARSENIC ACID.*

By F. A. GOOCH and JULIA C. MORRIS.

THE interaction of a soluble arseniate and a soluble iodide in a suitably acidulated solution results, as is well known, in the reduction of the arsenic acid (more or less completely according to conditions of temperature and proportions of reagents and solvents) with the corresponding liberation of two atoms of iodine for every molecule of arsenic acid (H_3O_3AsO) reduced. Inasmuch, however, as the reaction of this process is reversible, it is necessary, in order that the reduction may be complete, to nullify the oxidising action of the iodine liberated. Theoretically this end may be accomplished in either of two ways, by volatilising the free iodine bodily or by destroying the oxidising power of the iodine by converting it to hydriodic acid. The former method was followed in a process devised for the estimation of arsenic acid and elaborated in this laboratory (Gooch and Browning, *Amer. Journ. of Science*, 1890, xl., 66). This method, as originally put forward, consisted in adding to the solution of the arseniate potassium iodide in excess of the amount theoretically indicated, with 10 c.m.^{3} of sulphuric acid of half strength, and so arranging the dilution that the total volume of the liquid should be about 100 c.m.^{3}, boiling until the volume decreased to 40 c.m.^{3}, bleaching by the cautious addition of sulphurous acid the trace of free iodine still held by the hydriodic acids, diluting, cooling, neutralising with acid potassium carbonate, and titrating with iodine, after adding the starch indicator. This process, depending upon the removal by volatilisation of all but the last traces of liberated iodine and the conversion of this minute residue by sulphurous acid, involves no secondary reactions of a sort likely to influence the main effect. It is exact and fairly rapid.

The method of Williamson (*Journ. Soc. Dyers and Colorists*, 1896, 86-89), brought forward more recently, depends upon the conversion of the liberated iodine to hydriodic acid. The interaction at ordinary temperatures of a suitably strong acid, hydrochloric or sulphuric acid, upon the mixture of the arseniate and iodide,, sets free iodine, and the liberated iodine is converted to hydriodic acid by the action of sodium thiosulphate, the end-point being the disappearance of the iodine colour.

According to Williamson's directions, 25 c.m.^{3} portions of the solution of the arseniate are treated with potassium iodide and mixed with an equal volume of hydrochloric acid of sp. gr. 1·16. The precaution is recommended that the strength of the solution of the arseniate shall not exceed the decinormal value, in order that the dilution consequent upon titration by the thiosulphate may not be too great, the reducing action brought about by the action of the strong acid upon the arseniate and iodide being reversible upon the dilution of liquid with water. This procedure thus limits the process to the determination of about 0·18 grm. of arsenic acid in 25 c.m.^{3} of the solution to be treated with an equal volume of hydrochloric acid of sp. gr. 1·16. Obviously, however, the process should, so far as the reduction is concerned, be applicable to larger amounts of arsenic, provided the strength of the acid is kept up proportionately. It is essential that the liquid at the end of the titration should contain approximately 10 per cent of its mass of absolute hydrochloric acid, or about one-third of its volume of the aqueous acid of sp. gr. 1·16.

The arsenic acid is measured either by the amount of standard thiosulphate required to bleach the iodine or by the amount of iodine required to re-oxidise the reduced arsenious acid, after neutralising with acid potassium carbonate. If the former alternative is followed, the end-reaction must be the disappearance of the yellow colour of the iodine, since in solutions so strongly acid it is impossible to place dependence upon the starch indicator; in using the latter alternative, the starch indicator is, of course, permissible and preferable.

In the direct titration of the iodine by thiosulphate, two sources of error present themselves as possibilities; first, the excessive liberation of iodine by the action of air upon the strongly acidulated iodide; and second, the liability of the thiosulphate (Norton, *Amer. Journ. of Science*, vii., 287), if present even in momentary or local excess during the process of titration, to break down under the action of strong acid, thus changing its capacity to convert iodine to hydriodic acid. The latter contingency should be remote in proportion to the caution used in adding the thiosulphate and in keeping the liquid well stirred; the former must of necessity vary with the acidity of the solution containing the iodide, the time of exposure to atmospheric action, and the degree of contact with the air incidental to stirring. We have thought it desirable, therefore, to see how far each of these possibilities is likely to interfere in the practical conduct of an ordinary analysis.

The effects likely to result simply from the strong acidification of the solution containing potassium iodide, and their variations for conditions of dilution representing the beginning and the end of a titration on the lines laid down, are shown in Table I. The solution of potassium iodide was diluted as indicated before the addition of the acid, and the iodine set free was titrated by thiosulphate.

The proportionate strength of acid and the time before titration are, obviously, the essential factors. The absolute amount of acid present and the stirring seem to make little difference.

As to the action of the hydrochloric acid on small amounts of the thiosulphate, we have the evidence of the experiments detailed in the table (Table II.), in which 1, 2, and 5 c.m.^{3} of nearly *n*/10 thiosulphate are exposed to the action of 25 c.m.^{3} hydrochloric acid, sp. gr. 1·16, without dilution or diluted with an equal volume of water, were titrated with nearly *n*/10 iodine. The condition of acidity when the volume of 50 c.m.^{3} contains 25 c.m.^{3} of hydrochloric acid, sp. gr. 1·16, is that of the beginning of titration of Williamson's process. In order that the effect of error due to such action upon the determination of arsenic acid may appear immediately, the thiosulphate and iodine used are expressed in terms of that acid.

These two sources of error, the one due to a liberation of iodine and the other due to decomposition of the thiosulphate, would naturally tend to overcome one another, but the completeness of such neutralisation would naturally be largely a matter of chance in the varying conditions of actual analysis. The experiments of Table III.,

however, in which $n/10$ thiosulphate, to the amount of 1, 2, and 5 c.m.³ was added to the liquid, 50 c.m.³ and 75 c.m.³, containing 25 c.m.³ acid, and titrated with iodine at once, and after five minutes, were made to test the matter for the conditions of dilution at the beginning and at the end of a titration.

It is clear that, under the conditions covered by the experiments of the two preceding tables, the decomposition of the thiosulphate is likely to occur in greater or less degree, and that, when the acid of sp. gr. 1·16 is not much diluted, the products of decomposition are not oxidised by the iodine completely. The latter observation is quite in harmony with the fact that sulphur dioxide bleaches iodine in strong hydrochloric acid only slowly and incompletely. In such cases dilution favours further action of the iodine, but results obtained by titration with iodine in the acid solution diluted with an equal amount of water are unmodified by further dilution.

In the following tables (IV.) are recorded actual determinations of arsenic according to Williamson's process. To each 25 c.m.³ of the arseniate were added 1, 2, or 3 grms. of potassium iodide and 25 c.m.³ hydrochloric acid, sp. gr. 1·16. The iodine was bleached by nearly decinormal thiosulphate without addition of the starch indicator, which loses all delicacy in the presence of strong acid. The time occupied by each titration was about five minutes. The standards of the arseniate were determined by the vaporisation process (Gooch and Browning, *loc cit.*), the purity of reagents employed in that process having been proved by trying the process in the estimation of a solution of arsenic acid made by oxidising pure decinormal arsenious acid by iodine.

The range of error in these results is from +0·0023 grm. to +0·0042 grm., with a mean of +0·0031 grm.—not very different from what might be expected from the effect of the interaction of the strong hydrochloric acid and the iodide alone. The counter-effect due to the decomposition of the thiosulphate is not large, yet it is probably real, as will appear in the sequel. In the following series of determinations (V.), made with new solutions and new standards throughout, the arsenic acid was determined, first, by titrating the iodine set free by 25 c.m.³ of hydrochloric acid, sp. gr. 1·16, and 3 grms. potassium iodide, the solution having a total volume of

50 c.m.³ at beginning and of 75 c.m.³ at the end of titration, and, secondly, the arsenious acid produced in the first reaction was titrated, after being neutralised with acid potassium carbonate by iodine in the presence of the starch indicator.

The average error of the first operation is 0·0029 grm., not far from that of the previous series; the error of the second operation, the titration of the arsenious acid, amounts on the average to 0·0014 grm. In the second operation the error due to over-use of the thiosulphate by iodine set free outside the main reaction is obviously eliminated. The tetrathionate present after neutralisation with acid potassium carbonate, is unaffected by iodine, as we have found by titrating 25 c.m.³ *n*/10 iodine mixed with 25 c.m.³ hydrochloric acid, sp. gr. 1·16, by the thiosulphate, neutralising with acid potassium carbonate,* adding starch, and getting the starch blue with a single drop of *n*/10 iodine. The average error of this process, therefore, 0·0014, is probably due to the products of decomposition of the thiosulphate in the first operation.

From the foregoing experiments it is clear that an arbitrary correction of about 0·0030 grm. must be deducted from the indications of Williamson's process of direct titration by thiosulphate made with the greatest care under the conditions mentioned; and that a correction varying from one-half that amount (0·0015 grm.) to nothing (according to the amount of arsenious acid present) when the determination is made by iodine after neutralisation with acid potassium carbonate. After making these arbitrary corrections in the results of the preceding table, the individual variations fall within reasonable limits.

On the other hand, the vaporisation process, in which the arseniate is reduced by boiling with sulphuric acid and potassium iodide in the manner described (*loc. cit.*), gives indications reasonably regular and accurate without the application of an arbitrary correction. This process, moreover, may be shortened by restricting the volume at which heating begins so that the boiling need not be extended beyond five or six minutes. According to this slight modification, the solution of the arseniate is heated in an Erlenmeyer flask with potassium iodide to an amount about 0·5 grm. in excess of the amount theoretically required and 10 c.m.³ of sulphuric acid of half-strength in a total volume of between 50 c.m.³ and 75 c.m.³. The liquid is boiled till the iodine vapours are no longer visible in the flask above the liquid, the iodine colour in the still hot liquid is bleached by the cautious addition of sulphurous acid; the whole is diluted with cold water, and cooled quickly. The solution is nearly neutralised with potassium hydroxide, and the neutralisation is completed with acid potassium carbonate. The reduced acid is titrated with iodine after adding the starch indicator. By this procedure the results given in Table VI. were obtained.

Royal Institution.—On Tuesday next, January 15, Professor J. A. Ewing, F.R.S., will deliver the first of a Course of Six Lectures at the Royal Institution, on "Practical Mechanics (Experimentally Treated): First Principles and Modern Illustrations." On Thursday next, January 17, Dr. Arthur Willey will begin a Course of Two Lectures on "The Origin of Vertebrate Animals," and on Saturday (Jan. 19), Professor R. K. Douglas will deliver the first of Two Lectures on "The Government and People of China." The Friday Evening Discourse of January 16 will be delivered by Professor Dewar, his subject being "Gases at the beginning and end of the Century."

* It is worthy of note that, as we have found by experience, it is not possible to substitute an alkaline hydroxide for the carbonate in the early stages of the process of neutralisation, on account of the decomposing effect of the former reagent upon the tetrathionate. This effect is in proportion to the heating of the solution, but is never wholly absent even when ice is intermixed with the liquid and the greatest care taken to prevent a rise of temperature.

THE ACTION OF REDUCING AGENTS UPON NITROGEN IODIDE.*

By F. D. CHATTAWAY and H. P. STEVENS

(Concluded from page 10).

Action of Arsenious Oxide on Nitrogen Iodide.

When a solution of arsenious oxide is slowly added to nitrogen iodide suspended in excess of a solution of sodium bicarbonate until the particles disappear, ammonia, arsenic acid, and hydriodic acid are produced, and the amount of arsenious acid oxidised is found to be exactly double that which is equivalent to the hydriodic acid formed. The experiments were carried out much as before, the hydriodic acid, however, being estimated by making the liquid acid, adding silver nitrate in slight excess, and estimating the excess added by potassium thiocyanate.

Number of experiment.	N/10 $\frac{As_2O_3}{4}$ oxidised.	N/10 HI produced.	Ratio.

IV.	44·5	22·3	2 : 1·002
VI.	43·8	21·9	2 : 1
VII.	33·2	16·6	2 : 1

Similar results were obtained when the hydriodic acid was estimated by determining the amount of a standard solution of potassium permanganate required to oxidise it to iodic acid.

Action of Antimonious Oxide on Nitrogen Iodide.

The action of antimonious oxide on nitrogen iodide is exactly similar to that of arsenious oxide, the compound being converted into the higher oxide, while ammonia and hydriodic acid are produced. Similarly the quantity oxidised is double the amount equivalent to the hydriodic acid formed. The experiments were carried out as with arsenious oxide, a decinormal solution of tartar emetic being used, and sodium bicarbonate added in larger excess.

Action of Stannous Chloride upon Nitrogen Iodide.

Stannous chloride, dissolved in the least possible quantity of dilute hydrochloric acid, readily reacts with nitrogen iodide, and if it be added slowly a little iodine is liberated. If the addition be continued till this liberated iodine just disappears, stannic chloride, ammonium chloride, and hydriodic acid alone are formed. The latter can be estimated by converting it into iodic acid by a solution of potassium permanganate, the ammonium being first expelled by a slight excess of caustic soda. The quantity of hydriodic acid formed is found to be half the amount equivalent to the stannous chloride oxidised.

* From the *American Chemical Journal*, xxiii., No. 5.

The ratio usually comes out slightly too high. This, as in the case of sulphurous acid, is due to a small quantity of the nitrogen iodide breaking down into nitrogen and hydriodic acid under the influence of the hydrochloric acid which must be present to keep the stannous chloride in solution.

Action of Hydrogen Sulphide on Nitrogen Iodide.

On a solution of hydrogen sulphide being added to nitrogen iodide suspended in water the solid particles rapidly disappear, sulphur is precipitated, and ammonia and hydriodic acid are produced as in other cases. If the solution of hydrogen sulphide be very slowly added, iodine is set free, and the end of the reaction can be recognised easily by its disappearance. The investigation of this action is complicated by the circumstance that during it a considerable portion of the nitrogen iodide decomposes into nitrogen and hydriodic acid, and thus the ratio between the hydrogen sulphide oxidised and the hydriodic acid produced appears too great if the latter is directly estimated.

The following estimations show that the ratio thus obtained is variable but approximately 2 : 1·2*. The hydriodic acid was determined by adding a small excess of silver nitrate, and estimating this excess by potassium thiocyanate.

Number of experiment.	N/10 $\frac{H_2S}{2}$ oxidised. C.c.	N/10 HI produced. C.c.	Ratio.
I.	28·4	16·7	2 : 1·18
II.	31·2	18·9	2 : 1·21
III.	27·3	16·8	2 : 1·23
IV.	33 0	19·8	2 : 1·2
VI.	31·6	19·5	2 : 1·23
VII.	35·8	22·5	2 : 1·26

As, however, the composition of nitrogen iodide has been definitely determined, the amount which actually reacts with the hydrogen sulphide, and consequently the quantity of hydriodic acid liberated, can be calculated from the ammonia formed. In the following experiments this was done, the nitrogen iodide which breaks up into nitrogen and hydriodic acid being neglected :—

Number of experiment.	N/10 $\frac{H_2S}{2}$ oxidised. C.c.	N/10 HI produced. C.c.	Ratio.
I.	30·8	15·4	2 : 1
II.	24·7	12·3	2 : 0·995
III.	32·2	16·2	2 : 1·005
IV.	40·4	20·3	2 : 1 005
VI.	26·8	13·4	2 : 1
VII.	20·9	10·5	2 : 1 003

It is seen that the action of hydrogen sulphide upon nitrogen iodide is perfectly normal, and that the amount of hydrogen sulphide oxidised is twice that equivalent to the hydriodic acid produced.

The close agreement between all the results obtained with such very different reducing agents places it beyond doubt that, when nitrogen iodide reacts with any reducing agent, the ratio between the amount of the latter oxidised and that of the hydriodic acid produced is as 2 : 1; in other words, that the iodine contained in nitrogen iodide behaves in these reactions like the chlorine contained in a hypochlorite, and exerts twice its normal oxidising action.

* Compare Bineau's (*Ann. Chim. Phys.*, [3], 1845, xv., 71), and Gladstone's (*Chim. Soc. Journ.*, 1852, iv., 34, and 1854, vii., 51), analytical results obtained by this method. They differ among themselves, and this accompanying decomposition was not observed.

AN IMPROVED METHOD FOR THE PRESERVATION OF NORMAL SODIUM HYDRATE.

By EDWIN DOWZARD, F.C.S.

The normal solution of sodium hydrate has always been a cause of trouble and annoyance to chemists; sometimes the stopper becomes so tightly cemented into the neck of the bottle, that the bottle has to be broken; then the continual opening of the bottle exposes the contents to the action of CO_2 present in the atmosphere, which of course is very undesirable.

A number of devices have been proposed to remedy these defects: the fault of a great number is that no surplus solution can be returned to the stock-bottle without some little trouble.

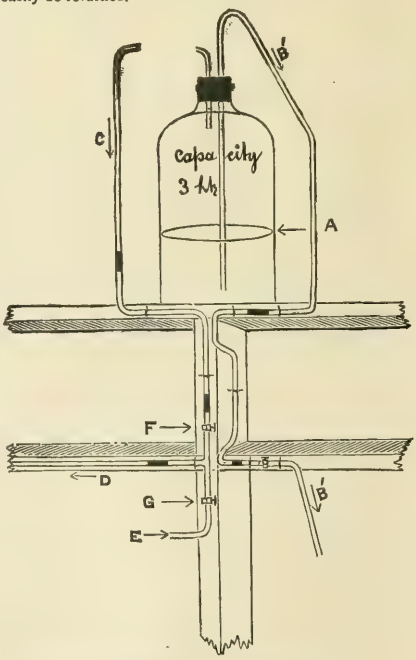
The following piece of apparatus has several advantages which recommend it:—

1. The solution is covered by a layer of white mineral oil which protects it from the action of CO_2, and also prevents evaporation.

2. The solution drawn from the bottle is always perfectly clear and free from sediment.

3. The solution is always of the same strength.

4. If too much has been withdrawn the surplus can easily be returned.



A, Layer of white mineral oil (B. P. 1898), ¼ inch thick.
B', B', Syphon with glass tap near the lower end.
C, Glass tube which can be connected to a filter-pump.
D, Filter-pump main.
E, End of filter-pump main.
F, Tap which is always kept closed except when the solution is being withdrawn or returned.

To return any unused solution to the bottle it is only necessary to start the pump, open F, close G, and place the syphon B' B' in the test-glass containing the solution; the syphon tap is now opened, when the liquid will be sucked back into the bottle.

Although this seems rather complicated, a few seconds only are required for the operation. I have had this piece of apparatus in use for about four years, and am perfectly satisfied with its action.

A NEW GENERAL METHOD FOR THE SEPARATION OF THE METALS OF THE PLATINUM GROUP.

By M. LEIDIÉ.

The methods at present in use for the extraction of platinum and iridium leave residues of which the analysis is of great interest, as they are the sole source of a certain number of the rare metals, viz., osmium, ruthenium, palladium and rhodium, besides the iridium and platinum they still contain. The following method, based on the properties of the double alkaline nitrites of these metals, enables us to effect their separation much more easily than by the dry methods of MM. H. Sainte-Claire Deville and Debray.

I. *Elimination of the Foreign Metals and Transformation of the Metals of the Platinum Group into Double Alkaline Nitrites.*

The residues of the platinum group are roasted at a dull red heat with free access of air, and are then reduced by hydrogen; the residue is washed first with water and then with dilute hydrochloric acid; finally it is again reduced by hydrogen. This preliminary operation is for the purpose of destroying the compounds in which the residual metals occur, bringing them into the metallic state and eliminating the soluble alkaline salts as well as the greater part of the iron and zinc which may have been introduced during the course of the operations.

The metallic matter is then mixed with twice its weight of fused, powdered chloride of sodium, and the mixture is heated in a current of dry chlorine to a dull red heat; the products of volatilisation, which might get lost, are condensed by means of a suitable apparatus.

In this manner all the metals are transformed into chlorides or double chlorides of more or less solubility. Both the fixed and the volatilised products are treated with water containing a little hydrochloric acid and filtered; if necessary, on account of the unattacked residue being too great, the operation is repeated. By using a quantity of water equal to 20 or 25 times the weight of the metal, but little of the chloride of lead is dissolved, and nearly the whole of the chloride of silver is removed by means of the chloride of sodium.

The solution, which must be partially neutralised with carbonate of sodium, is brought nearly to boiling point, and gradually treated with nitrite of sodium until it becomes neutral to litmus; at this moment carbonate of sodium must be further added until the precipitate no longer increases; it is then boiled for a few moments, allowed to cool, and filtered. The nitrite of sodium has precipitated the iron in the state of sesquioxide, and the gold in the metallic state; the carbonate of sodium has precipitated in the form of carbonates all the other metals, such as lead, silver, zinc, tin, bismuth, copper, &c., which were originally in the mineral or which may have been introduced accidentally during the series of operations which this latter has undergone. The metals of the platinum group have remained in solution in the state of soluble double nitrites of sodium, having the following respective formulæ:—

Nitrite of ruthenium and sodium	..	$Ru_2(NO_2)_6.4NO_2Na$
Do.	platinum	do.	.. $Pt(NO_2)_2.2NO_2Na$
Do.	palladium	do.	.. $Pd(NO_2)_2.2NO_2Na$
Do.	iridium	do.	.. $Ir_2(NO_2)_6.6NO_2Na$
Do.	rhodium	do.	.. $Rh_2(NO_2)_6\,6NO_2Na$

The osmium is present in the form of chloro-osmite, $OsCl_3.3NaCl$.

II. *Separation of the Metals of the Platinum Group.*

Osmium, Ruthenium.—The above-mentioned nitrites have the property of not being precipitated either by the alkalis or the alkaline carbonates. Their solution is treated with caustic soda and a current of chlorine is then passed through; this operation is carried out in a distilling apparatus made of glass, and of which all the parts are connected by ground joints (as for the preparation of perruthenic anhydride), and the volatile products are collected in water containing a little alcohol. The salts of osmium and of ruthenium are thus transformed into peroxides of osmium and of ruthenium, OsO_4 and RuO_4, which are volatile; gentle heat is applied towards the end of the operation to cause them to distil over with the steam; they are reduced by the alcohol to the state of osmium and ruthenium. The mixture of these two bodies is collected and the osmium separated from the ruthenium by H. Sainte-Claire Deville and Debray's method (*Annales de Chimie et de Physique* [5], vol. lvi., pp. 476, 480).

Iridium, Rhodium.—The alkaline solution, freed from osmium and ruthenium, is acidulated with hydrochloric acid and boiled; then, to re-convert the chlorides which were formed under the influence of the chlorine into nitrites, nitrite of sodium is added until the solution is neutral; it is then allowed to cool. Chloride of ammonium is then added almost to saturation point. The iridium and the rhodium are then precipitated in the form of double nitrites of ammonium: $[Ir_2(NO_2)_6.6(NO_2.NH_4)]$ and $[Rh_2(NO_2)_6.6(NO_2.NH_4)]$, which are insoluble in solutions of sal-ammoniac. The precipitate is collected after twenty-four hours and treated several times with hot aqua regia, so as to transform it into iridic chloride, $IrCl_4$, and hydrated sesquichloride of rhodium, Rh_2Cl_6. The aqua regia is driven off by evaporation, and the residue taken up with cold water saturated with chlorine. This solution is then saturated with chloride of ammonium.

The iridium is precipitated in the form of chloroiridiate of ammonium; this latter is collected, dried, mixed with its own weight of sea salt, and heated to 440—450° in a current of chlorine. The ammoniacal salt is decomposed and the iridium remains in the state of chloroiridiate of sodium, soluble in water; the rhodium which might have been entangled with it is found in the form of anhydrous sesquichloride, insoluble in water. The chloroiridiate of sodium is, by double decomposition, again transformed into chloroiridiate of ammonium. This latter, reduced at a red heat in a current of hydrogen, gives *Iridium*.

The solution from which the iridium has been precipitated is evaporated until it crystallises. The crystals of chlororhodite of ammonium, $Rh_2Cl_6\,6NH_4Cl$, are separated from those of the chloride of ammonium. The salt of rhodium is dissolved in water, transformed into the double nitrite of sodium, which is then precipitated in the form of double nitrite of ammonium (that salt of iridium, being a little more soluble, will remain in the mother liquors). This double nitrite is re-transformed by hydrochloric acid into chlororhodite of ammonium, and the latter, by reduction at a red heat in a current of hydrogen, gives *Rhodium*.

Platinum, Palladium.—The solution, freed from iridium and rhodium, now contains only platinum and palladium in the form of double nitrites; it is evaporated to dryness after the addition of hydrochloric acid to transform the nitrites into chlorides.

As the presence of chloride of sodium, which has by

this time become fairly considerable, would interfere with the complete precipitation of the platinum, the dry residue is reduced in hydrogen, and the product of the reduction washed with water, so as to leave nothing but the two metals, platinum and palladium, in the metallic form. These are dissolved in aqua regia, the excess of which is driven off by suitable evaporation, and the residue is taken up with water.

As this solution contains platinic chloride, palladic chloride, and sometimes, if the operations have been carelessly performed, *traces* of iridic chloride, and as all three are precipitable by chloride of ammonium, the second metal is transformed into palladous chloride and the third into hydrated sesquichloride of iridium, which are not precipitable. For this purpose their solution, placed in a flask which it nearly fills, is submitted to the action of a current of carbonic acid gas to drive off the air, then to a current of binoxide of nitrogen which acts as a reducing agent,* and finally to a second current of carbonic acid to drive off the binoxide of nitrogen.

The solution is then saturated with chloride of ammonium, the chloroplatinate of ammonium is collected after twenty-four hours, and crystallised two or three times in boiling water; this substance by reduction at a red heat in a current of hydrogen gives *Platinum*.

To the mother liquors mercuric cyanide is added; the palladium is precipitated in the form of palladous cyanide, $PdCy_2$. This latter is decomposed by heat, the palladium is dissolved in nitric acid, the nitrate is transformed into palladous chloride, then into nitrite of palladium and potassium; finally this latter, by the action of hydrochloric acid, is transformed into chloropalladite of potassium, which can be crystallised. This salt is then reduced at a red heat in a current of hydrogen, and the residue, cooled in a current of carbonic acid, is washed with water to remove the chloride of potassium; in this manner *Palladium* is obtained.

The metals thus prepared are in the form of a porous sponge. To obtain them in ingots they must be melted. The osmium and the ruthenium can be melted in Ducretet and Lejeune's electric furnace, in which the operation can be carried out away from contact with the air in an inert atmosphere; the others in a Sainte-Claire Deville and Debray's lime furnace, by means of a blowpipe supplied with coal-gas in the case of platinum and palladium, and with hydrogen for the iridium and rhodium.

The method I have just described has as its principal advantages, first of all the elimination, from the very commencement, of all foreign materials, the complete volatilisation of the ruthenium by which the iridium obtained by the other methods is always contaminated, and finally the fact that it does not necessitate the installation of special apparatus as in the case of the dry methods. —*Journal de Pharmacie et de Chimie*, Series 6, vol. xiii., No. 1.

Calvert's Mechanics' Almanack and Workshop Companion contains, in addition to the usual matter of an almanack, a lot of practical, technical, and industrial information for artisans and handicraftsmen, and those engaged in mechanical engineering, and building and constructive trades. There are also several pages of useful engineering diagrams.

The Gloucester Diary for 1901, published for the Gloucester Railway Carriage and Wagon Company, Limited, contains, amongst other useful information, a convenient table for immediately finding the dates of certain days of the week on which regular appointments occur; for instance, the second Tuesday, or the third Thursday in any or every month. This will be handy for finding the dates of Directors' Meetings or At Home days.

* This reducing agent is much to be preferred to those which are generally used, such as sulphurous acid or sulphydric acid. The first gives double sulphites possessing little known properties, the second sulphides which cause a loss in the returns.

THE ALLOTROPIC FORMS OF SELENIUM.*

By A. P. SAUNDERS.

(Continued from p. 8).

9. *Specific Gravity Determinations.*

THE difficulty in determining the specific gravity of selenium lies in the fact that even the smallest particles of it may contain air cavities: so that it is usually necessary, in order to get satisfactory results, that the material shall be in a state of fine powder, and that it shall be subjected to exhaustion. The easiest way to effect this is to cover the powder with some of the liquid used for filling the specific gravity bulb, place this in a desiccator, and pump out. The liquid used may be alcohol or benzene. It is to be noted that when alcohol is used, it is best, if the liquid be not pure, to pour off that part of it which has stood over the selenium, when exhausted, since it may have suffered a change of density due to the vaporisation of the more volatile component.

The determinations recorded below were all made at 25° in a specific gravity bottle of capacity 50 c.c. This was left in a bath at constant temperature for fifteen minutes. In order to test whether this was a sufficient time, the bottle was replaced in one instance, after weighing, and left in the bath for two hours longer; at the end of that time the difference in weight was only 1 m.g. The bath used was an ordinary Ostwald thermostat provided with a thermo-regulator of the usual size, but filled with toluene. This forms an instrument of a very high degree of sensitiveness, so that it was possible to keep the total variations in temperature within 0·01° for hours at a time.

It was found better to dispense with the usual stopcock where toluene was used; this was done by altering the gas-entry tube as indicated in the accompanying figure. (Fig. 3.) The tube *a* is partly filled with

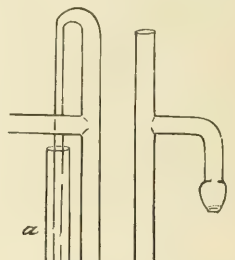


FIG. 3.

mercury, and when the desired temperature has been reached, is slipped over the end of the drawn-out tube, and held in place by a cork tied on to the neighbouring upright. The rest of the piece is arranged in the usual manner.

An attempt to use the floating method with amorphous selenium failed. The double nitrate of thallium and silver (Retgers, *Jahrb. f. Min.*, 1893 and 1896), gives a liquid of sufficient density, but selenium is at once acted upon by it.

The specific gravities of the different forms of selenium have been very often determined, and sometimes with widely varying results. The variations have been, in the main, due to the difficulty mentioned above. When the element

* From the *Journal of Physical Chemistry*, vol. iv., No. 6.

is present in fragments, these contain air cavities, which render specific gravity determinations quite hopeless.* The only method by which uniform results can certainly be obtained is to powder the material, and then exhaust for some time, best under the liquid in which the density is to be determined. This liquid should not be water, because it does not readily wet any one of the modifications of selenium; alcohol has been used in all of the more careful determinations.

Berzelius (1818), who had observed the change from the vitreous to the grey form, records the specific gravity of the former at—

4·3—4·32

and says that the transformation into the grey form causes no change of density.

The next data are those of Schaffgotsch (1848), who recognised the difficulties to be encountered, and avoided them by making the weighings in alcohol, and exhausting to get rid of the adhering air. He found at 20° for vitreous selenium, 4·276 to 4·286; for metallic selenium, prepared by heating to 250° on a sand-bath, and very slowly cooling, 4·796 to 4·805; and for the amorphous red form, 4·259 to 4·269.

Hittorf (1851), determined the density of the crystals which separate from solutions of selenides of the alkalis, and found the value 4·808; he gives no information regarding his method of determination.

In 1853, Schaffgotsch returned to the subject, and made a series of more elaborate determinations.

I. Vitreous selenium, prepared by rapid cooling, from the fused element:—

Four determinations with fragments which proved afterwards to contain air cavities, and with powder which, although boiled with water, was not rendered free from air, gave values varying by but little from 3·9. The powder, on being boiled, must certainly have gone over to the metallic form, yet Schaffgotsch records the density observed in this case as 3·9267; which goes to show how large the errors due to air cavities may be, and, particularly, the importance of choosing an appropriate liquid in which to work.

A second series, carried out with fragments which were not investigated with regard to enclosed air, gave 4·259 to 4·269.

The third series was made with air-free vitreous selenium (Schaffgotsch appears to have satisfied himself of this by inspection only), and with powder which was freed from air by repeated exhaustion under water or determined in alcohol, which, the author says, renders the use of the air-pump unnecessary. The results are very concordant, varying only from 4·276 to 4·286; or, in the mean, 4·281.

II. Metallic selenium, prepared by melting, and then very slowly cooling, gave, when powdered and determined under alcohol, values which varied in four determinations, between 4·796 and 4·805.

III. Amorphous selenium—selenium blood as Schaffgotsch calls it—gave varying results, from 4·245 to 4·275. After causing it to coagulate by heating to 50°, the results ran from 4·250 to 4·277, thus showing no difference from the powder. These last determinations were made in water. Schaffgotsch considers that, in view of the difficulties of the determination, the results are to be considered as indicating a density identical with that of vitreous selenium. The material was prepared by the addition of hydrochloric acid to a solution of selenium in sodium sulphite.

Mitscherlich (1855), studied the two red forms which separate from carbon disulphide solutions, and found their specific gravity to be 4·46 to 4·51. He seems to have taken the two forms as being identical except in crystal habit, and his density determination was possibly made with a mixture of the two. He states that it was possible by heating them to 150°, to transform them into the grey modification, whose specific gravity he found to be 4·7. The determinations were made in alcohol at 15°, and without powdering the material. The crystals which separate from selenide solutions had a density, according to Mitscherlich's results, of 4·76 to 4·79. Both of these forms—the black crystals as well as the grey material obtained from the red crystals at 150°—he therefore considered to be identical with the ordinary grey selenium whose density Schaffgotsch had found to be 4·80.

Neumann (1865), made a determination of the specific gravity of metallic selenium, and records the density of this substance "in fragments" as 4·41. This value, lying as it does so far below 4·8, suggested the possibility of there being a second form of grey metallic selenium, and most of the modern text-books describe two forms. The only further confirmation of this view is supplied by the experiments of Rammelsberg (1874), which will be found discussed below.

The next density determinations were those of Bettendorf and Wüllner (1868), who were also engaged upon the question of specific heat. The only value they give is for a sample of red amorphous selenium, which had been heated for a week in a steam-oven, and had at the end of that time a density of 4·797 at 20°. No details of the work are given, but it is obvious that they had in hand the grey form. The accuracy of the value found is due to the fact that the material, being obtained from the red powder, was already in a state of fine division, and hence no considerable error from air cavities should enter in. We come then to the paper by Rammelsberg (1874). The discrepancy between the results of Neumann's observations and those of earlier investigators seemed, to Rammelsberg, to call for a re-determination of the specific gravity of all the various forms of selenium. His determinations were made partly in alcohol, partly in water; but it does not appear that the material was powdered, nor that the air-pump was used, except perhaps in the determinations under water.

The amorphous variety obtained by the reduction of selenious acid in solution, by sulphur dioxide, gave values between 4·27 and 4·34, while melted selenium, *i.e.*, vitreous, gave 4·29 to 4·36. The crystals obtained from carbon disulphide, which are described as brownish-red and transparent, were subjected to a large number of separate determinations in alcohol; only small quantities of the crystals were used, and with very variable results, the mean values of which are given as—

4·418—4·54—4·59,

i.e., about the same as Mitscherlich had found. For the crystals which separate from selenide solutions the figures given are—

4·77—4·79—4·86.

But the most interesting values are those which Rammelsberg found for the grey metallic selenium which he prepared by heating the vitreous form to 120—150°. The product is described as insoluble in carbon disulphide, and it may therefore be assumed that it contained no considerable quantity of the vitreous form unchanged. The results for determinations made partly in alcohol and partly in water, are—

4·437—4·464—4·487—4·545—4·563—4·590,

or, in the mean, 4·514. One would have thought that the extremely large variation in these results would have aroused Rammelsberg's suspicions as to their value; but apparently not. He remarks merely that they all lie very much nearer to Neumann's value 4·4, than to Schaffgotsch's of 4·8, which is not the case. Neumann expressly states that his figure referred to selenium "in fragments," and Rammelsberg leaves the same to be inferred regarding his, whereas Schaffgotsch's determinations were made with powdered material. I made an experiment to find what difference would be observed in the density of the same material in fragments and in powder. To this end, about 2 grms. of vitreous selenium were

* The same kind of difficulty is encountered in determining the specific gravity of tellurium. (See Lenher and Morgan, *Journ. Am. Chem. Soc.*, 1900, xxii., 29).

heated for an hour at 120—150°. The product was entirely grey, and the fracture had the same colour; no trace of the red form could be observed in it. The determinations were made in alcohol at 25°. The first was made with the material broken up only enough to allow of its being brought into the specific gravity bottle. The value found was 4·55. The selenium was then taken out, dried, and powdered, replaced in the bottle, covered with alcohol, pumped out for half-an-hour, and then re-determined. The new value was 4·77. In view of these results there can be little doubt that both Rammelsberg and Neumann had in hand ordinary metallic selenium, and that the variations from the true value, 4·8, displayed by their results, are due to experimental error. This view is confirmed by the fact that Neumann found the same value for the specific heat as did Bettendorf and Wüllner, while these authors found 4·797 for the density of their material. As a further illustration of the extent to which error of this kind is possible, attention may again be called to the remark of Berzelius that the change from the vitreous to the metallic form causes no change whatever in the density (4·3). The accuracy of Rammelsberg's results with the other modifications is due to the fact that these forms having separated from solution, do not contain air cavities.

A number of density determinations were made by Petersen (1891), who prepared metallic selenium by heating the vitreous modification to 250°, then cooling to 180°, and keeping it at that temperature for a long time; finally, the material was slowly cooled. It was found to contain about 1 per cent of soluble selenium. The density determined at 17—18° was found to be 4·63 (4·62—4·64). The explanation for this very low value is to be found in the fact that the determinations, though carefully made, were carried out in water, which has always yielded unsatisfactory results with this form of the element. We have seen that Schaffgotsch obtained in this way a value as low as 4·39. The method of procedure used by Petersen was to bring the substance into the pycnometer, cover with air-free water, warm, place under the pump, and pump out until the water was caused to boil. That author drew from his result the conclusion that specific gravity cannot be taken as a criterion for the crystalline forms of selenium. But this conclusion hardly seems called for, considering that all determinations carried out with alcohol under appropriate conditions have yielded, for the metallic form, values which lie very near to 4·8.

The monoclinic red crystals obtained by extraction of amorphous selenium with carbon disulphide, yielded, by the same method as above, the values 4·44—4·47. When compared with Mitscherlich's results, which are, as before pointed out, not free from possible error, this gives as the most probable value for the density of monoclinic red selenium, a figure not differing by much from 4·47.

It will be noticed that all accurate determinations of the densities of amorphous and vitreous selenium yield results indicating a slightly lower value for the amorphous form. The following are the data on the subject:—

	Amorphous.	Vitreous.
Schaffgotsch (1848) ..	4·259—4·264	4·276—4·286
— (1853) ..	4·245—4·275	4·276—4·286
Rammelsberg ..	4·27 —4·34	4·29 —4·36

The difference is so slight as to be quite within the limits of experimental error, and the observers themselves have generally attributed it to that source; yet its constant recurrence, always in the same direction, leads to the conclusion that the two forms may really possess slightly different densities, although representing one and the same modification of the element. If this is so, the difference is due to the fact that the material exposes in one case a maximum, in the other a minimum of surface; for the amorphous form, which gives colloidal solutions with water when freshly precipitated, is in a state of extremely fine division. It is quite possible that the difference in the state of aggregation should cause a difference in density as well as in other properties of the substance. Any experiments made with selenium itself with the idea of establishiug such a difference would be rendered inconclusive by the possibility of the formation of a small amount of metallic selenium during the course of the experiment. It is, on the other hand, very easy to find analogous cases among the other elements; colloidal solutions have been prepared of gold, silver, copper, mercury, sulphur, and other elements, and all of these are obtainable in the form of impalpable powders, quite different in appearance from the compact material. Some experiments are now in progress to determine whether a measurable difference of density exists in such cases. This is not improbable if the idea suggested by Van der Waals (Ostwald, *Lehrb.*, i., 540), be correct—that there is no discontinuous change between a liquid and a vapour above it; for if there is a film of intermediate density in the case of an ordinary liquid and its vapour, it is entirely probable that solids would also have a bounding surface of lower density than the material within; equally so a viscous substance like amorphous selenium. Increasing the surface for a given weight of material would then always bring about a lowering of the density, and if the surface were made relatively large, this lowering might become apparent.

(To be continued).

CORRESPONDENCE.

DETECTION OF ARSENIC.

To the Editor of the Chemical News.

SIR,—With reference to the use of the aluminium test for arsenic, as recommended by Mr. H. G. Madan in the CHEMICAL NEWS of December 21, I would point out that this is an old and well-known test, having been first described by me, and published in the CHEMICAL NEWS of April 18, 1873. In its application care must be taken to use the purest sodic hydrate or potassic hydrate, as some specimens or "white sticks" of soda at present on the market yield distinct indications of arsenic in a blank experiment.—I am, &c.,

J. W. GATEHOUSE, F.I.C.

Grove Street, Bath.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, del'Académie des Sciences. Vol. cxxxi., No. 25, December 17, 1900.

This number contains an account of the Public Annual Meeting of the Académie.

M. MAURICE LEVY addressed the meeting, referring to the fact that during the last sixty years of this closing century science has advanced with miraculous strides. He discusses the fact as to why these discoveries should have taken place just during this period and not before.

The Jecker Prize in Chemistry is awarded to M. A. Béhal. His researches on the acetylenic carbides, the derivatives of malonic acid, chloral, chloralimide, and their derivatives are already classical. M. Béhal began in conjunction with M. Desvignes, in 1892, a series of difficult researches on asboline. These were continued with M. Choay in 1893—1895 on wood oils, in particular on the phenols which these oils contain. M. Béhal's researches on the constitution of camphor, which were re-examined by Tiemann, are those upon which the final

constitution of camphor was established. Various other investigations followed, the action of acetic acid on ethylenic and acetylenic carbides at high temperatures, the conditions for obtaining thionyle, SO, rotatory power of tartaric ethers, isomerism of tropine and pseudotropine, tantomeric forms of acetylacetic ether, distinction between crystalline and chemical molecules, commercial chloroforms, and the means of ascertaining their purity, &c. Finally, M. Béhal is the author of a "Treatise of Organic Chemistry according to Modern Theories."

The Wilde Prize was given to M. Delépine for his experimental researches on aldehydes. He especially gave attention to the ammonia compounds of the aldehydes, and to compounds of aldehydes with the alcohols, which have received the name of acetals. The derivatives of polyatomic alcohols, remarkable for their analogy with cane-sugar and the complex sugars of the same order, are specially worthy of notice. M. Delépine's researches were conducted by ordinary chemical and thermo-chemical methods. They comprise, amongst others, special determinations on formic aldehyde generated from sugars, one of the most interesting bodies of modern chemistry.

The Vaillant Prize was divided between M. Henri Gautier and M. F. Osmond. The Academy proposed the two following questions for the 1900 Vaillant Prize:—(1). Study of Metallic Alloys. (2). Precise Determinations of one or several Atomic Weights.

M. Gautier sent in papers on each of these two subjects. He proposed to investigate the fusibility of a great number of binary metallic alloys and to trace the corresponding fusibility curves. Besides this, M. Gautier investigated the atomic weight of boron by means of absolutely pure boron sulphide, which was decomposed by water. As the mean of his numerous experiments the number 11·01 was obtained.

M. Osmond's researches were on the properties of iron containing carbon. Whilst studying the different transformations of carbon he discovered a new allotropic modification of iron itself. As a result of his researches this metal is shown to possess three molecular states:—α-Iron, which is only stable at temperatures below 700°. β-Iron, which is formed between 700° and 760°, absorbing a certain amount of heat. It loses its magnetic properties, is less malleable, and a less good conductor of electricity. γ-Iron, which is formed towards 860° with a further absorption of heat, is in the same way as β-iron deprived of its magnetic properties. It is less dense than the other varieties, and a still worse conductor of electricty.

Oxidation of the Bibasic Acids of the Fatty Series by Acid Permanganate of Potash.—L. Perdrix.—A very long paper, not suitable for abstraction.

Action of Hexamethylenetetramine on the Ethers of the Chlor- and Brom-acetic Acids.—R. Loquin.—Hexamethylenetetramine was suspended in five times its weight of chloroform, and the theoretical quantity of chloracetate of methyl added. The mixture became heated spontaneously, while at the same time the hexamethylenetetramine was partially dissolved. On cooling the whole mass became beautifully crystalline, the crystals were analysed after draining, washing in chloroform, and desiccation in vacuo. The crystals are colourless, very soluble in water, fairly so in alcohol, and insoluble in ether, chloroform, and benzine; they melt at 141°. Analysis shows that this compound is the product of addition of a molecule of hexamethyleneamine and a molecule of chloracetate of methyl. Its formula is shown to be $C_6H_{12}N_4.CH_2ClCO_2CH_3$ or $C_6H_{12}N_4CH_2Cl.CO_2CH_3+H_2O$. Under the conditions existing it was deposited with a molecule of water of crystallisation. This reaction can be extended to the ethers of the halogen acetic acids, but experiments seem to show that it cannot be applied to the ethers of the other halogen fatty acids.

Action of Sulphurous and Sulphydric Acids on Pyridine.—G. André.—Already noticed.

Chemical Fermentation by means of Yeast in an Antiseptic Medium.—J. de Rey-Pailhade.—A quantity of brewery yeast is taken when the fermentation in a vat is just finished; it is rapidly compressed, and a little syrup of maltose added containing enough fluoride of sodium to form from 1 to 1·2 per cent of the whole. This is placed in a flask, which it should nearly fill, and closed with a cork fitted with a tap; it is kept in a cool place, and occasionally shaken. For the first two days very little carbonic acid comes off, but on the third day there is a considerable quantity formed. By watching the course of the solution of the albumenoid materials in the liquid in another flask, we observe that at the commencement, the supernatant liquid, when boiled, does not become very cloudy, while on the third day, a plentiful white coagulum is obtained. At first the still active yeast ferments but little or not at all; later on the prolonged action of the antiseptic having destroyed its vital power, it dissolves, and the primitive chemical action takes place with the evolution of carbonic acid and the probable formation of alcohol. This, however, is a point which the author has not yet confirmed. If the yeast, separated by filtration, is mixed with an aqueous solution of glucose there is no sign of fermentation; this is a proof of the death of the organism. The evolution of gas observed in contact with the antiseptic is simply a chemical phenomenon accomplished without the intervention of a living organism. The following observation appears to be of importance: the antiseptic mixture, when three days old, is rubbed up with sulphur, and almost instantaneously the evolution of carbonic acid ceases. The sulphur, acting with the yeast, gives off sulphuretted hydrogen through its combination with the *philothion* or *hydrogenase*, discovered by the author in the year 1888. This can easily be shown experimentally, by placing in two test-tubes inverted over mercury 20 c.c. each of the simple mixture, and the mixture ground up with sulphur; in the first, the evolution of gas continues for five or six days, and attains a volume of about 20 c.c.; in the latter the gas very quickly ceases to come off.

MISCELLANEOUS.

A Simple Method for the Preparation of Sulphides, Chlorides, and Bromides of the Metals from Cerite.—W. Muthmann and L. Stützel.—**I.** *Sulphides.* We start with a crystallised sulphate which is dehydrated by gentle calcination; it is then placed in a porcelain boat and heated for several hours in a combustion tube through which a current of thoroughly dry sulphuretted hydrogen is passing, raising the temperature to dull red. The colour of the product becomes darker, and in this manner we obtain perfectly pure sulphides, M_2S_3, stable in the air at the ordinary temperature, more especially if the calcination has been strong; they are only slowly attacked by boiling water, rapidly by dilute acids with the evolution of H_2S. When heated in the air these sulphides take fire; they often appear pyrophoric; in this manner oxide and sulphate are formed.

	Colour.	Density.
Cerous sulphide, Ce_2S_3 ..	Brown or black	4·9108
Sulphide of lanthanum, La_2S_3..	Yellow ..	5·020
Sulphide of neodymium, Nd_2S_3	Olive green ..	5·042
Sulphide of praseodymium, Pr_2S_3,	Bright chocolate	5·179

We have not succeeded in the preparation of Ce_2S_3, crystallising in golden-yellow flakes according to Mosander. **II.** *Chlorides and Bromides.*—We heat the sulphate, prepared as has been already described, in a current of pure thoroughly dried HCl or HBr gas; the substance becomes discoloured, and at the end of an hour a powder consisting of pure anhydrous chloride, MCl_3 (or bromide) is

obtained. Cerous chloride and bromide and chloride of lanthanum occur as white crystalline powders or masses; the chloride of neodymium is rose-coloured, that of praseodymium green. All these products greedily absorb water; they are very soluble in water and alcohol, forming a limpid solution. They are fairly fusible and slightly volatile.—*Berichte*, vol. xxxii., p. 3413.

The Sulphoxyarseniates.—L. W. McCay.– I. *Action of the Alkalis on Pentasulphide of Arsenic.*—Berzelius showed that the alkaline lyes dissolved As_2S_5, giving an arseniate and a sulpharsenate. This is not exactly true; the author has not been able to obtain a trace of precipitate of ammonio-magnesian arseniate. As a matter of fact, in this reaction (with KHO, NaHO, NH_3, or even the alkaline earths) a mixture of sulpharseniate and monosulphoxyarseniate is formed:—

$$As_2S_5+6ROH=AsS_4R_3+AsO_3SR_3+3H_2O.$$

At the same time a little disulphoxyarseniate is always likely to be formed. To prove these statements we add $SrCl_2$ to the sodic solution of As_2S_5, shake thoroughly and allow to stand for twenty-four hours. The precipitate is collected, boiled with a solution of CO_3Na_2, and the filtered liquid precipitated with alcohol; $AsO_3SNa_3+12H_2O$ is obtained. The mother-liquors of the strontium salt, treated with $BaCl_2$, deposit disulphoxyarseniate of barium, which, if treated in the same manner with CO_3Na_2, gives $AsO_2S_2Na_3+10H_2O$ on precipitating the solution with alcohol. II. *Preparation of Monosulphoxyarseniate of Sodium from a Solution of Arsenic Acid treated with Sulphydric Acid.*—Through a dilute solution of As_2O_5, a current of H_2S is passed until an abundant precipitate is formed and a quantity of finely-divided asbestos is added; the excess of H_2S is driven off by means of a strong current of air and the liquid is filtered. An excess of MgO is added to the filtered liquid to remove the unattacked As_2O_5. After filtering off the $(AsO_4)_2Mg_3$, KOH is added to precipitate the $Mg(OH)_2$, and then $Ba(OH)_2$, which precipitates the whole of the tribarytic sulphoxyarseniate in an impure state. The salt is, as before, boiled with CO_3Na_2, and the filtered liquid precipitated with alcohol until it becomes cloudy. After a few hours there is a deposit of beautiful crystals of $AsO_3SNa_3+12H_2O$ in a very pure state. The arsenious acid always remains in solution. We can obtain a solution of acid AsO_3SH_3 fairly stable in the cold, by treating the barytic salt in suspension in water with the strictly necessary quantity of dilute SO_4H_2.—*Berichte*, vol. xxxii, p. 2471.

MEETINGS FOR THE WEEK.

Monday, 14th.—Society of Arts, 8. (Cantor Lectures). "Elementary Art Education," by J. Liberty Tadd.

Tuesday, 15th.—Royal Institution, 3. "Practical Mechanics" (Experimentally treated); by Prof. J. A. Ewing, M.A., F.R.S., M.Inst.C.E.

—— Society of Arts, 8. "Cameos," by Cyril Davenport, F.S.A.

Wednesday, 16th.—Society of Arts, 8. "Photography of Natural Colours by the McDonough-Joly Process," by H. Snowden Ward.

—— Microscopical, 8. Annual Address by the President.

Thursday, 17th.—Chemical, 8. "The Preparation of Esters from other Esters of the same Acid," by T. S. Patterson and Cyril Dickinson. "Tecomin — a New Colouring-matter derived from *Bignonia tecoma*," by T. H. Lee. "A New Method for the Measurement of Ionic Velocities in Aqueous Solution," by B. D. Steele, B.Sc. "Metal-ammonia Compounds in Aqueous Solution—(II.) The Absorptive Powers of Dilute Solutions of Salts of the Alkali Metals," by H. M. Dawson and J. McCrae.

—— Royal Institution, 3. "The Origin of Vertebrate Animals," by Arthur Willey, M.A., D.Sc.

—— Society of Arts, 4.30. "Metalliferous Mining in India," by Dr. John W. Evans, LL.B., &c.

Friday, 18th.—Royal Institution, 9. "Gases at the Beginning and End of the Century," by Prof. Dewar, F.R.S., &c.

Saturday 19th.—Royal Institution, 3. "The Government and People of China," by Prof. R. K. Douglas.

SUPPLEMENTARY CATALOGUE OF CHEMICAL AND SCIENTIFIC BOOKS
New and Second-hand (No. 110), post free on application.

IMPORTANT TO EXPORTERS.

The Firm of E. HEUER, Chemical Manufactory, in Aussig, Austria, begs to call the attention of Exporters to the Exporting Products of the Factory.

ALCOHOL DERIVATIVES in general, and in particular Ethers of all kinds, such as Sulphuric, Acetic, Rum, Formic, Nitrous, Œnanthic, Butter, Fruit, Grain, and Saccharine Ethers in every specific gravity, all degrees of concentration, and grades of purity.

ABSOLUTE ALCOHOL—98, 99, 99 2/3, and 99 5/7 per cent.

SUPERIOR RUM ESSENCES in all concentrations and contents of spirits.

FIRST CLASS FRUIT ESSENCES, Amylic Alcohols, Amylic Acetates, and Amylic Oxides.

PHARMACEUTICAL CHLOROFORM and Special Brand E.H. CHLOROFORM for Narcosis.

Special Brand E.H. SULPHURIC ETHER for Narcosis.

Correspondence desired.

New Term Commenced January 7th.

BIRKBECK INSTITUTION,

Bream's Buildings, Chancery Lane, E.C.

Principal: G. ARMITAGE-SMITH, M.A.

DAY AND EVENING CLASSES.

UNIVERSITY OF LONDON.—Complete Day Courses for all the Examinations in Science, and Complete Evening Courses for all the Examinations for the Science, Arts, and Law Degrees.

SCIENCE CLASSES in every Branch, with Practical Work. Well equipped Laboratories for CHEMISTRY, PHYSICS, and METALLURGY.

CONJOINT BOARD: Lectures and Practical Work in Chemistry, Physics, Biology, and Practical Pharmacy.

Prospectus free. Calendar 6d. *(by post* 8d.*) on application to Secretary.*

Vol. LXXXIII., No. 2147.

THE ESTIMATION OF MANGANESE IN FERRO-CHROMIUM ALLOYS.

Any person undertaking the complete analysis of these alloys will find, however diligently he may search, that very few reliable methods, and only a few makeshifts, are available for the estimation of the minor elements. Processes anything like as convenient as those used for the analysis of iron and some other iron alloys do not exist. The following process may therefore be useful:—

Fuse 1 grm. of the powdered alloy with several times its weight of soda peroxide in a nickel crucible, dissolve the melt in water, boil for five or ten minutes, and filter off the peroxides of iron, manganese, and nickel. As the mixed oxides filter badly, but settle readily, they should be boiled repeatedly with water containing a little ammonium carbonate, and collected on the filter only when the yellow chromate colour is barely or not at all visible in the filtrate.

The residue and filter (asbestos) are returned to the beaker, nitric acid (1·20) and water in equal volumes are added along with as much ferrous sulphate solution as is needed to completely reduce the higher oxides of manganese and nickel.* When the precipitate has dissolved, the solution is made quite cold, oxidised with soda bismuthate, and the filtered permanganate titrated with hydrogen peroxide, according to the instructions of Reddrop and Ramage (*Journ. Chem. Soc.*, lxvii., 268).

The titrated solution is green, owing to the nickel derived from the crucible. A small excess of permanganate mixing with the green solution makes it quite colourless. The nickel of the crucible is usually quite free from manganese.

The ferro-chromiums used in steel-making are never quite free from manganese, and may contain as much as 1·5 per cent.

In order to test the above process, weighed amounts of a known iron-manganese alloy were fused along with the ferro-chromium. The amounts added in this way, and subsequently recovered in addition to that already existing in the alloy, were—

Per cent added.	Per cent found.
1·01	1·00
2·02	1·97
2·02	2·03

J. T.

* When the solution is boiled without adding any ferrous sulphate, much of the manganese is converted by the higher oxide of nickel into permanganate.

ACTION OF SUNLIGHT ON NATURAL WATERS.

By Dr. T. L. PHIPSON.

1. It has been known for a long time that when spring-water, rain-water, and river-water are exposed to sunlight, or even to diffused daylight, for a sufficient length of time in summer, the gradual development of what has been termed the "green matter" of Priestley occurs. This consists of certain mono-cellular algæ, and I have proved experimentally that they are derived (fall into the water), from the atmosphere. They are brought down very abundantly by a first fall of snow, and in rain-water. When the water is boiled and the neck of the flask closed with a good plug of cotton-wool, no development of green substance occurs after many months' exposure to sunlight; but if freely exposed to the air the microscopic plants will form in the course of a few weeks, or a few months, according to the season and temperature.

2. If a small quantity of pure crystallised cane-sugar be dissolved in the water before it is exposed to the sunlight, a different thing occurs:—

1 grm. of sugar to 300 grms. of water, exposed in a flask, the neck of which has a plug of cotton-wool to prevent germs entering from the external atmosphere, and with a summer-heat of 70° to 80° Fahrenheit, produces no green matter, but instead there form, in the course of a few days, very minute white specks, which increase in size, becoming more and more visible, and finally flocculent. Under the microscope they are found to consist of isolated mono-cellular beings like the algæ of the green matter referred to above, but these microbes are much smaller; they are extremely minute, colourless, oval cells, without any trace of green chlorophyll, and they secrete from their walls a fluid which causes them to adhere together by countless myriads, forming in the course of some months a "zoogloea," or membranous-like substance which remains *in statu quo* for more than a year.

The water filtered from it still contains sugar (after sixteen months' exposure to the sunlight).

3. It has been imagined by certain chemists that the appearance of white flocks of this kind in water containing sugar is a sign of the water being impure and unfit for drinking; but I have found that all waters, even those of exceptional purity, give rise to the same phenomenon.

My observations in this respect were made during the last two years with specimens of water of great purity from Madeira, with Thames water, and with samples of well-waters from the country.

The well-waters appear to form the white flocks rather more abundantly and rather more rapidly than the others; but the white microbe in question was developed in all.

I have also found that if the solution of sugar be boiled, and so sterilised before being added to the water, it does not prevent the occurrence of the phenomenon in question. But if the water experimented on be boiled for a quarter of an hour before the sugar is added no formation of the white microbe occurs.

This experiment proves conclusively that the germs are in the water (not in the sugar), and previous experiments have shown me that they are derived from the atmosphere.

Casa Mia, Putney, January 10, 1901.

ARSENIC IN BEER.

By E. W. T. JONES.

I beg to lay before the readers of the Chemical News the method I have been using for the detection of arsenic in beer since the beginning of December last, when the scare inundated most public analysts like myself with beer samples. I do so, notwithstanding the report of the method published by the Commission of the Manchester Brewers' Association, because, although in the main their method differs but little from mine, I personally prefer my procedure because it secures immediately on the addition of the acid the requisite conditions of Reinsch's test for the deposition of the arsenic on the copper. Before the addition of the hydrochloric acid there is no fear of arsenic being lost by the evaporation.

I also append the method I have employed with success for the *estimation* of the arsenic on the lines of Dr. Clark (*Journ. Chem. Soc.*, 1893).

Qualitative Test.

250 c.c. of the beer are evaporated in a porcelain dish over a low Fletcher burner to about 100 c.c., then 25 c.c. of pure strong hydrochloric acid are added, and into the still boiling liquid is put a piece of fine copper gauze (I prefer this to foil), about 1 inch by ½ inch, and the boiling continued for a quarter of an hour; if no darkening occurs by this time certainly less than $\frac{1}{10}$th grain per gallon of arsenic is present. If the gauze is suspiciously darkened, wash with hot distilled water, then with alcohol and dry. Roll up into a small size, and introduce into a small glass tube about three inches long, and heat the gauze with a very small flame whilst holding the tube in a horizontal position; examine any sublimate under the microscope, using a ⅛th objective. The tubing I have found very convenient is of elliptical section (I had it made originally for absorption spectroscopical work); it lies conveniently on the stage of the microscope, held on to the usual glass slips by two thin indiarubber bands, and I prepare such pieces of tube by drawing out to furnish a shoulder for the piece of gauze, and also that I may concentrate the sublimate in the narrower part.

Unmistakable octahedral or tetrahedral crystals of arsenious oxide are obtained without the least difficulty by the above procedure when $\frac{1}{10}$th grain per gallon is present.

For glucose, syrups, jams, &c., I use 50 grms., and make to 100 c.c. at once with hot distilled water, and proceed in the same way.

To prepare the copper gauze I heat a strip about an inch wide to redness in a Bunsen burner, and then remove the black oxide with nitric acid, well wash, and dry; from these beautifully bright strips I cut pieces off about a ½ inch wide for the qualitative test, and about 3½ inches long for the rolls I use for the quantitative tests.

Quantitative Test.

250 c.c. (or more) of the beer are evaporated as above in a porcelain dish to about 100 c.c., and 25 c.c. of pure strong hydrochloric acid added, then a piece of the pure bright copper gauze 1 inch × 3½ inches, in the shape of a loose roll, is put in, and the liquid is kept just on the *boil* with occasional stirring for say an hour, addition of hot distilled water being made from time to time to prevent the bulk by evaporation getting too small; considerable concentration is *advantageous* before the bulk is brought back with distilled water. The roll of gauze is now removed and washed with hot distilled water, the first washings being returned to the dish, and then another roll is put in, and the *boiling* continued.

The blackened and thoroughly washed roll is now put into a small beaker, ⅞ inch diameter and 1½ inches high, containing 5 c.c. N. sodic hydrate diluted to just cover the roll, and then 3 or 4 drops of a 10 vol. solution of peroxide of hydrogen solution added; by moving the coil up and down this solution is mixed, and on standing in the cold the gauze is gradually denuded of its black coating, and on acquiring its original colour is removed and washed into another larger beaker, these washings being reserved.

The second roll of gauze after half-an-hour's boiling in the acid beer solution is examined; if dark, is removed, washed, and treated as the first; then the first cleaned roll is introduced again, and so on, till no further deposit shows; generally the third roll shows that all the arsenic has been removed. Each roll is treated as the first, a drop or two more peroxide of hydrogen being added if required to expedite the removal of the arsenical coating.

The alkaline solution of arsenate and the washings are united and heated on the hot plate for an hour or so; then the copper precipitates, and can be filtered off. 7 c.c. of $N.H_2SO_4$ are added to the clear filtrate, and then a little pure sulphurous acid solution till the solution smells of SO_2; the solution is now boiled and concentrated till every trace of this is expelled, and to the solution, whilst hot, is added its own bulk, say 50 c.c., of saturated H_2S water; then H_2S passed through the still warm solution for a time; then it is removed to a warm place and left uncovered all night; on the following morning the As_2S_3 has collected and can be filtered off through a very small filter, and washed with water till the washings are quite free from saline matter; the As_2S_3 is now dissolved off the filter with the least possible amount of hot, very dilute ammonia water, this solution being evaporated to dryness on the hot plate in a small flat capsule (very small Petri dish covers 1¼ inches to 2 inches diam.); when cool, two or three drops of hot distilled water are added, and drop by drop *very* dilute HCl (one drop of the concentrated acid to 10 to 15 c.c. water), till the faintest acidity to litmus (this is to decompose any sulphide of ammonium); evaporate again to dryness, add 2 or 3 c.c. of H_2S water, and evaporate again to dryness; now rinse the residue with a few c.c. of distilled water, and pour off; this is easily done without detaching the sulphide; dry, boil up with CS_2 to remove S, pour off, rinse with strong alcohol, again with water, and heat on plate till *quite* dry, put under the desiccator till *dead* cold, then remove on balance with a pair of cold forceps (not with warm fingers), and weigh to the tenth of a m.grm.

Now treat the residue in the capsule with hot ammonia water; this immediately dissolves the As_2S_3, and leaves attached to the dish any trace of copper sulphide; put the solution from the dish and the rinsings into a beaker, and reserve; dry the capsule again on hot plate, and with same precautions, when cold, weigh again; the difference being As_2S_3 found.

One or two experiments should be made with pure beer, fulfilling all the conditions to see if anything is obtained from the reagents used.

To a non-arsenical beer I added at the rate of 0·1 grain per gallon of As_4O_6, and I found by the procedure I have described 0·0896, say 0·09 grain.

As a check I re-precipitated the dissolved As_2S_3 obtained, and compare with that from a solution of known strength, viz., where 1 c.c. contains 0·00018 grm. of As_4O_6, and in 250 c.c. of beer would equal 0·05 ($\frac{1}{20}$th) of a grain per gallon.

It will be observed that the actual arsenic obtained from the beer is kept and can be easily corroborated again if desired.

SMOKELESS POWDER.

By H. C. ASPINWALL.

ALTHOUGH the manufacture of smokeless powder has made enormous progress during the last few years, I am of the opinion that the question is still in the experimental stage, and that both chemists and manufacturers should continue to make great efforts to obtain the best results possible. I am well aware of the fact that the powder factories in the United States daily produce from 12,000 to 18,000 pounds of smokeless powder, the properties of which have been deemed satisfactory by the experts both of their army and their navy. It is certain that they have obtained excellent results, but the problem is one which time alone can solve: do these powders fulfil all the conditions which may arise from prolonged storage, climatic changes, &c.? As far as we know at present there is no reason to say that they do not.

Although the history of smokeless powder is probably known to many chemists, I think nevertheless that it will be of interest to recall briefly the different phases through which it has passed before reaching its present state of development.

In 1832 Braconnot discovered that on treating starch, ligneous fibres, and analogous substances with concentrated nitric acid, an extremely combustible substance could be obtained, to which he gave the name xylidine. These experiments were taken up and completed by Pelouze in 1838, and this chemist also had recourse to paper as the raw material. Some time afterwards Dumas prepared

a substance, also from paper, which he called nitramidine, and from which he proposed to make cartridges. But this substance was found to be irregular and uncertain in its action, and his researches had no practicable result up to the time when Schönbein, in 1845, announced to the world the invention of gun-cotton. In 1846 Bœttger also announced the production of gun-cotton. Eventually these two chemists became associated, finding that their discoveries were identical. At the end of 1846 Otto described a process for the manufacture of gun-cotton, and in 1847 W. Knop, in Germany, and Taylor, in England, found that gun-cotton could be prepared by means of a mixture of nitric and sulphuric acids.

At this time numerous experiments were undertaken in many countries with a view to replacing ordinary powder by this new explosive. It was, however, soon found that this was hardly possible; terrible and inexplicable explosions were of frequent occurrence, and this circumstance caused the abandonment of the experiments. Nevertheless, in Austria, Baron von Lenk was not to be frightened, and in 1862 he patented his process in England. In 1865 Abel in his turn took out a patent for an improvement which consisted essentially of reducing the gun-cotton to the form of a paste, which enabled all traces of acid and other impurities to be eliminated, and rendered it more stable.

The cutting and grinding of cellulose fibres in the apparatus then brought into use, permitted the expulsion of the free acid which they held by capillarity, and thus there was a means of removing one cause of instability. This is the method in use at the present day, and it is that which has made the extended use of gun-cotton possible.

Nitro-glycerin was discovered by Sobrero, who, by the advice of Pelouze, undertook the examination of the action of nitric acid on glycerin. It is, however, to Alfred Nobel that belongs the credit of having actually prepared the development of smokeless powder. After having invented explosive gelatin, this chemist observed that by means of a suitable solvent, nitro-glycerin and gun-cotton could be mixed in variable proportions.

In this manner he prepared a hard, horny substance, capable of being formed into grains, and of being used with perfect security as the propelling force in cannons, a substance to which he gave the name of ballistite. The most recent history of smokeless powder dates from 1886, at which time Vieille prepared B powder; in France Captain Schultz's powder appeared at almost the same time. In 1882 Reid and Johnson had introduced C. E. powder, and this had been adopted for artillery. Nobel's ballistite was patented in 1888. Since that time innumerable compositions have been proposed, the greater number of which have not given the good results expected of them.

The term gun-cotton used up to now in this article, to designate in a general manner all the varieties of nitrated cellulose, is not entirely conformable with the facts, since under this designation is generally included the most nitrated cellulose, insoluble in ether-alcohol. In what now follows the term nitro-cellulose will be employed, as better answering the conditions, and including both the soluble and insoluble varieties.

Smokeless powders known at the present time may be divided into three principal groups.

Group I.

Powders composed of nitro-cellulose, either with or without the addition of salts capable of liberating oxygen, or of inert organic substances. The group has several sub-divisions, from the point of view of the degree of nitration and the solubility of the nitro-cellulose.

a. Powder composed of detonating cotton (trinitro-cellulose containing 14·14 per cent of nitrogen, though in practice the proportion rarely exceeds 13·35 per cent). This powder is insoluble in a mixture of two parts of ether and one part of absolute alcohol, and only contains a very small proportion of soluble nitro-cellulose, generally less than 1 per cent.

b. Powders composed of a mixture of insoluble nitro-cellulose and soluble nitro-cellulose.

c. Powders composed of soluble nitro-celluloses. These three sub-divisions may be varied indefinitely by the addition of salts capable of liberating oxygen (generally alkaline nitrates), or inert organic substances, such as camphor, colouring materials, vegetable oils, mineral hydrocarbides, &c.).

Group II.

Powders containing nitro-glycerin in combination with nitro-cellulose. This group may also be sub-divided into sub-groups, from the point of view of the variety of nitro-cellulose used, and the presence or absence of oxygenated salts or inert materials.

Group III.

Powders, into the composition of which enter picrates, picric acid, or the nitro-substituted products of the aromatic carbides, in combination with one or more of the substances enumerated in groups I. and II.

Smokeless powder may also be classed according to their physical properties; that is to say, a distinction should be drawn between the powders called "bulk loading," and "compact" powders. The first have a low specific gravity, and are manufactured in such a manner that they may be changed, charge for charge, for black powder; that is to say, that the same measure which serves for the measurement of black powder can be utilised for measuring an equal volume of this class of smokeless powder, so as to give, volume for volume, approximately the same speed and the same pressure. These powders are almost exclusively used for artillery, and less often for sporting-guns using lead bullets; that is to say, in cases where it is not desirable that the speed should be higher than that given by the regular charge of black powder. The "compact" powders, on the contrary, have a high specific gravity, and the charges are made preferably by weight, seeing that the volume occupied by a full charge is not more than one-third or one-half of the volume occupied by an equivalent charge of black powder.

The smokeless powders for big guns are compact powders, the specific weight of which varies between 1·58 and 1·67, being very close to that of black powder.

It is not my intention to praise any particular class of smokeless powder. They all have their merits and their faults, and the ideal compound is yet to be found.

The manufacture of smokeless powder is a delicate operation, and to obtain satisfactory results it is necessary to observe certain indispensable conditions; the principal of which are enumerated below:—

1. The powder must be chemically stable, and when stored for a more or less prolonged period should not exhibit any signs of decomposition or disaggregation.

2. It should not undergo any change when exposed to the action of moisture, heat, cold, or climatic variations.

3. It must not be very sensitive to shock or friction.

4. It must be easy to manipulate and capable of being transported without danger.

5. The gases of combustion should not have a disagreeable odour, and should not exert any deleterious action on human beings.

6. It must be capable of being easily formed into grains of any size, and the shape of these latter should not be liable to change except within very narrow limits.

7. It must be perfectly homogeneous.

8. It should possess the highest possible ballistic power; or, in other words, it must be able to communicate the highest possible speed to the projectile, while at the same time exercising the lowest possible pressure in the gun.

It appears that nitro-cellulose, soluble or insoluble, is the material which is adapted for the manufacture of a smokeless powder fulfilling these conditions in the nearest degree. This substance enters into the composition of nearly all the smokeless powders at present known, and the ballistic results obtained are very satis-

factory, both when the nitro-cellulose is mixed with other materials and when it is used in the form of a simple colloid of nitro-cellulose.

Nitro-cellulose, in combination with nitro-glycerin, also gives very good results. It is this compound which constitutes English cordite, which is composed of 58 per cent nitro-glycerin, 37 per cent trinitro-ceilulose, and 5 per cent of vaseline.

But, on the other hand, a certain number of compounds containing nitro-glycerin, in relatively small quantity, in combination with nitro-cellulose, soluble or insoluble, have not given good results, and we are still ignorant whether this is due to the composition or the granulation, or to both these factors at once.

Nitro-glycerin, constituting a stable chemical compound, seems to be the best adapted to the preparation of smokeless powder. The action of nitric acid on glycerin,—

$$C_3H_5O_3H_3+3HNO_3=C_3H_5O_3(NO_2)_3+3H_2O,$$

produces a compound which, when purified by repeated washings, is homogeneous and stable.

Nitro-cellulose, although perfectly stable, cannot be looked upon as a definite chemical compound; it consists of a mixture of nitro-celluloses of different degrees of nitration. In view of the structure of the cellulose fibre, it has been impossible to obtain theoretical results by nitrating with a mixture of nitric and sulphuric acids.

The product known under the name of trinitro-cellulose, $C_6H_{10}O_5+3HNO_3=C_6H_7O_5(NO_2)_3+3H_2O$, yields with the nitrometer 14·14 per cent of nitrogen, while in practice we cannot obtain more than 13·35 to 13·65 per cent. The difference is due to the presence of untransformed cellulose, and perhaps also to the presence of very small quantities of lower nitrates. The soluble nitro-celluloses, whose use is very widespread in the manufacture of smokeless powders, undoubtedly consists of a mixture of nitro-celluloses of different degrees of nitration, and, for that reason, it does not seem to be as satisfactory as a definite homogeneous chemical compound.

Another disadvantage in the use of nitro-cellulose is its price, which is higher than that of nitro-glycerin.

It is not without interest to mention that Eder prepared a nitro-cellulose soluble in etherised alcohol, a substance which he called penta-nitro-cellulose,—

$$C_{12}H_5O_5(ONO_2)_5=12\cdot75 \text{ per cent nitrogen,}$$

and which appeared to be more soluble than any of the other known nitro-celluloses. However, I have quite recently prepared a soluble nitro-cellulose, showing 22·91 per cent of nitrogen with the nitrometer.—*Moniteur Scientifique*, Series 4, vol. xiv., December, 1900.

THE ALLOTROPIC FORMS OF SELENIUM.*

By A. P. SAUNDERS.

(Continued from p. 22).

Summary of Specific Gravity Results.

THE most careful determinations which have been made of the specific gravity of the various forms of selenium lead to the following results for the different modifications, at ordinary temperatures:—

Amorphous	4·26
Vitreous	4·28
Red crystalline	4·47
Metallic	4·80

Atomic Volumes.

Taking the atomic weight as 79·2, these values give the following atomic volumes:—

Amorphous	18·6
Vitreous	18·5
Red crystalline	17·7
Metallic	16·5

* From the *Journal of Physical Chemistry*, vol. iv., No. 6.

10. *Conductivity of Selenium. Action of Light.*

Beyond a vague experiment of Knox (1839), there is no information of value regarding the conductivity of selenium before 1851, when Hittorf found that the vitreous form was a very good insulator, whereas in the metallic state the element conducts electricity fairly well, and furthermore shows an unusual property, in that, unlike typically metallic substances, but like tellurium, its resistance decreases with rising temperature up to the point of fusion; at that point it suddenly increases. Hittorf used carbon plates as electrodes in his experiments.

In 1873 Willoughby Smith announced that the resistance of selenium to the passage of electricity was diminished by light. We have no details regarding the preparation of the selenium, which was in rods 5—10 c.m. long, and 1—1·5 m.m. thick. They were, plainly, of the metallic modification, as the later correspondence shows, and were sealed in glass tubes, through the ends of which platinum wires were fused for the purposes of connection. Even the light of an ordinary gas burner was found to exercise a marked influence upon the conductivity, which rose and fell according as the cell was exposed to the rays of the burner, or shaded by interposing the hand. The difference with even so feeble a source of light as this amounted to 15 to 20 per cent. "If the light be intercepted by rock salt, or by glass of various colours, the resistance varies according to the amount of light passing through the glass. To ensure that temperature was in no way affecting the experiments, one of the bars was placed in a trough of water, so that there was about an inch of water for the light to pass through, but the results were the same; and when a strong light from the ignition of a narrow band of magnesium was held about nine inches above the water, the resistance immediately fell more than two-thirds, returning to its normal condition immediately the light was extinguished."

These observations excited widespread interest, and elicited some correspondence, which will be found in the volume of *Nature* for the year 1873.

Later in the same year, Sale presented before the Royal Society the results of his researches, confirming the observations of Smith, and showing in addition that the part of the spectrum most active on selenium is just outside the red rays, at a place nearly coincident with the locus of the maximum of the heat rays. He showed further that the effect of light, on exposure, is instantaneous, but that on cutting off the light, the return to the normal resistance is not so rapid.

In 1874 Lord Rosse announced some experiments which he had made for the purpose of establishing that it was light and not heat which was the cause of the change. He compared the action of the selenium cell with that of a thermopile under similar conditions, and found no accordance between them at all. The non-luminous radiation from hot bodies had no action upon the cell, whereas the effect of candle light was not very materially diminished when allowed to pass through a plate of glass or a solution of alum.

Further confirmation of these results was supplied in 1875 by Siemens, who adds some very interesting information regarding the preparation of the cells. He found that no satisfactory results were to be obtained from material which had been transformed into the metallic modification by heating to 100° or 150°, but that by long heating to 210° or even by cooling melted selenium down to 210°, and maintaining it at that temperature for some time, "another modification," as Siemens says, is obtained, and this shows a higher degree of conductivity as well as a normal behaviour toward changes of temperature, the resistance rising as the temperature is raised. The action of light upon such material is also very much more marked, and entirely constant, the earlier cells having given variable results. Two flat spirals of platinum wire, about 1 m.m. apart, between mica plates, formed the cell, and a layer of selenium was fused over the spirals so as to fill the interspaces. This formed a very sensitive

instrument, and Siemens found that heat causes a diminution of conductivity, whereas direct sunlight increased it more than tenfold, the increase being nearly proportional to the square root of the intensity of the light. In the same year appeared a paper by Adams, bringing further confirmation of the statement that the light rays alone are active. He found that a marked effect was produced by the light of the moon, and that of the various parts of the spectrum the greenish-yellow rays were the most powerful.

Practical application of these new properties of selenium was now made in the construction of instruments for the measurement of light intensities, &c. Thus in the year 1875 Siemens described his "Electrical Photometer," Bell his "Photophone" in 1880, Bidwell his "Telephotograph" in 1881, and so on. Since the construction of these instruments had added nothing to the theory of the matter in hand, a mere mention of them will suffice.

The year 1876 is rich in memoirs. Draper and Moss undertook to determine what they call the "precise molecular state" of light sensitive selenium; but though they describe several forms of metallic selenium, which show varying behaviour toward the electric current, nothing is said of the methods of their preparation.

Later, Moss made a study of the action of mercury vapour on rods of vitreous selenium, and found that when these are allowed to stand over mercury they acquire a film of high conductivity, no doubt selenide of mercury. The same result is obtained by dipping them into mercury. Rods of the metallic modification also show increased conductivity under like circumstances. Adams, in the same year, showed that the change in resistance of selenium under light stimulus is proportional to the square root of the illuminating power. Experiments with tellurium cells indicated a distinct though very slight influence of light upon their conductivity. Adams and Day then showed that there is a change of resistance when the direction of the current passing through a selenium cell is reversed. Their method of preparation of the cell was to fuse platinum wires against the ends of a rod of vitreous selenium, and then place this in a bath of hot sand for some time. They showed, moreover, that on the whole there is a general diminution of resistance in the selenium as the battery power is increased.

Their results indicate that the conductivity of selenium cells is electrolytic. After passing the current for some time through the selenium, and then disengaging the electrodes from the battery and connecting them with the galvanometer, a current, sometimes of considerable intensity, was set up in the opposite direction, thus showing a polarisation effect. Light has an action upon this polarisation current; indeed they found that light is capable of setting up a current in such an arrangement even where no current has previously passed. The sensitiveness is different in different parts of the same piece of selenium, but in general the current is set up from the less towards the more illuminated regions. It is produced instantaneously, and falls at once to zero when the light is shut off. When the light fell upon a junction the current passed from the selenium to the platinum, through the junction.

A most important contribution to a knowledge of the subject was supplied in this year by Siemens. He endeavoured, in the first place, to find other substances showing a behaviour to light similar to that which is manifested by selenium, but in vain. Even in the case of tellurium, to which Adams had attributed this property, Siemens could find no distinct action which could not be explained as a heat effect.

In order to repeat the observation of Hittorf under better conditions, he prepared a cell with vitreous selenium and carbon electrodes. This was connected to a single Daniell cell, and plunged into a bath of paraffin maintained at 280°. A thermometer standing in the centre of the cell showed the change in temperature in the mass of the selenium, and any differences in its conductivity were read off upon a galvanometer. The results are shown in the accompanying diagram (Fig. 4).

The curve A represents the temperature of the selenium, the curve B the conductivity, and C represents a normal change of temperature for the conditions of the experiment. Time is plotted on the horizontal axis, and the values upon the vertical axis indicate temperatures for the A and C curves, and conductivities for the B curve.

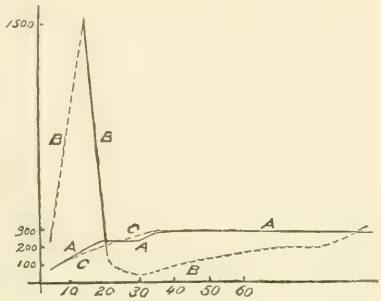

FIG. 4.

Considering first the A and C curves, we find that at about 100°, where the transformation into the metallic form would naturally begin, there is an abnormal rise in temperature. This is due to the heat of transformation. On the other hand, when we come to about 220°, there is a retardation because we have arrived at the melting-point; after complete fusion, the two curves run together again. Consider now the A and B curves. Siemens records that at 80° there was still complete non-conduction; when the thermometer had reached 162° the deflection of the galvanometer had risen to 870 scale divisions; plainly by this time a good deal of the material had gone over into the metallic (conducting) state. At 200° the deflection was 1520, but when the thermometer registered 215° it had fallen to 120 scale divisions. The thermometer, being in the middle of the mass, shows a certain lag, so that this reading of 215° doubtless corresponds to a higher temperature throughout the mass, and the fall of conductivity is due to the fact that a good deal of the selenium had already passed into a state of fusion. At about the time that complete fusion is reached, the conductivity shows a minimum, and after that, with constant temperature, it rises gradually to the end of the experiment, the temperature of the selenium remaining at about 250° to the last. The conclusion drawn from these observations by Siemens, that metallic selenium shows increasing conductivity with rising temperature, rests on insufficient ground, because the entire period between the beginning of the experiment, and the moment when the melting-point was reached was less than twenty minutes, and five minutes of this time were occupied in raising the temperature to 100°. During the remaining period there was probably a continuous change going on from the vitreous to the metallic modification, which would, of itself, bring about an increase of conductivity until the change in this direction, in the cooler parts of the cell, was balanced by a change in the opposite direction, due to fusion, in the hotter parts.

Later experiments, however, showed that the conductivity of grey selenium does increase with rising temperature.

The gradual rise in the B curve is difficult to explain except on the ground of chemical action. Shelford Badwell has shown, in a paper published somewhat later, that the peculiar behaviour of selenium cells may be due to the formation of selenides. Such a reaction might

easily go on in this case with the metallic impurities contained in the carbon electrodes; but of that more will be said later.

In another experiment, where the direct heat of a flame was used, Siemens found that the conductivity increased up to 350°, where rapid vaporisation of the selenium set in.

The remark of Siemens that, in the case of both solid and liquid selenium, the conductivity decreases with continued heating, stands in unexplained contradiction with the results of the above experiment.

If the current be passed for some time, Siemens finds a diminution of conductivity, as if polarisation had set in, opposing itself to the passage of the current.

Experiments made with metallic selenium prepared by heating the vitreous form to 150°, show that the conductivity does slowly fall when the temperature is kept constant, and also that a higher result is always obtained at a given point of temperature by cooling down to it than by heating up to it.

Siemens passed next to the use of other electrodes, namely, those of platinum and iron, having, as he says satisfied himself that solid selenium did not attack these metals. Yet it will be seen that in all the preparations he used, it was not solid selenium alone which came into contact with the metals, but liquid selenium as well, and at high temperatures. The electrodes in these experiments were either in the form of spirals, or lattice work, so as to expose a maximum surface of contact with the selenium while permitting of full illumination. On the effect of changing temperatures, the following experiment is worth transcribing.

Two cells, numbered 33 and 36, were placed in a paraffin bath, whose temperature was then rapidly raised to 200°. Both cells began to conduct at about 100°, and reached a maximum at 200°. Cell No. 33 had then a conductivity of 2720, No. 36 of 2120, in arbitrary units. The temperature was maintained for four hours.

The change with the time is shown in the table:—

	Cond.	
Time elapsed.	No. 33.	No. 36.
1 hr.	1240	940
2 hrs.	1090	820
4 hrs.	1000	800

No. 36 was then rapidly cooled, and No. 33, being slowly cooled, gave the following readings:—

Temp.	Cond.
180°	1020
150	2460
130	5730
120	8320
100	17020
80	21280

after which it diminished. On the following day it showed, at ordinary temperatures, a conductivity of 6190. Meanwhile No. 36, when suddenly cooled to room temperature, had been found to have a conductivity of 16450; after half an hour, of 14330; and on the following day 7710.

Thus these cells show a decreasing conductivity when maintained at 200°; but when cooled down, whether slowly or rapidly, the conductivity rises rapidly. This is in direct opposition to the results obtained with metallic selenium prepared in the ordinary way. The difference in preparation is that the "ordinary" form is made by heating vitreous selenium to 150°, whereas this form is produced when the same material is heated to 200°. But it must be noticed that the experiments on the other form were made with quite a different kind of cell, provided with carbon poles. The cell in these later experiments, by exposing so large a surface to the selenium, increases very much the possibility of a marked influence due to the formation of selenide at the surfaces of contact.

Bellati and Lussana (*Alt. Inst. Veneto*, 1887, [6], vi., 189, or *Ostwald's Lehrbuch*, II., ii., 422) have measured the conductivities of metallic selenides, and they find that, in general, these compounds show increasing resistance with rising temperature; *i.e.*, they conduct like metals. Furthermore, they find, in the case of copper and silver selenides, curious breaks in the curves at higher temperatures. It seems, therefore, not at all improbable that the change in selenium cells by long heating at 200°, which causes them to conduct metallically, may be explained by the formation of selenides.

Siemens finds that a cell which is only heated for a short time to 200° does not behave differently from one containing the ordinary metallic modification. In order to give to the cells the property of metallic conduction, it is necessary that the selenium should be first in the vitreous state, and that this should then be heated directly to 200°. If it has first been heated for some time at 100° and the temperature subsequently raised to 200°, the effect is either not produced at all, or to a far less degree. Nor does selenium which has been melted and cooled to 210°, and then maintained at that temperature, display any abnormal behaviour. It conducts like ordinary crystalline selenium.

Now vitreous selenium when heated to 200° is quite soft, and would be much more likely to attack metallic surfaces than the crystalline form, so that it is natural to suppose that in so far as the formation of selenide may be responsible for the behaviour of these cells, the method of heating adopted by Siemens would be most likely to produce the effect desired. By heating at 100° the mass would be almost entirely transformed at a temperature where it would be much less likely to act on the metals, and we would not expect to find any very marked reaction on heating this then to 200°.

But the second observation of Siemens recorded above, regarding the failure to prepare cells by cooling down fused selenium to 210° is, as he himself points out, in contradiction with his earlier experiments in the same direction, and it is certainly not plain why this method of preparation should not bring about as good results as the other.

From the remaining experiments reported in this paper, the following conclusions are drawn:—The observation of Adams that the conductivity of selenium cells increases for higher electromotive forces, is confirmed for such cells as have been prepared by heating vitreous selenium at once to 200°, but not for those where the transformation has been effected at lower temperatures. The effect of a continued passage of a current through a cell is the same as if a heating were thereby produced, *i. e.*, for one kind of cell it causes a rise, for the other a fall in conductivity. The change is shown not to be due to temperature. Reversing the current brings about such various phenomena that no general statement can be made about them. In some cells there is no effect at all; in others, evidence of a polarisation current.

With the cells prepared at 200°, if the heating at that temperature has been sufficiently long continued, so that the conductivity has attained a constant value, then when the temperature is lowered the conductivity shows an immediate rise. If the heating was less protracted the conductivity falls at first with falling temperature, reaches a minimum, and then rises again. The position of this minimum on the scale of temperature is dependent upon the length of the previous heating.

Selenium shows an extraordinary behaviour on change of temperature. It assumes a new conductivity value at once when the temperature is altered, and this change for rising temperature is in the direction of higher conductivity, if the selenium is of the first form (ordinary metallic), lower conductivity if it is of the second (prepared at 200°). But the new value does not remain constant For the second form, it falls after every change of temperature, no matter whether this change be up or down, and approaches a limiting value, slowly at first, then more rapidly. The

farther below the turning-point (minimum, see above) the new temperature lies, the greater is the conductivity which is at first manifested, but the more rapid also is its diminution. If the selenium has been maintained for some time at a lower temperature, so that its conductivity has fallen to a minimum, the peculiar phenomenon may be observed with the second form, that a rise of temperature brings with it at first an increase of conductivity. This is followed by a fall, and the end value is of course less than that for the lower temperature.

Cooling to -15° destroys the peculiar properties of the second form, and converts it apparently into ordinary metallic selenium.

Siemens noted the influence of the size of the surface of the electrodes on the behaviour of the cell, and also the importance of uniform contact between the selenium and the metal.

In explanation of the extraordinary behaviour of the element, he assumes that a third form is produced by continued heating at 200°, that this form is only stable at that temperature, and is at lower temperatures prevented from complete decomposition by being dissolved in, or combined with, ordinary metallic selenium. This view offers an explanation of the turning-point, beyond which the character of the conduction changes from metallic to electrolytic, and also of the fact that the cells show such a remarkable lack of uniformity of behaviour with changes of temperature.

That this assumption of a second form of metallic selenium has met with no support in my own experiments, has been shown above. Whether it will be possible to clear up all of Siemens's results by a further study of the influence of selenides upon the conductivity of selenium cells, must remain for the present an open question. Meanwhile, it is to be remembered that many of the irregularities which he noted may have had their seat in changing and irregular contact between selenium and metal; the cells were prepared with vitreous selenium, and when this goes over to the metallic form there is, as we know, a very considerable diminution in its volume: this would tend to cause rupture at any surface of contact, as well as to introduce air cavities everywhere through the material.

(To be continued).

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Extra Meeting, December 13th, 1900.

Professor Thorpe, C.B., F.R.S., President, in the Chair.

Professor H. A. Miers, D.Sc., F.R.S., delivered the Rammelsberg Memorial Lecture.

Karl Friedrich Rammelsberg was born on April 1, 1813, at Berlin, and succeeded Heinrich Rose as Professor of Inorganic Chemistry in the University of Berlin in 1874. He was also Instructor in Chemistry (1850—1883), at the Gewerbe-akademie, which became the Technische Hochschule, and was transferred to Charlottenburg in 1883; from 1883 to 1891, he was Director of the Second Chemical Institute of the University. He was twice married; in 1846, to the daughter of Oberbergrath Zincken; in 1859, to the daughter of C. G. Ehrenberg. In 1841, as Privatdocent, he started a private laboratory, in which was given the first practical chemical instruction in Berlin. He published an immense number of papers dealing with inorganic chemistry, crystallography, and mineralogy, but never himself engaged in any research work relating to organic chemistry. He was the author of numerous chemical text-books, one of which, *Grundriss der Chemie gemäss den neueren Ansichten* (1866), was the first to explain the new principles of organic chemistry. He was also the first of the old school of chemists to adopt the new system of formulæ.

Two of his books were encyclopædic works of reference: the *Handbuch der Krystallographischphysikalischen Chemie* (1855—1881), contained the crystallographic, optical, and physical constants of all crystallised compounds; the *Handbuch der Mineralchemie* (1841—1895), was an exhaustive treatise on the composition of all minerals.

He was equally eminent as Inorganic Chemist, Crystallographer, and Mineralogist. In chemistry, his work upon the halogen compounds, the phosphates, and the cyanides may be taken as samples of his researches. He prepared and studied an enormous number of bromides, of the ammonia compounds of the bromides and iodides; of bromates, iodates, and periodates; of phosphates, phosphites, and hypophosphites; our knowledge of the double cyanides is almost entirely due to him; equally laborious and important were his researches upon the sulphantimonates, hyposulphites, sulphites, nitrites, vanadates, phosphomolybdates. One of his important papers, on the Mexican amalgamation process, was communicated to this Society (1881). In crystallography, he did more than any other man to carry on the work of Mitscherlich, and investigated an immense number of isomorphous compounds; he studied the isomorphism of sulphur and selenium; he pointed out the isomorphism of vanadinite and pyromorphite, and first suggested that vanadic acid is V_2O_5; in his work upon the crystallisation of the sulphates $RSO_4,7H_2O$ from mixed solutions, he was one of the pioneers of modern physical chemistry.

In mineralogy also he contributed more than any one to our knowledge of the composition of minerals, and was practically the father of modern mineral chemistry; he published more than 300 papers on mineralogical subjects (including those on the analysis of rocks and meteorites); he first established the presence and the relationship of the ferrous and ferric iron in the group of the augites and hornblendes; he was the first to accept Tschermak's theory of the felspar group; and his laborious analyses ranged over about two-thirds of the mineral kingdom; he was strongly opposed to Penfield's views on the mutual replacement of fluorine and hydroxyl. Rammelsberg's active labours in mineral chemistry continued to the end of his long life, and at the age of 82 he published an elaborate supplement to his *Handbuch der Mineralchemie*. He died on December 28, 1899, at Gross Lichterfeld near Berlin, after a life of almost unexampled industry.

On the motion of Dr. Hugo Müller, seconded by Prof. M'Leod, a vote of thanks was passed to Prof. Miers for his Lecture.

Ordinary Meeting, December 20th, 1900.

Professor Thorpe, C.B., F.R.S., President, in the Chair.

The following certificates were read for the first time:—Messrs. Merrick William Burrows, Dunkirk, Devizes; Robert Waley Cohen, 11, Hyde Park Terrace, London, W.; Reginald Williams Ferguson, 8, Havelock Terrace, Paisley Road, Glasgow: John Lloyd Thomas Jones, United Service Club, Calcutta; James Menzies, 39, Winterbrook Road, Herne Hill, London, S.E.; Arthur W. Nunn, 313, Sydenham Road, Sydenham, S.E.; Herbert Kilburn Scott, P.O. Box 634, Rio de Janeiro, Brazil; Albert Edward Thomas, 34, South Road, Kingswood, Bristol.

Of the following papers, those marked * were read:—

*169. "*On the Union of Hydrogen and Chlorine.*" By J. W. Mellor, B.Sc.

At the suggestion of Professor H. B. Dixon the author undertook to investigate the mode in which light brings about the combination of hydrogen with chlorine. The

electrolysis of hydrochloric acid and of the solution of chlorine in this acid were first studied, as an exact knowledge of these is necessary to interpret the work of previous investigators.

Bunsen and Roscoe state that under certain conditions the gas resulting from the electrolysis of hydrochloric acid consists of a practically pure mixture of hydrogen and chlorine. The author finds, however, that under the most favourable conditions oxygen is present to the extent of 0·009 per cent.

In order to find out if the distribution of the gases in Bunsen and Roscoe's insolation vessel is effected by the absorption of hydrogen chloride, a more complete investigation was made. By plotting the respective amounts of chlorine and hydrogen chloride in the solution, it is found that two distinct and intersecting curves appear: (1). If the hydrochloric acid be less than one-fifth of normal strength, the amount of chlorine absorbed decreases as the amount of hydrogen chloride increases. The explanation is based on Jakowkin's work on the distribution ratio of chlorine between water and carbon tetrachloride, where the action of chlorine on water (in darkness) is shown to be a trimolecular one—

$$Cl_2Aq \rightleftarrows (\overset{+}{H} + \overset{-}{Cl} + HOCl)Aq.$$

The number of $\overset{+}{H}$ and $\overset{-}{Cl}$ ions is evidently increased by the addition of hydrogen chloride, and therefore in agreement with Nernst's distribution law, the number of ions derived from the chlorine is diminished. This involves a decrease in the solubility of that gas.

(2). If the strength of the solutions of hydrochloric acid be greater than one-fifth of the normal the amount of chlorine (λ) absorbed *increases* as the amount of hydrogen chloride (p) increases.

The increase is a linear function of the amount of hydrogen chloride present. $\lambda = 0{\cdot}07p + 1{\cdot}528$.

The phenomenon is probably due to the formation of a compound of hydrogen chloride with the chlorine, say HCl_3. There is no sharply defined point of transition, because the phases $\overset{+}{H}\overset{-}{Cl} + HCl_3$, &c., co-exist in the solution.

A slight contraction occurs when chlorine and hydrogen chloride gases are allowed to diffuse into each other.

*170. "*The Nitration of the Three Tolueneazophenols.*" By J. T. Hewitt and J. H. Lindfield.

The three tolueneazophenols have been nitrated by warm dilute nitric acid, and in each case the nitro-group has been found to enter the phenol nucleus in the ortho-position relatively to the hydroxyl. This agrees with the results previously obtained in the cases of oxyazobenzene and benzeneazosalicycle acid.

The following substances were described:—o-*Toluene-azo-o-nitrophenol*, m. p. 146°; the *ethyl ether*, m. p. 93°; the *acetate*, m. p. 120·5°; the *benzoate*, m. p., 132°.

m-*Toleneazo-o-nitrophenol*, m. p. 128·5°; the *ethyl ether*, m. p. 92°.

p-*Toleueneazo-o-nitrophenol*, m. p. 147°; the *ethyl ether*, m. p. 116°; the *acetate*, m. p. 94°; the *benzoate*, m. p. 129°.

The conditions under which *m*-toluneneazo-*o*-nitrophenol can be acetylated or benzoylated have not been discovered, as excess of benzoyl chloride fails to change the substance. The other acylations take place easily and normally. It is also noteworthy that difficulty is experienced in alkylating *o*-toluneneazo-*o*-nitrophenol with sodium ethoxide and ethyl bromide; the other alkylations are, however, normal.

The *ethyl ether* of *benzeneazo-o-nitrophenol* was prepared for purposes of comparison; it melts at 93°.

Discussion.

Dr. George Young inquired what evidence there was to show that acetylisation of a hydroxyazo-compound always produced an acetoxy- and not an acethydrazone derivative. It seemed curious that a change of position of a methyl group in the benzene should influence the acetylisation of the phenol side of the molecule.

Dr. Hewitt stated that though Goldschmidt claimed to have completely reduced the acetyl derivative of benzeneazo-*p*-cresol to acetanilide and *p*-cresol, MacPherson had obtained compounds by the action of benzoylphenylhydrazine on quinones which were isomeric, and not identical with the benzoyl derivatives of the azophenols. Hence it would appear that the acetyl and benzoyl derivatives of the azophenols are true oxygen ethers.

*171. "*The Bromination of the Ortho-oxyazo-compounds and its bearing on their Constitution.*" By J. T. Hewitt and H. A. Phillips.

The effect of substituting agents on numerous oxyazo-compounds of the *para*-series has been studied by one of the authors of this communication and his pupils. So far, bromination or nitration of *ortho*-oxyazo-compounds has not been examined, but it was expected that such compounds would behave as *ortho*quinone-hydrazones, and substitute in the nucleus which had been derived from the diazotised aromatic base. Thus benzeneazo-*p*-cresol was expected to give *para*- or *ortho*-bromobenzeneazo-*p*-cresol, whereas experiment has shown that when the substance is dissolved in glacial acetic acid with an excess of sodium acetate and then brominated, benzeneazo-*o*-bromo-*p*-cresol results. Ortho-oxyazo-compounds appear thus to react towards bromine as true oxyazo-compounds.

In the course of this investigation, the following compounds have been prepared and their properties examined:

Benzeneazo-o-bromo-p-cresol, m. p. 123°; *benzeneazo-o-bromo-p-cresyl acetate*, m. p. 83°; *benzeneazo-o-bromo-p-cresyl benzoate*, m. p. 110°; *o-bromobenzeneazo-p-cresol*, m. p. 116°; *o-bromobenzeneazo-p-cresyl acetate*, m. p. 85; *o-bromobenzeneazo-p-cresyl benzoate*, m. p. 106·5°; *m-bromobenzeneazo-p-cresol*, m. p. 112°; *m-bromobenzeneazo-p-cresyl acetate*, m. p. 61—62°; *m-bromobenzeneazo-p-cresyl benzoate*, m. p. 94°; *p-bromobenzeneazo-p-cresol*, m. p. 147°; *p-bromobenzeneazo-p-cresyl acetate*, m. p. 123°; *p-bromobenzeneazo-p-cresyl benzoate*, m. p. 112°.

172. "*On the use of Pyridine for Molecular Weight Determinations by the Ebullioscopic Method.*" By William Ross Innes.

The author described the precautions necessary to obtain accurate results. The constant for pyridine is 29·5. Acids, alcohols, and phenols were shown to give normal molecular weights. Pyridine therefore does not favour the association of dissolved substances.

173. "*The Influence of the Methyl Group on Ring Formation.*" By A. W. Gilbody and C. H. G. Sprankling.

The authors have prepared and analysed *p*-ethoxyphenylsuccinamic acid and the following alkyl substituted derivatives:—(1) p-*ethoxyphenylsuccinamic acid*, m. p. 166—167°; (2) *methyl*-p-*ethoxyphenylsuccinamic acid*, m. p. 149—150°; (3) as-*dimethyl*-p-*ethoxyphenylsuccinamic acid*, m. p. 160—161°; (4) trans-s-*dimethyl*-p-*ethoxyphenylsuccinamic acid*, m. p. 184—185°; (5) cis-s-*dimethyl*-p-*ethoxyphenylsuccinamic acid*, m. p. 155—156°; (6) *trimethyl*-p-*ethoxyphenylsuccinamic acid*, m. p. 128—129°; (7) *isopropyl*-p-*ethoxyphenylsuccinamic acid*, m. p. 151—152°.

Two forms of the asymmetrically substituted acids should exist according to theory, but only one has been observed during the research. The anilides of the corresponding phenylsuccinamic acids also seem to behave in a similar manner, for previous investigators have found only one acid, where two might be expected.

The scanty evidence at our disposal (Blaise, *Comptes Rendus*, 1898, cxxvi., 753) tends to show that of the two formulæ for methyl-*p*-ethoxyphenylsuccinamic acid, for example,—

$$\begin{array}{l} CH_3{\cdot}CH{\cdot}CO_2H \\ \quad\quad\quad | \\ CH_2{\cdot}CO{\cdot}NH{\cdot}C_6H_4OC_2H_5 \end{array}$$

and—

$$\begin{array}{l} CH_2{\cdot}CO_2H \\ | \\ CH_3{\cdot}CH{\cdot}CO{\cdot}NH{\cdot}C_6H_4OC_2H_5, \end{array}$$

the former is the correct one.

Under the conditions employed, the lower members of the series readily yielded anhydrous sodium salts, but the salts of the trimethyl and isopropyl-"aminic" acids have not so far been obtained pure, owing to the easy formation of the ring compounds (pyrantins).

The above acids were then converted into the corresponding *p*-ethoxyphenylsuccinimide (pyrantin) derivative, and the stability of the substituted succinimide ring so produced estimated according to the well-known equation $\frac{I}{T} \cdot \frac{X}{A-x} = Ac$; the figures given being the mean of two or more determinations (compare Miolati and Longo, *Att. Accad. Lincei Rend.*, 1894, [5], iii., 515, 597; 1895, [5], iv., 351; Miolati and Lotti, 1896, [5], vi., 88; Piutti, *Ber.*, 1896, xxix., 85).

It was necessary to carry out the experiments in alcoholic solution because of the insolubility of the substances in water.

Pyrantin (m. p. 155°)	Ac=0·0949
Methylpyrantin (m. p. 105—106°)	Ac=0·1831
as-Dimethylpyrantin (m. p. 70—71°)	Ac=0·0872
cis-s-Dimethylpyrantin (m. p. 114—115°) ..	Ac=0·1393
Trimethylpyrantin (m. p. 87—88°)	Ac=0·0446
*iso*Propylpyrantin (m. p. 98—99)	Ac=0·1432

The stability constant was determined for phenylsuccinimide in both aqueous and alcoholic solution, in order to compare the results obtained with those of Miolati for the tolyl- and xylyl-succinimides in aqueous solution.

Phenylsuccinimide was found to be 40·03 times more stable in alcoholic than in aqueous solution, and a correction had also to be made for the value of the ethoxyl group which decreased the stability in alcoholic solution 1·704 times.

The results can then be calculated and tabulated, for the methyl substituted phenylsuccinimides.

	Ac found. Pyrantin in alcoholic solution.	Ac calculated. Phenyl-succinimide in alcoholic solution divided by 1·704.	Ac calculated. Phenyl-succinimide in aqueous solution (G. and S.) multiplied by 40·03; or found (Miolati).
Pyrantin	0·0949	0·0557	2·23
Methylpyrantin ..	0·1831	0·1075	4·30
Isopropylpyrantin ..	0·1432	0·0840	3·36
cis-Dimethylpyrantin	0·1393	0·0818	3·27
Phenylsuccinimide ..	Mean of both Miolati and authors' experiments.		2·23
as-Dimethylpyrantin	0·0872	0·0512	2·05
3:5-Xylylsuccinimide	—	—	1·145
p-Tolylsuccinimide..	—	—	1·12
m- ,, ..	—	—	1·10
Trimethylpyrantin ..	0·0446	0·0262	1·05
2:5-Xylylsuccinimide	—	—	0·88
o-Tolylsuccinimide..	—	—	0·856
2:3-Xylylsuccinimide	—	—	0·815
2:6- ,,	—	—	0·16

A glance at the above table easily shows in how great a degree the stability of the succinimide ring can be decreased by the introduction of methyl groups into the fatty ring, whereas Miolati's experiments prove that the introduction of methyl groups into the aromatic nucleus increase the stability.

Substances having the constitution formulated above but containing methyl groups in both rings do not appear to have been prepared, although the list given is long enough to anticipate the result which might be expected in such cases.

The reason the authors chose the pyrantins and calculated the results was that they might obtain some information about the antipyretic action of the methyl group, but unfortunately the substances obtained proved so insoluble in water that no definite result has been obtained.

174. "*Experiments on the Production of Optically Active Compounds from Inactive Substances.*" By F. Stanley Kipping, Ph.D., D.Sc., F.R.S.

The note by Cohen and Whiteley under the above title (*Proc.*, p. 212), deals with experiments which are very similar to some in which the author, assisted by Mr. Hunter, has been recently engaged, the results of which it thus becomes desirable to place on record.

Guided by practically the same considerations, and working with the same object as Cohen and Whiteley, attempts have been made to prepare directly unequal quantities of two enantiomorphously related substances by synthesising an asymmetric carbon group in presence of, or in combination with, some optically active compound, in the hope that the latter would have some directive action on the atoms or groups entering into combination.

Among those experiments in which an optically active substance was used merely as a medium in which the synthesis took place, mention may be made of the preparation of benzoin by the action of potassium cyanide on benzaldehyde in a concentrated alcoholic solution of camphor; mandelic nitrile was also prepared from benzaldehyde and hydrogen cyanide in an alcoholic solution of camphor, and then hydrolysed with hydrochloric acid; pyruvic acid and methyl ethyl ketone were also separately reduced in concentrated glucose solution. The results were negative in all these cases.

Among the experiments in which the optically active substance was combined with the inactive nucleus the following may be noted:—The reduction of quinine pyruvate and of quinine lævulinate with sodium amalgam or aluminium amalgam; the reduction of *bornyl pyruvate* (b. p. 149—150°, 15 m.m.); the reduction of the *oxime* (m. p. about 90°) of bornyl pyruvate, and the reduction of bornyl lævulinate (b. p. 170—171°, 20—25 m.m.). After eliminating the original optically active base or alcohol, the product, namely, lactic acid, α-amidopropionic acid, or γ-hydroxyvaleric acid (as lactone), as the case might be, was found to be inactive.

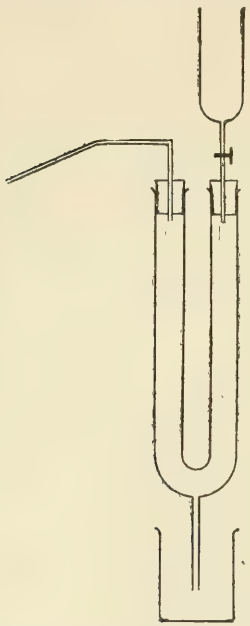
Owing to its low specific rotation and the difficulty of isolating it, the experiments in which lactic acid was obtained are by no means satisfactory, and mandelic acid, which has a high specific rotation, was therefore prepared by the reduction of *bornyl benoylformate*; this ethereal salt separates from light petroleum in crystals melting at about 78°, and is reduced to the corresponding hydroxy-salt by sodium amalgam in presence of a little acetic acid; after hydrolysis with potash, it gave inactive mandelic acid.

The failure of these experiments may be caused by racemisation taking place during hydrolysis of the original product, and this possibility is being investigated; even the apparently strong evidence obtained by combining these results with those of Cohen and Whiteley can hardly be considered to settle the question as to the possibility of directly synthesising *unequal* quantities of enantiomorphously related forms, in view of the actual results obtained in the case of the sugars, and the theoretical conclusions by which they may be supported.

175. "*A Lecture Table Experiment for the Preparation of Nitric Oxide.*" By Alfred Senier.

When nitric oxide is prepared by the interaction of copper and diluted nitric acid in a flask in the ordinary way, a difficulty arises owing to the accumulation of water. This gives rise to the formation of a large propor-

tion of nitrous oxide. By employing concentrated nitric acid and an excess of copper in the apparatus shown this may be obviated. The figure explains itself. In the apparatus employed the U-tube has a diameter of 3 c.m., and together with the small tube beneath measures 36 c.m. in height. The larger tube is loosely packed with copper turnings, water is put into the beaker below, and



nitric acid (68 per cent), is dropped from the stoppered funnel. Each drop of acid acts on the copper, liberating nitric oxide, while a solution of cupric nitrate and dilute nitric acid passes into the beaker. The gas after ascending the second arm of the U-tube is quite colourless, and contains only traces of nitrous oxide as shown by absorption with ferrous sulphate.

(To be continued).

NOTICES OF BOOKS.

Evolution of the Thermometer, 1592—1743. By Henry Carrington Bolton. Easton, Pa.: The Chemical Publishing Company. Edinburgh: W. F. Clay. 12mo. Illustrated. 1900.

In this attractive little book the author has undertaken to sketch in an impartial way the history of the evolution of the thermometer from its first beginnings in Italy, through its crude early forms down to the three standards now commonly used in all enlightened countries. The author shows how the Italian physician Sanatorius wrote in 1613 to his friend Galileo of his employment of the instrument "which you invented." This establishes the fact that Galileo was the actual inventor of the open air-thermoscope sometime prior to 1595. The claim for Drebbel is examined and proved to be a myth.

Nearly fifty years after Galileo the thermometer was rendered independent of the pressure of the air by Ferdinand II., Grand Duke of Tuscany, who closed the glass tube partially filled with coloured alcohol, and seventy years more elapsed before reliable and comparable thermometers were introduced.

The author traces the long series of efforts made by Robert Hooke, Hon. Robert Boyle, the famous Academy of Experiments in Florence, Newton, and Amontons, to devise convenient and reliable fixed points for a standard scale, efforts that finally were crowned with success by Fahrenheit. He gives credit to Jean Rey (the author of the treatise: "Why do Lead and Tin increase in Weight when Calcined?"), for first constructing a thermoscope containing water as the dilating liquid; to Fabri for dividing the interval between the temperature of snow and of midsummer heat; and to Renaldini for first proposing the freezing- and boiling-points of water as fixed points in the scale. The improvements made in thermometers by Réaumur and by Celsius are briefly described.

The author has evidently taken pains to consult the best and earliest authorities on the early history of the thermometer, a list of which occupies the latter pages of the volume; the Chronological Epitome and the table of thirty-five thermometer scales will be found useful.

The book is clearly printed on heavy paper, and tastefully bound in two shades of blue. The illustrations are appropriate. There is an index.

CORRESPONDENCE.

DETECTION OF ARSENIC.

To the Editor of the Chemical News.

Sir,—Concerning the use of aluminium and sodium hydrate in the Berzelius-Marsh test for arsenic, it may be well to point out that minute quantities of arsenic are not evolved as AsH_3 from an alkaline solution. While with perfectly pure zinc and boiled hydrochloric acid as little as 0·005 m.grm. of arsenious acid gives a distinct mirror, I have not been able to get any indication of a mirror with Al and NaOH and 0·01, 0·05, 0·1, and 0·2 m.grms. of arsenious acid in about 25 c.c. of solution. I have not ascertained the minimum amount of arsenic which will show under these circumstances. It is, however, possible that, as various kinds of pure zinc vary widely as to their sensitiveness to the test, so different samples of aluminium may show a similar behaviour.

I have found it quite necessary to test every batch of new material, after absence of arsenic was proved, for sensitiveness, and to prepare from every batch comparison-mirrors.—I am, &c.,

Otto Hehner.

The Laboratory,
11, Billiter Square, London, E.C.,
January 12, 1901.

Carbide of Calcium as a Reducing Agent in Analyses by the Dry Way.—M. Tarugi.—At about 1400° carbide of calcium reduces the oxide and the salts of copper, forming a calcic alloy which loses its calcium by the action of hydrochloric acid. Lead also forms an alloy. The salts of Au, Ag, Pt, Sn, Bi, Sb, Cd, Zn, Ni, and Co, whatever they may be, give an alloy of the metal with calcium, at a red heat: the alloy is easily decomposed by water. The salts of Hg and As give the free element Hg or As. It would be of advantage, in fire analysis, to heat the substance with 5 parts of carbide in a test-tube, instead of using the old method of reduction in the flame, or by means of cyanide of potassium.—*Gazz. Chim. Ital.*, xxix. p. 509.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Note.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, del'Académie des Sciences. Vol. cxxxi., No. 26, December 24, 1900.

The Origin of Chemical Combination. Union of Silver with Oxygen.—M. Berthelot.—The author performed various experiments, the results of which throw a new light on the formation and the decomposition of silver oxide. A known weight of pure silver was introduced into a hard glass tube, the end of which was drawn off. A gas, such as oxygen, air, hydrogen, nitrogen, carbon dioxide, carbon monoxide, or water vapour, was then introduced into the tube and the end sealed. The tube was heated to a definite temperature for some hours, after which a complete analysis of the gas was made, with an examination of the metallic substance.

Silver and Carbonic Oxide.—M. Berthelot.—Experiments made with carbonic oxide in presence of silver, show that the deposition of carbon appears at a lower temperature than if the gas were alone. The author's explanation of this phenomenon becomes very simple, since the discovery of the property of carbonic oxide of combining with nickel or iron to form volatile compounds. In contact with silver, a precipitation of carbon takes place at about 300°, and the simultaneous disintegration of the silver seems to show that this double phenomenon is the consequence of the beginning of the formation of a compound analogous to iron carbonyl.

Hydrogen and Silver.—M. Berthelot.—When hydrogen is kept in presence of silver at 500—550° in a sealed tube for five hours, indications of disintegration and traces of powder show themselves; much less marked, however, than when oxygen or carbonic oxide are used, but contrasting strongly with the inalterability of the metal kept at the same temperature in presence of pure nitrogen, carbonic acid, or water-vapour. It is probable that the change stated above is due to the slight formation of metallic hydride.

Rarefied Gases.—Albert Colson.— Red and yellow oxides of mercury were examined by the author in vacuum tubes exhausted from air. He finds that the red oxide of mercury is less alterable than the yellow oxide, but that both these are reduced by the glass. He carefully ascertained whether this influence was due only to the chemical composition of the glass, or if hydrogen—of which Armand Gautier has shown a decided quantity in atmospheric air—is capable of passing through the glass, or if the intimate contact of such a substance, glass or powder, sur-excites the activity of the hydrogen, as HCl or H_2O sur-excites that of fluorine in M. Moissan's experiments. The author's researches confirm the fact that, apart from all electric or luminous excitement, the glass emits the reducing gases, which are renewed in proportion to their absorption, as if they possessed a fixed tension, and of which the reducing power exceeds that of free hydrogen.

Influence of Pressure in Phenomena of Chemical Equilibrium.—O. Boudouard.—The author has shown in a previous paper that the numerical results obtained during the investigation of the reversible reaction $2CO \rightleftarrows CO_2+C$ verify the formula giving the general law applied to the equilibrium of gaseous systems at all temperatures, but in this verification the pressure did not alter during the experiments. The author now shows that whilst operating at pressures differing from atmospheric pressure, the results obtained still verify the formula.

Copper Selenides.—M. Fonzes-Diacon.—The author prepares cupric selenide, CuSe, by new methods. He also obtains cuprous selenide, by the wet method, in the form of a green precipitate; this same compound, in a perfectly crystalline form, can be prepared by the reduction of cupric selenide by means of hydrogen, by the reduction of copper selenate by carbon, and by the action of seleniuretted hydrogen on the chlorides of copper at a high temperature.

Some Chlorobromides of Thallium.—V. Thomas.—In a previous paper the author drew attention to the action which bromine has on thallous chloride, and announced the existence of chlorobromides belonging to one of the following types of compounds:—Tl_2X_3, TlX_2, and TlX_3. The present paper contains an account of researches on chlorobromides of the type Tl_2X_3, obtained directly by the action of bromine on the chloride TlCl in presence of water.

Action of Reducing Agents on the two Isomeric Nitrodimethylacrylic Ethers.—L. Bouveault and A. Wahl.—In two preceding papers the authors have shown that the direct nitration of ethyl dimethylacrylate results in a nitrogen derivative of constitution $\begin{matrix}CH_3\\CH_3\end{matrix}\!\!>\!C=C(NO_2)\!-\!COOC_2H_5$. This latter substance, when treated with alcoholic potash, gives the potassium derivative of an isomeric nitrogen derivative, $\begin{matrix}CH_2\\CH_3\end{matrix}\!\!>\!C\!-\!CH(NO_2)\!-\!COOC_2H_5$. The authors have since tried the action of various reducing agents on these two substances.

Uranium Nitrate.— Œchsner de Coninck.—A very pure salt, possessing the normal composition, was employed for the author's experiments. He first determined the density of some solutions of this material in water and in dilute ethyl alcohol; he then ascertained in what media this uranium nitrate was soluble, and measured the solubility in water for temperatures in the neighbourhood of 15° and the heat of solution in the same substance; the latter number, determined at temperatures 17·5° and 18·2°, gives as a mean result −3·8 cal. The author is continuing these researches.

Reaction of *p*-Diazobenzene Sulphonate of Sodium on Iron Cystinate existing in Contaminated Waters.—H. Causse.—Referring to the work of M. Molinié on this subject, the author states that he cannot accept any of Molinié's conclusions. The above reaction is characteristic rather of a group than of a substance. When the waters contain ferrous combinations containing the group CSH or COS, they give the positive reaction not destroyed by sulphuric acid. The polyatomic phenols, resorcine, pyrocatechine, and ordinary phenol present the same peculiarities with characteristic colours. The two groups CSH and COS, being most certainly the result of putrid fermentations, can show the relation which ought to exist between the degree of contamination of a water and its action of the reagent, as well as the services which this reagent renders in analysis.

Some Derivatives of Methylnonylketone. — H. Carette.—Methylnonylketone, when pure, is colourless and non-fluorescent, contrary to previous statements. It boils at 230·6° under a pressure of 766 m.m., at 122° under a pressure of 24 m.m., and at 112° under that of 17 m.m. The author prepares the oxime of this ketone, and also studies the products of condensation of methylnonylketone with benzoic aldehyde. The first process of condensation consists in the elimination of a molecule of water, $C_{11}H_{22}O+C_7H_6O=H_2O+C_{18}H_{26}O$. The second process of condensation with benzylal results in a new product fusible at 116° and having the formula $(C_{18}H_{26}O)_2$.

Chemical Transformations which take place during the Evolution of a Bud.—G. André.

Tannase.—A. Fernbach.

Tannase. Splitting-up of Gallotannic Acid by Diastase.—Henri Pottevin.

MISCELLANEOUS.

New Method for the Separation of the Earths of Gadolinite, and the Preparation of Pure Yttria.—W. Muthmann and R. Böhm.—This process consists of fractional precipitation in the form of chromate. To carry this out the mixture of the rare earths in the form of oxides is triturated with more than double its weight of CrO_3, and diluted with a large quantity of water. A lively reaction takes place, the whole going into solution in the form of bichromate. The solution is placed in a large retort and brought to boiling point, while at the same time steam is passed continually through the mass, and a solution of CrO_4K_2 is added drop by drop, the amount added being an aliquot part of the quantity necessary for complete precipitation. The authors have in this manner treated a sample of commercial *pure Yttria*, operating in six portions. The true yttria was collected in the two last fractions; in less than a fortnight they obtained 15 per cent. of the original mixture in a state of perfect purity.—*Berichte*, vol. xxxiii, p. 42.

Citrate of Lime and its Analysis.—A. Soldaini and E. Berté.—Citrate of lime comes principally from Sicily, whence it is exported in large quantities, principally to England, for the manufacture of citric acid. 10,000 lemons—that is, about 1000 kilogrms. of fruit—give 3·7 kilogrms. of essence and 400 litres of juice, from which 30 to 31 kilogrms. of citrate, containing 64 to 66 per cent of citric acid, are precipitated by means of lime. The residual pulp, weighing about 500 kilogrms., serves as food for cattle. The analysis is generally made by the precipitation of a pure citrate of calcium or lead. In the latter case the precipitate is decomposed by H_2S, and the citric acid set free can be titrated. These two methods give differences of 2 per cent on a commercial citrate; it would, therefore, be of great advantage to adopt one well-proved method, which could be relied upon for commercial analyses. The lime process, which is the better of the two, should be carried out as follows:—One grm. of the moderately powdered sample is rubbed up with 10 c.c. of warm water, then treated with 20 drops of hydrochloric acid, neutralised in the cold with N/2NaOH in the presence of phthalein until the rose-colour remains, and then treated with 3 c.c. of acetic acid. The solution is filtered, and, with the washings, evaporated to dryness on the water-bath in a porcelain crucible; it is then taken up with 20 c.c. of boiling water, well rubbed up, filtered, and carefully washed with 55 c.c. of water, dried and calcined for ten minutes, and the CaO weighed. A grave source of error is to attempt to dissolve the citrate in acetic acid. The pure salt is not entirely soluble; this gives rise to too low results. Pure citrate of lime is hygroscopic.—*Gazz. Chim. Ital.*, xxix., p. 489.

MEETINGS FOR THE WEEK.

Monday, 21st.—Society of Arts, 8. (Cantor Lectures). "Elementary Art Education," by J. Liberty Tadd.

Tuesday, 22nd.—Royal Institution, 3. "Practical Mechanics" (Experimentally treated), by Prof. J. A. Ewing, M.A., F.R.S., M.Inst.C.E.

—— Society of Arts, 4.30. "The Commonwealth of Australia," by the Hon. Sir John Alexander Cockburn, K.C.M.G.

Wednesday, 23rd.—Society of Arts, 8. "The proposed High-speed Electrical 'Monorail' between Liverpool and Manchester," by F. B. Behr.

Thursday, 24th.—Royal Institution, 3. "The Origin of Vertebrate Animals," by Arthur Willey, M.A., D.Sc.

Friday, 25th.—Royal Institution, 9. "Some Aspects of Seventeenth Century Pietism," by Adolphus William Ward, Litt.D., LL.D.

—— Physical, 5. "The New Physical Laboratories of the Royal College of Science," by Prof. A. W. Rücker, Sec.R.S. "Note on the Absolute Method Method for Determining the Hygrometric State of the Atmosphere," by E. B. H. Wade, M.A. Exhibition of an Experiment on the Migration of the Ions, by S. W. J. Smith.

Saturday, 26th.—Royal Institution, 3. "The Government and People of China," by Prof. R. K. Douglas.

MACMILLAN & CO.'S BOOKS
FOR
CHEMICAL STUDENTS.

Second Edition Now Ready.

THE SCIENTIFIC FOUNDATIONS of ANALYTICAL CHEMISTRY
Treated in an Elementary Manner.
By Professor WILHELM OSTWALD, Ph.D. Translated with the Author's sanction by GEORGE M'GOWAN, Ph.D.
Extra crown 8vo, 6s. net.

CHEMICAL NEWS.—"We can strongly recommend the book both to advanced chemists and to analytical students."

A SCHOOL CHEMISTRY INTENDED FOR USE IN HIGH SCHOOLS AND IN ELEMENTARY CLASSES IN COLLEGES. By JOHN WADDELL, B.A. (Dal. Coll.), B.Sc. (Lond.), Ph.D. (Heid.), D.Sc. (Edin.), &c. Cr. 8vo, 4s. net.

INTRODUCTION TO PHYSICAL CHEMISTRY. By JAMES WALKER, D.Sc., Ph.D., Professor of Chemistry in University College, Dundee. 8vo, 10s. net.

VOL. LXXXIII., No. 2148.

THE PHOSPHATE METHOD FOR THE ESTIMATION OF MANGANESE AND COBALT.

By H. D. DAKIN.

IN a former paper on "The Estimation of Zinc as Phosphate" (*Zeitschrift fur Analytische Chemie*, vol. xxxix., p. 273; also CHEMICAL NEWS, vol. lxxxii., p. 101) a modified process was described, which was capable of effecting quantitative conversion of tribasic zinc phosphate into zinc ammonium phosphate, without the aid of large quantities of ammonium salts, the presence of the latter having previously been stated to be essential. The object of the following note is to show that a similar method to that adopted in the case of zinc is applicable to the estimation of manganese and of cobalt.

The phosphate process has frequently been stated to be the most accurate of the different methods employed to bring manganese compounds into a readily weighable form. Recently the method has been re-examined by Gooch and Austin (*Amer. Journ. Sci.*, vi., p. 233), who, from the results of a large number of analyses, consider that the method as ordinarily described is subject to a grave source of error, in that, unless very large quantities of ammonium salts are present, the precipitate first thrown down when an alkaline phosphate is added to a solution of a manganese salt, is incompletely converted into manganese ammonium phosphate, and hence low results are obtained. This being so, it seemed of interest to see if the process adopted in the case of zinc was suitable for the estimation of manganese, especially since difficulties are said to attend the precipitation of zinc ammonium phosphate precisely similar to those encountered in the case of manganese.

For the experiments that follow pure sulphate of manganese was used. The salt was twice re-crystallised, and the small crystals dried on porous tiles. The proportion of manganese in it was determined by observing the weight of anhydrous $MnSO_4$ yielded by a known weight of the salt on gentle ignition. The ignition was performed in a similar way to that recommended by Gooch and Austin (*Amer. Journ. Sci.*, v., p. 209). The weighed salt, with the addition of a drop or two of strong sulphuric acid, was contained in a platinum crucible, the latter being jacketed with another larger crucible, containing a support at the bottom, so that the crucible containing the salt would not come into contact with the more strongly heated part of the arrangement. The method was found to give excellent results with manganese compounds of known composition. Duplicate determinations differed by less than 0·01 per cent of manganese.

The estimations were carried out as follows:—A known weight of the manganese sulphate was dissolved in 100 to 150 c.c. of hot distilled water, and, to the solution contained in a platinum basin, excess of hydrogen di-ammonium phosphate added, equal to from ten to twenty times the weight of metal present. The liquid was then heated on a water-bath, when the amorphous tri-basic manganous phosphate first thrown down is rapidly converted into beautifully crystalline manganese ammonium phosphate. No ammonium chloride or other salt was added to the solution. At the end of ten to fifteen minutes the liquid was allowed to cool, and after half an hour or more filtered, using the Gooch crucible with as small an asbestos felt as is possible to combine with efficient filtration. The precipitate was then washed with a hot 1 per cent ammonium phosphate solution. When washed free from sulphates, the small amount of phosphate solution adhering to the precipitate was removed by a few washings with dilute re-distilled alcohol. The crucible and contents were then dried, ignited, and weighed. The ignition was performed with free access of air, so as to allow of the ready escape of ammonia and water-vapour, since there is a possibility of the ammonia being partially decomposed into its elements and the liberated hydrogen reducing the pyrophosphate, and so leading to low results.

Table I. illustrates the accuracy of the process.

It will be seen that the numbers obtained agree fairly closely with those required by theory. The filtrates were in all cases tested for manganese, in some with bromine and ammonia, in the remainder with ammonium sulphide. In one case only was a minute trace found, this doubtless

being due to imperfect filtration or some other mechanical cause. No difference could be detected in the results whether the time allowed for precipitation extended over half an hour or twenty-four hours.

The main points on which the accuracy of the process depend are:—

(1). The use of a sufficiently large excess of ammonium phosphate.

(2). Thorough washing with hot 1 per cent phosphate solution.

In some analyses, in which these conditions were not adhered to, the results were some 3 m.grms. too low. The best proportion of ammonium phosphate to employ is about fifteen to twenty times the weight of manganese present, although good results may be obtained with less than this quantity, as may be seen from the test analyses. In estimating zinc as phosphate, the precipitate may be weighed either as $Zn(NH_4)PO_4$, dried at 100° C., or as ignited $Zn_2P_2O_7$. As far as I am aware, the corresponding manganese precipitate has always been converted into the pyrophosphate; it therefore seemed of interest to see whether it also might be weighed as the double ammonium salt. Experiments showed that good results were to be obtained in this way. The manganese precipitate differs from the zinc, however, in that it contains an additional molecule of water, which, even at very prolonged heating, at a temperature of 100° to 105° C., does not affect. The precipitate rapidly attains a perfectly constant weight, as is shown in Table II.

The numbers given represent the weights of the different precipitates dried for the length of time indicated.

The results obtained when the precipitate was weighed as the double ammonium phosphate are tabulated in Table III.

The results will be seen to be tolerably accurate, the error usually being less than half a m.grm.

The numbers for the amount of manganese, as calculated both from the weight of $MnNH_4PO_4.H_2O$ and of the $Mn_2P_2O_7$, agree very well with each other, so that the one method may safely be used to supplement the other.

Moreover, if the figures obtained in the two ways agree, fairly conclusive proof is afforded of the fact that the precipitates were of correct composition, and hence that the tri-basic manganese phosphate was completely converted into the double salt in the first instance. Ammonia determinations made on precipitates obtained in the same way as in an actual analysis yielded results differing by only two or three hundredths of a per cent from the theoretical amount. In the practical application of the process, the liquid containing the manganese must previous to precipitation be freed from any large excess of acid; but there is no necessity for the solution to be absolutely neutral, provided sufficient phosphate is used. The subsequent operations are identical with those previously described, and are, I think, simpler than those usually recommended.

The conclusion is drawn that, when the analysis is conducted as described, even in the absence of large amounts of ammonium salts, the precipitate obtained corresponds strictly to formula, and that good results may be obtained whether the manganese is weighed either as the pyrophosphate or as the double ammonium salt.

The accuracy of so many processes for the determination of metals as phosphates having been called in question during recent years, it seemed of interest to see if the modified process, as used for zinc and manganese, was also of use in estimating other metals. The determination of cobalt as phosphate has long been a well-recognised method specially useful in the presence of nickel. The cobalt used in the subsequent analyses was purified as follows:—A solution of the nitrate was acidified with acetic acid and filtered, and to this a clear solution of potassium nitrite in dilute acetic acid added, and then, before all the cobalt was precipitated, the double nitrate of potassium and cobalt was filtered off and well washed. The yellow precipitate was then decomposed by means of pure sulphuric acid, all nitrous fumes being expelled; the solution was then fractionally precipitated as carbonate. The precipitate was filtered off, washed, and dried, and the amount of cobalt in it determined by conversion into sulphate and also by analysis.

The analyses were conducted in the same way as in the case of manganese. A known weight of the cobalt carbonate was dissolved in dilute sulphuric, and the solution nearly neutralised with ammonia; di-ammonium hydrogen phosphate, equal to ten times the weight of cobalt present, was then added. At first an amorphous violet precipitate was thrown down, and this quickly changes into deep blue, and finally into the beautifully crystallised crimson cobalt ammonium phosphate. The liquid should be kept hot for ten minutes or so, then cooled and filtered, the precipitate being washed with hot 1 per cent ammonium phosphate solution, and then with dilute alcohol. In the same way as in the case of manganese, it was found that the precipitate could be weighed quite well, as the double salt dried at 100° to 105°, in addition to the pyrophosphate. Tables IV. and V. illustrate the accuracy of the method.

The filtrates were tested and found free from cobalt. The results will be seen to be equally accurate whether the precipitate be weighed as cobalt ammonium phosphate, $(CoNH_4PO_4.H_2O)$, or as cobalt pyrophosphate, $(Co_2P_2O_7)$. Hence it may be concluded that no difficulty is introduced into the estimation of cobalt as described, by any uncertainty in the composition of the precipitates obtained.—*Zeitsch. f. Anvlyt. Chem.*, xxxix., p. 784.

A BIBLIOGRAPHY OF STEEL WORKS ANALYSIS.

Part VII.

By HARRY BREARLEY.

(Continued from vol. lxxxii., p. 307).

CHROMIUM.

THE general arrangement is—

I. Separation from other Elements.

II. Gravimetric Estimation.
- *a.* In which Cr is the Base of the Weighed Salt.
- *b.* ,, ,, Acid ,, ,,

III. Volumetric Estimation.
- *a.* Titrating with Ferrous Salt.

- *c.* Miscellaneous Processes.

IV. Means of Converting to CrO_3.
- *a.* Dry Ways.
- *b.* Wet Ways.

V. Detection of Chromium.

VI. Miscellaneous Notes.

I. Separation from other Elements.

Iron.—

946. Gibbs (*C. N.*, xi., 101).—Oxidise to CrO_3 and precipitate Fe with acetate or AmHO. Similar process for Al.

947. Baubigny (*C. N.*, l., 18).—Ignited chromite oxidised with HNO_3+KClO_3, and Fe and Al precipitated by a slight excess of bicarbonate. The CrO_3 reduced with H_2S and precipitated as hydrate.

948. Brearley (*C. N.*, lxxvii., 49). — Separation from CrO_3 with acetates or alkalis the more complete the greater excess there is used. Deficiency due to basic ferric chromates. NaHO the best precipitant.

949. Knorre (*C. N.*, lix., 232).—Iron precipitated from HCl solutions with nitroso-β-naphthol. The Cr in the filtrate cannot be completely precipitated with AmHO.

950. Hess and Campbell (*C. N.*, lxxxi., 159).—Cr is precipitated quantitatively from solutions containing Fe, Ca, Mg, Mn, Co, and Ni by phenylhydrazine.

951. Boussingault (*J. I. S. I.*, 1886, 828).—Fe and Cr cannot be separated by heating in HCl gas, because Cr_2O_3 is thus volatilised (see 961). Havens and Way (*J. S. C. I.*, 1899, 1157) say the separation can be made at 200—300° in a stream of HCl containing Cl.

952. Venator and Etienne (*J. C. S.*, liii., 532).—Decompose the mineral with NaHO, evaporate solution of the fusion, and leach Na_2CrO_4 from the dried mass.

953. Bamber (*J. I. S. I.*, 1894, i., 319).—Add Na_2CO_3 short of alkalinity to the HNO_3 solution of the iron, evaporate, ignite, and dissolve out Na_2CrO_4 with water.

954. Jannasch and Cloedt (*J. C. S.*, lxx., ii., 222).—Mix with H_2O_2+AmHO, and heat under pressure. The filtered CrO_3 is reduced and precipitated with hydroxylamine chloride and ammonia.

Aluminium.—

955. Carnot (*C. N.*, xliv., 85).—The Al is precipitated from CrO_3 solution with soda phosphate and acetate.

956. Brearley (*C. N.*, lxxvii., 179).—Similar paper to 948. Na_2CO_3 the best alkaline precipitant; Na_3PO_4 available.

957. Hunt, Clapp, and Handy (*C. N.*, lxv., 223).—Cr-Al alloys are boiled with KHO; residue fused with $KHSO_4$, converted to CrO_3, but finally precipitated with AmHO.

Chromic Acid.—

958. Storer and Elliot (*C. N.*, vi., 121).—Precipitate Cr_2O_3 from dilute acid solution with AmHO.

959. Brearley (*C. N.*, lxxvii., 217).—Preceding process inaccurate. Separate with NaHO or Na_3PO_4.

Uranium.—

960. Gibbs (*C. N.*, xxviii., 63).—Oxidise to CrO_3, and precipitate Ur with NaHO, or the CrO_3 may be precipitated with $HgNO_3$ if no other precipitable non-volatile body is present.

961. Ditte (*C. N.*, xxxvi., 100).—The oxides of Fe, Cr, and Ur are heated in H and then in HCl to volatilise the Fe (see 951). Dissolve Ur from the residue with HNO_3.

962. Formanek (*J. C. S.*, liv., 531).—To precipitate the CrO_3 with $HgNO_3$ (960) is inaccurate. Ditte's process is also unsatisfactory.

Vanadium.—

963. Classen (*J. I. S. I.*, 1887, i., 473).—Precipitate together as lead salts, eliminate Pb from HCl solution with H_2S, fuse evaporated filtrate with NaHO and S, and extract V with water.

964. Von Klecki (*C. N.*, lxix., 54).—Precipitate V with uranic nitrate from an acetic solution.

965. *Copper.*—Prud'homme (*C. N.*, xxv., 215).—From a mixture of the oxides of Cu and Cr the Cu is dissolved by NaHO, but both oxides are dissolved by AmHO.

966. *Phosphorus.*—Granger (*C. N.*, lxxv., 95).—Fuse with KHO, dissolve, acidify with HNO_3, and precipitate with molybdate.

967. *Mercury.*—Jannasch (*J. C. S.*, lxxvi., ii., 6c).—Precipitate the Hg with hydroxylamine in the presence of oxalic acid.

II. Gravimetric Estimation of Chromium.

II.*a. Where Cr is the Base of the Weighed Compound.*—

968. Oudesluys (*C. N.*, v., 254).—Add Na_2CO_3+KNO_3 to the $KHSO_4$ fusion, precipitate Al_2O_3 with Am_2CO_3, reduce, precipitate with AmHO, and ignite to Cr_2O_3.

969. Genth (*C. N.*, vi., 31).—As above; but omit the KNO_3, and precipitate Al_2O_3, &c., by boiling with excess $AmNO_3$.

970. Cloubt (*C. N.*, xxiv., 304).—Fuse ore for six hours with Na_2CO_3, reduce CrO_3 with alcohol, and precipitate with AmHO.

971. Tamm (*C. N.*, xxiv., 305).—In general like 968; but the CrO_3 is reduced with HCl, and the nitrous oxide evolved (see 1064).

972. Kern (*C. N.*, xxxv., 67).—Precipitate Fe and Cr together with Am_2S, ignite, fuse with K_2CO_3+KNO_3, and precipitate reduced filtrate with AmHO.

973. Waller and Vulte (*C. N.*, lxvi., 17).—Fuse with Dittmar's flux (1009), evaporate extract with $AmNO_3$, re-dissolve, reduce, and precipitate with AmHO. A resumé of the means of opening up chromites.

974. Ziegler (*C. N.*, lxvi., 295).—Fuse Fe-Cr with KHO+KNO_3 in silver crucible in smoky flame, pass CO_2, separate associated elements, and precipitate with AmHO. Instructions for estimating P, &c., in ferro-chromium.

975. Fresenius and Bayerlein (*C. N.*, lxxvii., 141).—Treat chromite with HCl; residue, with Na_2O_2. After various separations (Fe with Na_2O_2), reduce with H_2O_2, and precipitate with AmHO.

976. Namias (*J. I. S. I.*, 1890, ii., 853).—Fuse FeCr with $KHSO_4$, precipitate neutralised solution with MgO, ignite, re-fuse, and precipitate reduced solution with AmHO.

977. Morse and Day (*C. N.*, xliv., 43; and xlvii., 177).—Fuse powdered chromite with KHO in an iron crucible, separate Al_2O_3 with AmHO, reduce, and precipitate with $BaCO_3$.

978. Dohler (*J. S. C. I.*, 1899, 1157).—Precipitate with $BaCO_3$ from FeO solution, fuse, separate SiO_2, &c., and precipitate as usual (see 1010).

979. Reinhardt (*J. I. S. I.*, 1889, ii., 480).—Process based on the fact that Cr_2O_3 is precipitated by ZnO, while ferrous and manganous salts remain in solution.

980. Ziegler (*J. I. S. I.*, 1890, i., 372).—Decompose chromeisen with bisulphate, and proceed as 979, using hypophosphite to reduce the iron.

981. Kern (*C. N.*, xxxv., 107).—Fuse ore with $KHSO_4$, dissolve in HNO_3, add $(NH_4)HS$, dissolve Fe_2O_3 from the ignited precipitate, and weigh the Cr_2O_3 residue.

982. Jannasch and Mai (*J. C. S.*, lxiv., ii., 500).—In presence of hydroxylamine Cr_2O_3 is thrown down by ammonia as a violet-red precipitate, more easily washed than the green one.

983. Souchay (*C. N.*, xlvii., 248)—$Cr_2(HO)_6$ precipitated with AmHO in glass vessels is always too high.

984. Treadwell (*J. S. C. I.*, 1882, 339).—Cr may be precipitated in glass vessels by AmHO without error. The precipitate strongly retains fixed alkalis.

985. Bloxam (*C. N.*, liii., 194).—$Cr_2(HO)_6$ precipitated with AmHO carries down large amounts of MgO; also some SO_3.

986. Arnold (*C. N.*, xlii., 285).—Criticism of the volumetric process (1001). Decompose steel with acids, fuse dried residue with Na_2CO_3+KNO_3, reduce filtered CrO_3, and precipitate with AmHO.

987. Hogg (*J. S. C. I.*, 1891, 340).—Discusses process 1001. Proceeds as in 986. Oxidise ignited Cr_2O_3 with HNO_3+$KClO_3$ to separate SiO_2, &c., and finally precipitate with AmHO. Percentage approximated by comparing colour of samples dissolved in H_2SO_4. Paper washed with Br or Cl and AmHO does not reduce CrO_3 (see 1077).

988. Carnot (*C. N.*, xlv., 243).—Precipitate with soda acetate and phosphate from a slightly acid solution. The precipitate ignited and weighed.

989. Arnold and Hardy (*C. N.*, lvii., 153),—Cr_2O_3 obtained by (986 may contain P; it is better to precipitate the Cr as basic phosphate ($3Cr_2O_3.2P_2O_5$), which can be obtained of invariably the same composition.

II.*b*. *Where Cr is the Acid of the Weighed Compound.*—

990. Gibbs (*C. N.*, xi., 101).—Oxidise to CrO_3 with Cl or Br in acetate solution, and precipitate with Pb or Ba. Ca, Mg, Zn, Ni, Co, and Mn do not interfere. Precipitation with $HgNO_3$ should be made in the cold. Ore decomposed with potassium fluoride.

991. Gibbs (*C. N.*, xxviii., 63).—Berzelius's method (precipitation with $HgNO_3$) is best performed in hot solutions.

992. Baubigny (*J. S. C. I.*, 1884, 457).—Precipitation as Hg_2CrO_4 not advisable in presence of ammonia salts. Precipitates with Am_2S.

993. Schöffel (*C. N.*, xli., 31).—Treat with copper solution, fuse residue, and precipitate with $HgNO_3$; or remove SiO_2 and precipitate with Am_2S. High Cr irons not decomposed by Cu solutions; after fusion, a process like 1026 is used.

994. Boussingault(*J. I. S. I.*, 1886, 807).—Fuse with $KHSO_4$, precipitate Fe and Cr with AmHO, fuse with $Na_2CO_3+KNO_3$, and precipitate with $HgNO_3$.

995. Clark (*J. I. S. I.*, 1895, ii., 602).—Decompose ore with $KHSO_4$, oxidise with HNO_3+KClO_3, separate Fe and Al with AmHO, and precipitate as $PbCrO_4$.

(To be continued).

DETECTION OF LEAD IN POTABLE WATER.

By M. BELLOCQ.

Water containing the most minute traces of lead offers to the practised eye a faint though persistent opalescence which is destroyed by nitric acid; this fact gives rise to the opinion that the toxic metal may be in combination with some organic matter.

Of such a character are waters which have remained for a long time in new pipes, or in old pipes which have been disturbed by some repair or soldering; waters exposed, when in contact with lead, to the siliceous and carbonated dust of the air, are always contaminated with nitrated particles. For this reason the cleaning of lead pipes should be proscribed. Absolutely limpid water gives no trace of lead with my zinc reaction (*Journ. de Pharm. et de Chim.*, [6], xii., p. 103), and there is reason to believe that the hydrocarbonate is perfectly insoluble.

For the detection of lead I use a zincic reagent, in which the soda has been replaced by ammonia.

Add to 1 or 2 litres of suspected water an excess of ammoniacal zincic reagent (5 to 10 c.c.), and leave perfectly quiet for some hours. Decant as much of the supernatant water as possible (this should be absolutely limpid) and throw the rest on a filter, 15 or 18 c.m. diameter, for waters of average composition.

This filtration is very rapid, and the dried precipitate is very easily detached from the filter.

The precipitate is decomposed with warm acetic acid containing a little acetate of ammonia, and filtered in a small funnel, through a plug of absorbent cotton-wool, into a test-tube; the clear acid filtrate is touched with a glass rod wetted with a solution of chromate of potassium.

If the water contains lead a yellow cloudiness appears, and after the lapse of some time a precipitate of chromate of lead is formed.—*Journ. de Pharm. et de Chim.*, Series 6, vol. xiii., No. 2.

Royal Institution.—In consequence of the lamented death of the Queen, the Patron of the Royal Institution, the President has decided that all lectures shall be abandoned until further notice.

THE OXIDISING ACTION OF PERSULPHATE OF AMMONIA ON SOME DIRECT PRINCIPLES OF ANIMAL ORGANISMS.

By L. HUGOUNENQ.

When Berthelot discovered persulphuric acid he described the very remarkable oxidising properties of this compound. For some time past several alkaline persulphates have become articles of commerce. As a source of active oxygen they have a certain number of advantages. It is this that has decided me to study their action on substances of animal origin.

I. *Uric acid* is oxidised in the cold by persulphate of ammonia.

If we mix together 1 part of uric acid and 4 parts of persulphate with 12 parts of water at the ordinary temperature, or better still in an incubator at 36°, the uric acid completely disappears after seven or eight days. Allanturic acid, urea, and glycocol are formed.

In the presence of an excess of alkali the oxidising action of the persulphate is much more energetic. By causing 20 parts of this salt to act on 6 parts of uric acid in the presence of 150 parts of water and 30 parts of ammonia, the temperature rises, a lively effervescence takes place, and the liquid becomes yellow and limpid; all the uric acid has disappeared. From the filtered liquid we can separate:—

1. A quantity of guanine (from about 1 to 3 per cent of the uric acid attacked). The guanine has been recognised by all its reactions and by the estimation of the nitrogen; it already existed in the uric acid used, and from which it is very difficult to be removed.

2. A white, badly crystallised, not very stable, ammoniacal salt, which was recognised, on analysis, as allanturate of ammonia.

In the mother-liquors of this salt a small quantity of oxalate of ammonia is also found.

3. After the separation of the greater part of the sulphate of ammonia, alcohol extracts from the final residue a body which occurs in large, soluble, transparent prisms, which by means of its properties, as well as by its proportion of nitrogen, is identified as urea.

For 100 parts of uric acid oxidised we obtain about 42 parts of urea, and 27 or 28 parts of allanturate of ammonia.

To sum up, the persulphate oxidises uric acid in the same manner as peroxide of lead, ferrocyanide of potassium, permanganate, or ozone; allantoïne is formed, which in alkaline solution, and in the presence of an excess of an oxidising agent, is decomposed, giving urea and allanturic acid:—

$$\underset{\text{Allantoïne.}}{C_4H_6N_4O_3}+H_2O=\underset{\text{Urea.}}{CH_4N_2O}+\underset{\text{Allanturic acid.}}{C_3H_4N_2O_3}.$$

If we diminish the proportion of persulphate so as to obtain allantoïne itself, and not its products of decomposition, the reaction becomes difficult; the greater portion of the uric acid remains unattacked.

II. *Bilirubine* in alkaline solution is transformed instantaneously by persulphate of ammonia into biliverdine, and this is, as a matter of fact, the most simple and convenient method for the preparation of this latter pigment, as well as being at the same time an analytical test for bilirubine.

III. *Hematine*, in ammoniacal solution, is attacked even in the cold, but very quickly when heated. After boiling for two or three minutes the liquid, which was black at first, becomes colourless, and leaves flocculent particles of peroxide of iron.

It would be very simple to apply this reaction to the estimation of the iron in hematine, and doubtless also in hemoglobine and the ferruginous nucleins.

IV. Blood, diluted and treated with an excess of ammonia, is decomposed and decolourised in a few hours in the cold by persulphate of ammonia. A clear yellow liquid is obtained, and a slight ochreous deposit formed.

This result is obtained in a few minutes when heat is applied; the albumins then form a colourless coagulum, floating on an almost colourless yellowish liquid.

I propose continuing the examination of the products formed by the decomposition of hematine by persulphate of ammonia, and also to try and determine the manner of the action of this salt on the albumenoid matters which are also attacked.—*Journ. de Pharm. et de Chim.*, Series 6, vol. xiii., No. 2.

THE ALLOTROPIC FORMS OF SELENIUM.*

By A. P. SAUNDERS.

(Concluded from p. 31).

LENHER and Morgan (*Journ. Amer. Chem. Soc.*, 1900, xxii., 28), in their experiments on the conductivity of tellurium, found that alterations in the contact between the material and the electrode used caused the widest variation in their results. Indeed the best values they could get are very far from uniform.

In the year 1877 there appeared a second paper, by Siemens, devoted to a more detailed consideration of the action of light. He finds the greatest activity in the red region of the spectrum; concludes that there are too many disturbing influences in the measurements to make it possible to find any fixed relationship between the light intensity and the resulting change of conductivity; and, finally, presents some detailed experiments on the effect of continued illumination upon the cells.

At the same time, Forssmann announced the results of some extended experiments upon the action of light of different colours. His first results go to show a maximum effect in the red and yellow, a minimum in the green; but he found indications later on, that even invisible rays may produce an effect. For instance, lamp-light which had passed through a solution of chromic chloride had a larger effect than the direct light itself, although the colour of the chromic chloride was so intense that it was opaque to the eye even in direct sunlight. Other salt solutions were studied as well, but no general conclusions could be drawn from the results.

In the following year (1878), Sabine published a paper on "Some Electrical Experiments with Crystallised Selenium," in which he brings out very clearly the enormous importance of the junctions in the behaviour of selenium cells. "A large portion of the observed resistance of a so-called selenium resistance may, and frequently does, reside in the junctions and not in the selenium." The same is shown to apply also to the alterations brought about by inversion of the current. Light and heat appear from his experiments to act in the same way upon the conductivity of selenium surfaces; and, finally, the alterations brought about by these means are shown to be probably in the nature of an actual change in resistance, rather than, as some investigators have supposed, an electromotive force set up in the selenium in the same direction as the battery current.

Alexander Graham Bell, in 1880, presented an account of his practical applications of the selenium cell in the construction of the photophone. He found that "brass, although chemically acted upon by the selenium, forms an excellent and convenient material. Indeed, we are inclined to believe that the chemical action between the brass and the selenium has contributed to the low resistance of our cells by forming an intimate bond of union between the selenium and the brass." There is but little of theoretical interest in the paper except that Bell finds the long heating and slow cooling formerly recommended in the preparation of selenium cells to be unnecessary; this is probably because selenium acts more rapidly upon brass than upon platinum.

* From the *Journal of Physical Chemistry*, vol. iv., No. 6.

Obach (1880), found that phosphorescent light caused a change in the conductivity of selenium. The phosphorescent material used was of unknown composition, but being a commercial article was probably one of the alkaline earth sulphide preparations. Its action was relatively slight, yet distinct. Strangely enough, it was entirely cut off by the interposition of red or yellow glass, while blue glass transmitted six-sevenths of the original effect.

There is through these years a large amount of literature on the applications of selenium cells, scattered through such journals as *Nature*, the *Journal of the Society of Telegraph Engineers*, &c. I have been at no special pains to collect references to such letters and short communications except in the cases where some fact of theoretical importance has been brought out. The best general account of this side of the subject will be found in Bell's paper cited above.

Kalischer's article in 1881 under the title of "Photophone without Battery," describes his attempts to produce a photophone in which the current was supplied by the electromotive force of the selenium preparation itself under illumination.

Moser (1881), records some very interesting observations on the nature of the contact between selenium and metals:—"On a copper plate I melted amorphous selenium, and put on it a second metal plate of zinc or copper. Then I heated gradually so that the selenium became crystalline; and I then annealed it. Whilst the amorphous selenium adheres very well to the metal plates, these cells proved very brittle when the selenium was crystalline. The selenium always split off from the copper plate. . . . Every lamina which split off was on the upper side light grey, and on the lower side blue-black, not brilliant, but dull. In the same way, the copper plate had now a similar dull blue-black covering. This blue black body is cuprous selenide. . . . This experiment shows that between the copper and the selenium, or rather the cuprous selenide, there is only a slight and imperfect contact."

The view advanced by Moser that "selenium is heated by light," and that the changes in its conductivity are produced through the expansion of the mass of selenium and consequent tightening of the contacts, was disproved by Shelford Bidwell in 1883. We have seen too that experiments made some years previous had shown that the peculiar action of selenium cells could not be explained as a heating effect.

Fritts, in 1883, described the preparation of selenium cells of hitherto unattained sensitiveness and of very low resistance. One of them showed fifteen times as high a resistance in the dark as it had in ordinary diffused daylight of the room. He finds that the best metals to use are "brass, zinc, or iron or copper thinly coated with tin." (Apparently only the copper was tin-plated). The properties of these cells are in other respects also quite unusual. It was found, for example, that the kind of battery has a great deal to do with the result; thus, some cells which were light sensitive when operated with a Leclanché battery gave no results at all with a bichromate battery. The effect of rapidly alternating currents was in some cases to reduce the resistance of a cell from many thousands of ohms to almost nothing; in other cases to raise it from next to nothing up among the thousands. These extremely variable results are left quite without explanation.

Fritts describes, in the latter part of his paper, the preparation of a new modification of selenium. The method of preparation is only imperfectly indicated, but seems to me by prolonged heating of selenium on a brass plate (to what temperature ?), and then gradually cooling, under pressure. "The plates so made have portions which are transparent, situated apparently where the temperature was highest. The remaining portions of the plates are black and red, interspersed with grey. Thus, upon one plate may be seen selenium in four different states or colours. . . . A small portion of the trans-

parent selenium having, perhaps, one-half square inch of surface, had a resistance of only three ohms. It was found to be affected by light very little, if at all."

This transparent film which he considers as a new modification of the element, was perhaps in reality a film of fused selenide; or, it may have been a thin film of vitreous selenium, which is almost colourless in very thin layers. In the latter case we must assume an experimental error in the measurement of its resistance.

Selenide of zinc is described as a reddish-yellow substance. It is possible that this may have been the transparent material observed by Fritts.

In 1884, Bidwell, in a short article on the resistance of sulphur and selenium cells, showed that sulphur also gives light-sensitive cells when it contains sulphide of silver, and that selenium which has never come into contact with a metal possesses a resistance enormously higher than the ordinary material in the selenium cell. In a longer article, in 1885, the same author puts forward the hypothesis that the peculiarities of the selenium cell are really due to the presence of selenides. If this is the case, then the conduction may very well be electrolytic, and would lead to the deposition of free selenium at one electrode, and of the metal at the other. A change of this kind in the nature of the contacts might easily give all the remarkable irregularities in the behaviour of selenium cells which have been recorded as the results of (1) a steady passage of the current, and (2) a reversal of its direction.

Kalischer (1887), studied the conditions under which the selenium cell becomes, as that author says, photoelectromotive. The cells have the ordinary form, but are constructed of two different metals, the selenium forming a connection between them. Copper and zinc were found to be a very efficient pair. They have, as a rule, a comparatively high resistance. "Besides the copper-zinc combination, I have used also copper-brass, zinc-brass, and copper platinum. In all of these, the direction of the current which is called forth by light is the same as in the ordinary galvanic elements. Thus, for instance, from zinc through the selenium to the copper." Nevertheless, the same results may be obtained, using only one metal for the electrodes, though the current is less marked in this case. With lapse of time, the cells lose their power, and this loss is coupled with a decrease in resistance.

It is in this direction that most of the more recent work on selenium cells has been done. Thus, v. Uljanin (1888) and Righi (1888) have both made important contributions to our knowledge of the electromotive force of selenium in the light.

Righi (1889), finds further that a selenium cell constructed with electrodes of different metals shows an electromotive force even in the dark.

Hesehus (1884), in a purely theoretical paper, discusses the different explanations which have been suggested for the abnormal conductivity of selenium, and favours the assumption of two metallic forms of the element—Siemens's idea.

Bidwell, in 1891, carries on the argument in favour of the theory that the behaviour of selenium cells is due to selenides. He shows that the "annealing" of the cell, which has almost always been regarded as absolutely necessary to the production of good light-sensitive cells, would in reality lead to the formation of a film of selenide at the junction. The deterioration of the cells with age he attributes to the gradual thickening of the layers of selenide at the expense of the free, badly-conducting selenium, and thus the resistance of the cells slowly falls. "At length the layers of selenide become so thick that the coatings upon the two wires actually meet and touch each other. Thereupon the cell is short-circuited; its resistance no longer depends upon the selenium, but upon the metallic selenide, which is a good conductor."

The deposition of free selenium upon the electrode in the form of a covering of red tufts was shown experimentally. This material is amorphous selenium, which, as we know, is a good insulator; hence the alterations in conductivity produced by continued use of the cell may well be large.

Since the appearance of this paper of Bidwell's no great addition has been made to the knowledge of the subject. Siemens, in his important paper, advanced the theory of a second form of metallic selenium, produced at 200°. That is the only good explanation, other than Bidwell's, which has been offered. Now we have seen in the other sections of this paper that it has been quite impossible to get any direct evidence of the formation of a new modification of selenium at higher temperatures. Furthermore, even granting its existence, there are still very many of the recorded observations which cannot be explained satisfactorily on that ground. The hypothesis of Bidwell gives much more hope of an ultimate clearing up of all the known facts. We have seen that selenides are undoubtedly produced when selenium is heated in contact with metals; that those metals—copper and brass—which are the most efficient in yielding sensitive cells, are among the ones most readily attacked. Hence the presence of selenides is certain. Bidwell has shown that there is a deposition of amorphous selenium at the anode, which would hardly be the case if the conduction were not really electrolytic. This deposition may well be the cause of the extraordinary differences observed on the reversal of the current, &c. Selenides are known to be good conductors; unfortunately, the action of light upon them has not been studied; but the fact that sulphur which contains silver sulphide displays the light-sensitiveness of a selenium cell supplies an argument by analogy of considerable force.

Furthermore, Bidwell found that a silver leaf placed upon glass and painted over with a solution of sulphur in carbon disulphide, if only partly shaded from the light, became, after fifteen minutes, dark brown in the illuminated part, while remaining whitish-yellow where shaded. It may be mentioned here that Schuller (1883), found that when selenium is distilled there is a residue left containing copper and lead; this indicates that the commercial material is probably always more or less contaminated with metals.

It has recently been announced (1900), by Perreau that the resistance of selenium cells is reduced by X-rays, in the same way as by light.

So much of the time spent in the study of selenium cells has been devoted to the devising of instruments which have in the end proved inefficient that, in spite of the large literature of the subject, very few really scientific observations are on record. By beginning now with a methodical study of the behaviour of selenides, and of selenium and selenide mixtures of known composition, there is every hope that a conclusion might be reached which would set the whole matter on a firm basis, and supply moreover an interesting chapter on the action of light on chemical compounds.

11. *Coefficient of Expansion.*

Fizeau (1869), gives the value for the linear coefficient of expansion for vitreous selenium as 0·00003368. It is to be inferred that the experiment covered a range of temperature from 10° to 80°, and the value given above represents a mean result for 40—50°.

Spring (1881), made a determination of the cubical expansion of selenium in the crystalline (metallic) form; the results are given below; the first series refers to the powdered crystals; for the second, these were subjected to a pressure of 6000 atmospheres, to get rid of air cavities. s is the specific gravity, β the mean coefficient of expansion from 0° to $t°$.

	t	0°	20°	40°	60°	80°	100°
I.	s	4·7312	4·7176	4·7010	4·6826	4·6623	4·6396
	$\beta.10^7$	—	1478	1635	1743	1857	1981
II.	s	4·7994	4·7869	4·7699	4·7526	4·7351	4·7167
	$\beta.10^7$	—	1307	1539	1644	1803	1751

It will be noticed that the specific gravity in each of these cases is somewhat less than the value to which the best of the other determinations have led. Spring's method was that of the weight thermometer filled with water; hence it would not be surprising if the material contained noticeable air cavities; this would explain the higher results for the uncompressed selenium.

VI. General Properties of the Element.

1. *Atomic Weight.*

The first determinations are those of Berzelius (1818), and his results have only been confirmed by the latest and most accurate experiments. He found that 1 grm. of selenium gave, when treated with chlorine, 2·79 grms. of $SeCl_4$. This gives the atomic weight as 79·2 (Cl = 35.45). As a control experiment the chloride was transformed into the acid H_2SeO_3, and the hydrochloric acid thus liberated determined by silver nitrate. The chloride obtained from 1 grm. selenium yielded, in this way, 7·2285 grms. silver chloride, from which we calculate the value 79·35.

Berzelius did not, as Ostwald (*Lehrbuch*, i., 106) states, lay the greater emphasis on the first value; on the contrary, he gives as the most probable result, the mean of the two, but he does not state that of two such double determinations which he made he considers the first as the better, because it was made with the larger quantity of material. By another method he found that 1·888 grms. of silver selenide, Ag_2Se, yielded 1·844 grms. of silver chloride, from which the atomic weight is found to be 77·98 (Ag = 107·9).

The analysis of barium selenate quoted by Ostwald was not made as a determination of atomic weight. The same remark applies to the work of Mitscherlich and Nitzsch, who made an analysis of selenic acid,

The next atomic weight determination is therefore that of Sacc (1847); in this case also several analyses of salts were made, which were recognised by that author as being unsuitable for atomic weight determinations. The methods upon which he laid stress were:—

(1). The reduction of selenium dioxide by ammonium bisulphite and hydrochloric acid. This method yielded the results 78·3—78·2—79 (O = 16), and

(2). The reduction of barium selenite by the same reagents, and weighing the mixture of barium sulphate and selenium which is precipitated. This is a less accurate method, and gave, as the mean of three determinations, about 78·6.

Erdmann and Marchand (1849), analysed mercuric selenide, and found that it contains 71·726—71·731—71·741 per cent of mercury. These values give as the atomic weight 78·96, 78·96, 78·93.

Dumas (1859), made a series of determinations in which he converted known weights of selenium into the chloride $SeCl_4$. His results vary from 79·2 to 79·66, and give as a mean value 79·46. As pointed out by Meyer and Seubert, Dumas has recorded in his article, in every case, the increase of weight as if it were the total final weight—*i.e.*, what he calls the weight of chloride is really the weight of the absorbed chlorine.

Petterson and Ekman (1876), used two different methods:—

(1). By weighing the silver obtained from silver selenite by heating, they obtained seven values varying between 78·90 and 79·18, and giving in the mean 79·01.

(2). By reducing weighed quantities of selenious acid by means of sulphur dioxide, and determining the weight of the selenium precipitated, they found in five results a variation from 79·06 to 79·10; in the mean, 79·08.

They consider the second method the more trustworthy, and give the value 79·08 as representing most nearly the true atomic weight.

Finally, Lenher (1898), made a very careful study of the problem by the following methods:—

(1). Silver selenite was converted into silver chloride; in this way, eleven results were obtained varying from 79·263 to 79·326.

(2). The silver chloride so obtained was then reduced in the case of eight of these, and gave values between 79·277 and 79·369.

(3). A weighed quantity of the bromide $(NH_4)_2SeBr_6$ was reduced by hydroxylamine, and the resultant selenium weighed. Eight determinations gave values between 79·226 and 79·367. Lenher's mean values are:—

From silver chloride	79·329 (eleven results).
From metallic silver	79·329 (eight results).
From bromide	79·285 ,,

The general mean is therefore 79·31.

The values given in the most recent standard tables of atomic weights are as follows:—

German Chemical Society (*Ber.*, 1898, xxxi., 2761) ..	79·1
F. W. Clarke (*J. Am. Chem. Soc.*, 1900, xxii., 70) ..	79·2
Richards (table for 1899, quoted by Clarke)	79·2

2. *Boiling-point.*

Carnelley and Williams (1879), found a value lying between 676° and 683°. Their method of determining the temperatures was by using substances of high melting-point previously determined, and exposing them to the vapour of the boiling liquid.

Troost (1882), found the boiling-point to be at about 665° under a pressure of 760 m.m. The temperature was measured with a form of air thermometer.

3. *Vapour-density.*

Sainte-Claire Deville and Troost (1863), in their researches on vapour-density at high temperatures, determined that of selenium at 1420°, and found it to be 5·68, corresponding to a molecular weight of 164·0°. The values for the molecular weight at lower temperatures are:

	Mol. wt.
At 1040°	184
At 860°	222

4. *Spectrum.*

In 1863 Werther published a note on the similarity between the spectra of selenium and lead. Ditte (1871), made a comparative study of the spectra of sulphur, selenium, and tellurium. He found well marked yellowish-green lines in the selenium spectrum toward the E line, and also two brilliant blue bands near to and to the left of the G line.

The work of Salet as well as that of Plücker and Hittorf is summarised in the report of a special committee of the British Association for the Advancement of Science (1884). The tables there given are too long to be quoted here.

5. *Absorption Spectrum.*

Gernez (1872), records that the vapour of selenium absorbs the rays of the spectrum up to about the C line; but at higher temperatures there is extinction in the blue and violet.

6. *Capillarity Constant.*

Quincke (1868), determined the capillarity constant of selenium by the method of drops, and found—

$$a = 7{\cdot}180 \text{ m.g. for } 2r = 1 \text{ m.m.}$$

VII. Conclusion.

In conclusion, I desire to express my sincerest thanks to Professor W. D. Bancroft, in whose laboratory this work was carried on; I am indebted to him not only for suggesting the subject of the investigation to me, but also for his continued interest and timely suggestions while it has been in progress.

LONDON WATER SUPPLY.

REPORT ON THE COMPOSITION AND QUALITY OF DAILY SAMPLES OF THE WATER SUPPLIED TO LONDON FOR THE MONTH ENDING DECEMBER 31ST, 1900.

By SIR WILLIAM CROOKES, F.R.S.,
and
PROFESSOR DEWAR, F.R.S.

To CHARLES PERRIN, Esq., M.Inst.C.E.,
Water Examiner, Metropolis Water Act, 1871.

London, January 10th, 1901.

SIR,—We submit herewith, at the request of the Directors, the results of our analyses of the 192 samples of water collected by us during the past month, at the several places and on the several days indicated, from the mains of the London Water Companies taking their supply from the Thames and Lea.

In Table I. we have recorded the analyses in detail of samples, one taken daily, from Dec. 1st to Dec. 31st inclusive. The purity of the water, in respect to organic matter, has been determined by the Oxygen and Combustion processes; and the results of our analyses by these methods are stated in Columns XIV. to XVIII.

We have recorded in Table II. the tint of the several samples of water, as determined by the colour-meter described in previous reports.

In Table III. we have recorded the oxygen required to oxidise the organic matter in all the samples submitted to analysis.

Of the 192 samples examined by us during the month, all were found to be clear, bright, and well filtered.

The rainfall at Oxford during December shows a slight excess for the first time since the month of August. The actual rainfall has been 2·20 inches, the average for the month is 2·10 inches, making an excess of 0·10 inch; this reduces the total deficit for the year to 3·12 inches, or 12·1 per cent on the thirty years' average, as will be seen by the following table:—

TABLE A.—*Rainfall in Inches at Oxford, Month by Month, during the Year* 1900.

	Actual fall. Inches.	Mean of 30 years. Inches.	Difference from the mean. Inch.	Inch.
January ..	2·30	2·16	—	+0·14
February ..	4·23	1·76	—	+2·47
March ..	0·50	1·50	−1·00	—
April	0·89	1·66	−0·77	—
May	1·33	1·83	−0·50	—
June	2·73	2·11	—	+0·62
July	0·88	2·68	−1·80	—
August ..	3·13	2·32	—	+0·81
September..	0·41	2·43	−2·02	—
October ..	2·35	2·75	−0·40	—
November..	1·65	2·42	−0·77	—
December..	2·20	2·10	—	+0·10

Our bacteriological examinations of 498 samples have given the results recorded in the following table; we have also examined 36 other samples, from special standpipes, &c., making a total of 534 samples in all:—

	Microbes per c.c.
New River, unfiltered (mean of 24 samples) ..	326
New River, filtered (mean of 126 samples) ..	10
Thames, unfiltered (mean of 24 samples) ..	1548
Thames-derived water, from the clear-water wells of eight Thames-derived supplies (mean of 264 samples)	15
Ditto ditto .. .. highest	194
Ditto ditto .. .. lowest	0
River Lea, unfiltered (mean of 24 samples) ..	397
River Lea, from the East London Company's clear-water wells (mean of 36 samples) ..	10

Of the 426 samples of the filtered water supplied to London, examined bacteriologically during the past month, only six samples, or 1·4 per cent of the whole number of samples examined, contained more than 100 microbes per c.c.

During the past year we have examined 6731 samples of London waters bacteriologically, as compared with 4792, 3500, and 3249 respectively in the three previous years. We have also made 2478 chemical analyses of London waters throughout this period, making a total of 9209 samples examined during the year.

The results of the filtration of the London waters are given in Tables B, C, and D.

Table B shows that during the first six months the Thames-derived Companies' clear-water wells contained on the average 24 bacteria per c.c., while the New River and River Lea supplies contained respectively 9 and 8. During the second six months, the number of bacteria in the waters from the three were respectively 18, 8, and 12.

From Table C it will be seen that from 1897, when the bacteriological condition of the London water supply was highly satisfactory, being much below 100 microbes per c.c., there has been, nevertheless, a steady improvement with each succeeding year. This improvement is not confined merely to the Thames-derived waters, but is more apparent in the New River and the Lea supply. It is interesting to note that in the year 1900, as compared with the year 1897, the average microbic purity has been raised about 55 per cent in the Thames derived waters, while in the New River it has been raised some 70 per cent, and in the case of the Lea, nearly 85 per cent. We attribute these extraordinary results to the increased knowledge of the scientific treatment of the filter beds, and to the fact that, as bacteriological examinations of each of the Companies' supplies are made every day, we are in a position to communicate immediately to the engineers in charge any retrograde change that may be taking place in the efficiency of the filtration.

We are, Sir,

Your obedient Servants,

WILLIAM CROOKES.
JAMES DEWAR.

A Compound of Fluoride of Silver and Fluoride of Ammonium.—B. Grützner.—The author makes use of commercial NH_4F. Into a solution of this salt, prepared in the cold, and as concentrated as possible, he drops Ag_2O freshly precipitated by NaOH free from the chloride, so long as this oxide is dissolved. On cooling the solution to 0°, crystalline needles are deposited (2 grms. for each 50 grms. of Ag_2O); these are washed with distilled water, and dried with blotting-paper, while being kept cool and away from the light. Their analysis shows that they consist of the double salt $2NH_4F+AgF+H_2O$. The property of AgCl of being slightly soluble in concentrated NH_4Cl thus reappears with AgF, which is much more easily soluble, forming the above double salt.—*Arch. de Pharm.*, vol. ccxxxviii., p. 1.

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Ordinary Meeting, December 20th, 1900.

Professor THORPE, C.B., F.R.S., President, in the Chair.

(Concluded from p. 34).

176. "*The Action of Ethylene Dibromide on Xylidine and Pseudocumidine.*" By ALFRED SENIER and WILLIAM GOODWIN.

The reaction between ethylene dibromide and aniline originally studied by Hofmann, and extended to homologues of both compounds by subsequent observers, has been applied to xylidine and pseudocumidine. Dixylylethylenediamine and dicumylethylenediamine were obtained, together with their related piperazines. From the diamines, derivatives were prepared homologous with those obtained by Mills (*Trans.*, 1900, lxxvii., 1020). *Dixylylethylenediamine*, $C_2H_4(NHC_6H_3Me_2)_2$, white feathery crystals, m. p. 74—75°. *Dixylylethylenediamine nitrate*, $C_2H_4(NHC_6H_3Me_2)_2(HNO_3)_2$, m. p. 166°. *Dixylylethylenediamine platinichloride*, $C_2H_4(NHC_6H_3Me_2)_2(HCl)_2PtCl_4$, bright yellow crystals. *Dixylylethylenediamine mercurichloride*, $C_2H_4(NHC_6H_3Me_2)_2HgCl_2$, pale yellow crystals, m. p. about 118°. *Tetranitrodixylylethylenediamine* $C_2H_4[NHC_6H(NO_2)_2Me_2]_2$, pale yellow crystals, m. p. 220°. An *isomeride*, m. p. 52—53°. *Mononitrodixylylethylenediamine*, m. p. 152—154°, and a *trinitro*-derivative, m. p. 191—192°. *Dixylylpiperazine*,—

$$Me_2H_3C_6N(C_2H_4)_2NC_6H_3Me_2,$$

consists of shining white leaflets, m. p. 151°. *Dipseudocumylethylenediamine*, $C_2H_4(NHC_6H_2Me_3)_2$, brilliant colourless needles, m. p. 168°. *Dipseudocumylethylenediamine nitrate*, $C_2H_4(NHC_6H_2Me_3)_2(HNO_3)_2$, colourless needles, m. p. 154°. *Dipseudocumylethylenediamine platinichloride*, $C_2H_4(NHC_6H_2Me_3)_2(HCl)_2PtCl_4$, buff-coloured powder. *Dipseudocumylethylenediamine mercurichloride* $C_2H_4(NHC_6H_2Me_3)_2HgCl_2$, crystals melting at 150°. *Dinitrodipseudocumylethylenediamine*, $C_2H_4[NHC_6H(NO)Me_3]_2$, yellow powder, m. p. 97—98°; an *isomeride*, m. p. 49—50°. *Dipseudocumylpiperazine*, $Me_3H_2C_6N(C_2H_4)_2NC_6H_2Me_3$, colourless needles, m. p. 148—150°.

177. "*The Action of Phenyl Carbimide on Diphenyl-, Dialphyl-, and Dinaphthyl-diamines.*" By ALFRED SENIER and WILLIAM GOODWIN.

When the two ethylenediamines described in the preceding abstract were treated with phenyl carbimide an interesting reaction resulting in the formation of ethylenediamines of the type $C_2H_4(NR'\cdot CO\cdot NHPh)_2$ was brought to light. These diamines are analogous to the ethylenediamine of Volhard (*Ann.*, 1861, cxix., 349), and to the trimethylene carbanilide of Hanssen (*Ber.*, 1887, xx., 783). The reaction is shown to be a general one by the formation of the following homologues:—*Dicarbanilido-diphenylethylenediamine*, $C_2H_4NPh\cdot CO\cdot NHPh)_2$, m. p. 220°. *Dicarbanilido-ditolyl ethylenediamines*,—

$$C_2H_4(NC_6H_4Me\cdot CO\cdot NHPh)_2.$$

The *ortho*-derivative melts at 195—196°, the *meta*- at 181·5°, and the *para*- at 186°. *Dicarbanilido-dixylylethylenediamine*, $C_2H_4(NC_6H_3Me_2\cdot CO\cdot NHPh)_2$, melts at 167°. *Dicarbanilido-dipseudocumylethylenediamine*, $C_2H_4(NC_6H_2Me_3\cdot CO\cdot NHPh)_2$, m. p. 191°. *Monocarbanilidodi-α-naphthylethylenediamine*,—

$$C_2H_4(NHC_{10}H_7)(NC_{10}H_7\cdot CO\cdot NHPh),$$

m. p. 266°.

178. "*Note on the Action of Nitrous Acid on β-nitroso-α-naphthylamine.*" By ARTHUR HARDEN and J. OKELL.

When β-nitroso-α-naphthylamine is treated in alcoholic solution with potassium nitrite and hydrochloric acid, it yields a potassium salt, $C_{10}H_6O_2N_3K$, which crystallises

in reddish-coloured needles, and decomposes vigorously at 250°. A different salt, described in a previous paper (*Ann.*, 1889, cclv., 148), was obtained by this reaction, which had the formula $C_{10}H_6O_4N_4KH$, and crystallised with $1\frac{1}{2}H_2O$, but on repeating the experiments the exact conditions necessary for the formation of this salt could not be ascertained, and the simpler salt, which differs from it by the elements of nitrous acid, was always obtained. Sodium nitrite yields the corresponding salt, $C_{10}H_6O_2N_3Na$. These salts behave towards acids in a manner similar to that already described, yielding, with hydrochloric acid and stannous chloride, a compound, $C_{10}H_6N_3{\cdot}OH$, which probably has the constitution of an imidazole,—

$$C_{10}H_6\begin{cases}\text{———}N\\ N(OH)\end{cases}\!\!>\!\!N$$

(compare Zincke and Schwarz, *Ann.*, 1900, cccxi., 329). This substance crystallises with $1H_2O$, decomposes violently at 222°, and acts as an acid, yielding crystalline salts of sodium, potassium, and barium. The silver salt has the formula $C_{10}H_6{\cdot}N_3OAg$, and not that previously ascribed to it. The acetate melts at 109°, and the silver salt yields colourless, crystalline derivatives when heated with methyl and ethyl iodides.

The isomeric *α*-nitroso-*β*-naphthylamine behaves towards nitrous acid in a similar manner, yielding a potassium salt, $C_{10}H_6N_3O_2K+H_2O$, which, with hydrochloric acid and stannous chloride, gives a compound, $C_{10}H_6N_3{\cdot}OH$, which decomposes at 245°, and is isomeric with that described above, which it closely resembles in its properties.

179. "1 : 2 : 4-*Metaxylidine-6-sulphonic Acid.*" By HENRY E. ARMSTRONG and L. P. WILSON.

One of the authors has on previous occasions discussed the conditions under which either ortho- or para- or meta derivatives are formed from benzenoid amines, and has argued that meta-derivatives are produced by the direct attack of the benzene nucleus, whilst ortho- and para compounds are formed by a process of isomeric change in which the radicle is transferred from the nitrogen into the nucleus. An opportunity of further testing this generalisation is afforded by 1 : 2 : 4-metaxylidine. When sulphonated by an excess of fuming acid, this is readily converted into the 5-sulphonic acid, the only metaxylidinesulphonic acid hitherto described; it was to be supposed that the 6-sulphonic acid would be readily obtained on heating the sulphate, and this proves to be the case.

When metaxylidine is mixed with a single molecular proportion of 100 per cent sulphuric acid, and the mixture heated at 185° to 195° during six hours, the product then dissolved in water, and the solution neutralised with potassium carbonate, 90 per cent of the theoretical amount of *potassium*-1 : 2 : 4 : 6-m-*xylidinesulphonate*, $C_6H_2(CH_3)_2(NH_2){\cdot}SO_3K$, is obtained. *Potassium*-1 : 2 : 4 : 6-*aceto*-m-*xylidinesulphonate*, $C_6H_2NH(CH_3)_2Ac{\cdot}SO_3K$, is obtained by heating the potassium sulphonate with acetic anhydride. It is a colourless substance crystallising from alcohol in spindle-shaped needles. On adding bromine to its solution in water, the sulphonic group is not affected, although it is easily displaced from the unacetylated acid.

Potassium-1 : 3 : 5-m-*xylenesulphonate*,—

$$C_6H_3(CH_3)_2{\cdot}SO_3K,\tfrac{1}{2}H_2O,$$

is obtained from the 1 : 2 : 4 : 6-*m*-xylidinesulphonate by diazotising, and then boiling with alcohol, or by means of the hydrazine; it crystallises from water in thin, colourless, lustrous leaves, and is nearly insoluble in alcohol. On fusing this salt with potash, it is converted into 1 : 3 : 5-*m*-xylenol, m. p. 65°. *Barium* 1 : 3 : 5-m-*xylenesulphonate*, $(C_6H_3Me_2{\cdot}SO_3)_2Ba,2H_2O$, crystallises from water in fine, colourless leaves. 1 : 3 : 5-m-*Xylenesulphonic acid* crystallises from water in thin, transparent flattened needles. 1 : 3 : 5-m-*Xylenesulphochloride*, $C_6H_3(CH_3)_2{\cdot}SO_2Cl$, crystallises from light petroleum and benzene in needles, and from chloroform in massive crystals; m. p. 94°. 1 : 3 : 5-m-*Xylenesulphobromide*, $C_6H_3(CH_3)_2{\cdot}SO_3Br$, resembles the sulphochloride in crystalline behaviour; m. p. 92—93°. 1 : 3 : 5-m-*Xylenesulphonamide*, $C_6H_3(CH_3)_2{\cdot}SO_2NH_2$, crystallises from water in very lustrous, colourless flakes, and from benzene in very fine needles; m. p. 134°. 1 : 3 : 5-m-*Xylenesulphanilide*, $C_6H_3(CH_3)_2{\cdot}SO_2{\cdot}NH{\cdot}C_6H_5$, crystallises from alcohol in large, monosymmetric crystals; m. p. 119°.

$$a : b : c = 0{\cdot}8718 : 1 : 0{\cdot}7341. \quad \beta = 110°58'.$$

1 : 3 : 5-m-*Xylenesulpho*-p-*toluidide*,—

$$C_6H_3(CH_3)_2{\cdot}SO_2NH{\cdot}C_6H_4{\cdot}CH_3.$$

crystallises from alcohol in monosymmetric crystals resembling the anilide; m. p. 121—122°.

$$a : b : c = 1{\cdot}18195 : 1 : 0{\cdot}9380. \quad \beta = 101°7'.$$

180. "*The Preparation of Acetylchloraminobenzene and Related Compounds.*" By F. D. CHATTAWAY and K. J. P. ORTON.

The authors reply to Armstrong's recent criticism of the authors' work. The statements which he calls in question are proved to be correct, and details are given of the method of preparing acetylchloraminobenzene. It is also shown that acetylchloramino-2 : 4-dichlorobenzene can be obtained by the direct action of chlorine on acetanilide.

CORRESPONDENCE.

DIVISION OF NITROGEN IN CHEMICAL MANURE COMPOUNDS.

To the Editor of the Chemical News.

SIR,—Having been engaged in connection with the manufacture of artificial fertilisers two or three years ago, I have also been much interested in that phase of manuring which Mr. J. Ostersetzer emphasises (CHEM. NEWS, lxxxiii., p. 3).

My attention was first drawn to the matter by the success of certain fertilisers of low percentage, as compared to more concentrated ones, which though well-balanced as regards their essential constituents, and with these constituents thoroughly well incorporated, gave poorer results than the low percentage manures, each being applied in proportional quantities.

These differences, though occurring in the hands of practical gardeners, &c., could only be explained as being due to the improper dilution of the concentrated fertiliser by mixing with dry earth or other material, and I came to the conclusion that this dilution was effective when thoroughly mixed, as would occur at a works, in not only separating the particles of phosphate, &c., one from another, but in still further disintegrating such particles, thus causing a much better distribution throughout the mass.

With this in view I tried a few experiments with a mixture of sand and gypsum, containing a maximum of 2 per cent of sulphate of ammonia, distributed by thoroughly mixing in a solution of the sulphate, thus ensuring fineness of division in, I should think, as perfect a manner as is possible.

The result of the use of such a mixture was surprising, for, tested against well compounded manures of the usual kind, the nitrogen was found to be almost four times as effective in producing growth of plants upon which it was tried.

I have been much confirmed in the importance that is to be attached to finenes of division, by the results obtained by a certain patented manure a few years ago. This contained only about 2 per cent of ammonia as sulphate, no phosphates, and only a trace of potash; yet its results, which I have seen for myself, certainly sur-

passed many fertilisers of a much higher percentage in ammonia, &c., when these latter have been applied in the manner usually adopted by the average gardener, that is by sprinkling the surface of the soil with the compound, or else imperfectly mixing with a little dry earth.

In the case of the patented manure mentioned nothing was claimed by the makers for the action of the ammonia, but its whole effect was put down to special properties which it was said to possess in the way of supplying silica in an assimilable form. On examination, however, I concluded that its merit depended entirely upon the ammonia, and this being so low in percentage, its efficiency must be due to its fine state of division, and this I consider proved by experiments with the mixture of sand, gypsum, and ammonia sulphate before mentioned.

In the case of compounds in which nitrogenous refuse matter is worked up by the aid of sulphuric acid, Mr. Ostersetzer has shown that part of the nitrogen present becomes converted into sulphate of ammonia, which becomes widely distributed throughout the mass by going into solution during the mixing in the excess of acid which is present in compounded manures of this class.

This gives a reason for the preference shown by many farmers for such manures; they give good results, and seem cheaper, though as a matter of fact they are generally sold at prices absurdly out of proportion to their value, reckoned on analysis. On the other hand, a concentrated form of fertiliser may give a comparatively poor reault, because the farmer must needs mix it with a diluent before he can spread it on his land, and this is too often done imperfectly, either through carelessness, ignorance, or lack of means.

If, however, the mixing were done on the farm in a proper manner, the concentrated forms would be the cheapest, as these being sold at prices more in accordance with the result of analysis, and as the source of ammonia must be inorganic in order to obtain a high percentage of ammonia, better value in this essential alone is assured. Added to this is the saving in cost of carriage.

If the farmer can succeed in making homogeneous mixings he may of course proceed to reap the full advantage of his skill, and do away with purchases of compounded fertilisers, mixing his own, or, still better, put his potash salts, phosphates, and nitrogenous material on the land in a well diluted condition at different seasons, and thus do his manuring in a truly rational manner. But until he can make a decent mixture the artificial manure manufacturer will still find customers among the agriculturalists.—I am, &c.

W. S. Lambert.

56 Leytonstone Road, Stratford, E.
January 16, 1901.

APPARATUS FOR STORING SOLUTIONS.

To the Editor of the Chemical News.

Sir,—The following is the description of an extremely simple apparatus which has all the perfections without having any of the obvious imperfections of the apparatus described by Mr. E. Dowzard in the Chemical News (vol. lxxxiii., p. 18):—

A cork in which two holes have been bored is fitted into the neck of the bottle in which the solution is to be stored; a funnel furnished with a tap, through which the solution may be returned to the bottle, is inserted in one hole, and a tube, also furnished with a tap, to allow air to flow in or out as the solution is run out or in, is inserted in the other; another tube having a tap through which the solution is run out, is fixed in a neck made low down at the side of the bottle. To prevent evaporation, &c., oil is poured on to the solution.—I am, &c.,

Nemo.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Note.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, del'Académie des Sciences. Vol. cxxxi., No. 27, December 31, 1900.

The Place of Indium in the Classification of the Elements.—C. Chabrié and E. Rengade.—The authors obtain double sulphates of indium and two well-defined alkaline metals, cæsium and rubidium. This fact, added to observations made by other chemists, seems to be sufficient to definitely include indium amongst the metals capable of giving sesquioxides. Apparently, also, the property of indium hydrate of being soluble in the alkalis, brings this metal nearer to aluminium than iron. It is worth remarking that indium acetylacetonate, so well-defined and beautifully crystalline, is not volatile and so cannot be used to determine the atomicity of indium. This latter fact brings indium nearer to iron and removes it from aluminium; the acetylacetonate of aluminium being volatile without decomposition.

Nitrate of Uranium.—Œchsner de Coninck.—The author determines the densities of several solutions of uranium nitrate in methyl alcohol—both commercial and pure—and in pure acetic acid of density 1·035. He examines the stability, with regard to diffused solar light, of the principal solutions of the same salt. He also measures the solubility of uranium nitrate in commercial methyl alcohol, in ethyl alcohol at 85°, in acetone purified from bisulphate, and in pure acetic acid.

Crystalline Form of Luteo-cobaltic Chlorosulphate and Chloroselenate.—T. Klobb.—During a preceding research, the author examined the form of crystals of luteo-cobaltic chlorosulphate, $(Co.6NH_3)SO_4.Cl+3H_2O$. The sharpness of the edges permitted excellent measurements to be taken. He now re-examines these, using more perfect crystals, and to confirm the conclusions drawn from the measurements of the above, he prepares luteo-cobaltic chloroselenate, $(Co.6NH_3)SeO_4.Cl+3H_2O$, a salt which is isomorphous with the above, and in which the mean value of $m\,m$ is 90° 4′ 30″. Very few substances have for their fundamental form a prism so near the quadratic prism. The derivative, $C_{22}H_{22}S_8$ has $m\,m$ of value 90° 8′, and the double tartrate of antimony and thallium is still less orthorhombic $m\,m$, having the value 90° 3′.

Osmosis of Liquids across a Membrane of Pig-bladder.—G. Flusin.—It has already been shown that the sense of velocity of osmosis of liquids across a vulcanised caoutchouc membrane depends on the capacity of absorption of the membrane for those liquids. The author endeavours to verify the fact, using methods and apparatus which he describes, that the same relation exists when a diaphragm such as pig-bladder is used. The numbers obtained show that the velocities of osmosis and the capacity of absorption vary in the same manner with pig-bladder as with vulcanised caoutchouc; the difference of affinity of the membrane for the two liquids with which it is in contact seems to determine the sense and intensity of the osmosis.

Indications of Organic Matter in certain Mineral Waters revealed by the Use of the Barium Hydrate Method.—F. Garrigou.—When barium hydrate is added to a mineral water, it precipitates all the metallic oxides contained in the water. This method of treatment enables a series of organic substances to be detected:—(1) Acids forming insoluble barium salts, perceived by the blackening of the barium precipitate on calcination. (2) The substances which barium hydrate leaves or sets free in the water, such as fatty materials and substances behaving as alkaloids; these can be extracted from the

water by means of benzine, petroleum ether, and chloroform. (3) An acid which is apparently freed from its compounds by sulphuric acid. (4) Substances which precipitate silver nitrate, in the same manner as the three halogens; these are probably the same as (3). (5) Finally, a neutral substance which remains in the last portions of the primitive liquid with the alkaline earths and the alkalis.

Presence of Methyl Alcohol in the Fermented Juice of various Fruits.—Jules Wolff.—Various authors have stated that methyl alcohol exists in the juice of certain plants previous to fermentation. This may be true to a certain degree, but the author shows that methyl alcohol appears during fermentation in the juice of a large number of fruits. He examines the juice of the following plants, and in all cases finds that the methyl alcohol has increased to a considerable extent:—Black currant, plum, cherry, apple, black and white grapes.

MISCELLANEOUS.

The Oxidising Value of the Alkaline Persulphates, and of Peroxide of Hydrogen.—B. Grutzner.—As_2O_5 is very well adapted for estimating the oxidising value of the persulphates:—

$$2K_2(SO_4)_2+As_2O_3+2H_2O=As_2O_5+2K_2SO_4+2H_2SO_4.$$

The operation is carried out warm in ordinary alkaline or ammoniacal solution. It is slower in acid solution. A $\frac{1}{10}$ N solution of As_2O_3 is used, the excess of which is estimated by a $\frac{1}{10}$ N solution of I. The valuation of H_2O_2 is made in the same manner, and gives results concordant with those furnished by the $KMnO_4$ method:—$As_2O_3+2H_2O_2=As_2O_5+2H_2O$. The author has not succeeded in titrating Na_2O_2 by the same method; the evolution of oxygen caused by this body is too rapid for the gas to combine integrally with the As_2O_3 at the moment of being set at liberty.—*Arch. de Pharm.*, ccxxxvii., p. 705.

Phosphide of Mercury and Compounds of Phosphonium.—A. Partheil and A. van Haaren.—The authors were unable to prepare phosphide of mercury, P_2Hg_3, by reacting with PH_3 on $HgCl_2$, either in the dry state or in solution; they were obliged to have recourse to Granger's method, which consists of reacting with P_2I_4 on Hg. By heating the P_2Hg_3 thus obtained with C_2H_5I, in sealed tubes to 160°, the body $P(C_2H_5)_4I.2HgI_2$ is obtained. This compound, treated with Ag_2O, gives the hydrate of tetrethylphosphonium:—

$$2[P(C_2H_5)_4I+2HgI_2]+5Ag_2O+H_2O=$$
$$=2P(C_2H_5)_4OH+10AgI+4HgO.$$

The base thus formed, when treated with HCl, gives the compound $P(C_2H_5)_4Cl$, which combines with $HgCl_2$, forming $P(C_2H_5)_4Cl.2HgCl_2$, and with $PtCl_4$ giving $[P(C_2H_5)_4Cl]_2PtCl_4$. The compounds obtained by this new method are identical with those prepared by the authors by the old process of A. W. Hofmann, C_2H_5I, reacting on $(C_2H_5)_3P$, &c. By heating CH_3I and P_2Hg_3 in sealed tubes to 150°, we obtain $P(CH_3)_4I.2HgI_2$, then successively $P(CH_3)_4Cl.HgCl_2$, $[P(CH_3)_4Cl]_2.PtCl_4$, and $P(CH_3)_4Cl.AuCl_3$.—*Arch. de Pharm.*, vol. ccxxxviii.

Some Properties of Gelatin.—C. Th. Mörner.—Gelatin may be washed for several weeks at the ordinary temperature with solutions of 0·2 to 0·5 per cent potash, without in any way losing its property of forming jelly, and without losing its sulphur. By this treatment the ash is reduced from 1·87 per cent to 0·13 or 0·16 per cent; but this is, however, independent of the washing with potash, as the same result can be obtained by simply washing with water. As many writers have found about 0·5 per cent of sulphur in gelatin, the author brings forward the hypothesis that there exist some gelatins containing one atom of sulphur and others containing two. Contrary to the statements of many writers, the Millon reaction has always been found to be positive. The author further shows that gelatin is really precipitable by acetic ferrocyanide, but that the precipitate is easily soluble in an excess of the reagent. Dilute solutions are precipitated more easily than concentrated ones. An increase of temperature, even to 30°, or the presence of neutral salts, diminishes or prevents the precipitation. The property of jellifying does not diminish with the increase of ash; this is contrary to the assertions of Nasse. The author contests the reality of the saline digestion, described by Dastre and Floresco (*Arch. de Physiol.*, xxvii., 701). The presence of neutral salts interferes with jellification, but digestion with salts in no way modifies the gelatin.—*Zeit. Phys. Chim.*, vol. xxviii., p. 471.

Action of Aluminium Amalgam on the Alcohols, Alcoholates of Aluminium, their Properties and Reactions.—V. Tistchenko.—The author has studied the action of aluminium amalgam on the various primary, secondary, and tertiary alcohols: all univalent alcohols are able to react on aluminium amalgam, giving alcoholates, $Al(OR)_3$; the essential condition of the reaction is that both the alcohol and the amalgam must be entirely free from water; the speed and ease of the formation, and of the separation of the alcoholates, depend on the nature of the alcohols; as a general rule, the primary alcohols react more easily than the secondary alcohols, and these more readily than the tertiary. The physical properties of the principal alcoholates obtained have already been described; it may, however, be remarked that the tendency to crystallise is only slightly remarked in the alcoholates of the normal primary alcohols, but it becomes more and more apparent as the number of molecules of CH_2 increases; the aluminates of the isobutyric and isopropylic alcohols, of trimethyl carbinol, and of dimethylethyl carbinol, can be obtained, however, in fairly large crystals, from their solutions in benzene or toluene. The molecular weight of the alcoholates has not been established by their vapour density, though many of them are volatile without decomposition; but the cryoscopic method indicates the general formula $Al(OR)_3$.—*Journ. Soc. Phys. Chim. R.*, xxxi., p. 694.

MEETINGS FOR THE WEEK.

Monday, 28th.—Society of Arts, 8. (Cantor Lectures). "Elementary Art Education," by J. Liberty Tadd.

Tuesday, 29th.—Society of Arts, 8. "Some Examples of Romanesque Architecture in North Italy," by Hugh Stannus.

Wednesday, 30th.—Society of Arts, 8. "Evolution of Form in English Silver Plate," by Percy T. Macquoid.

New Term Commenced January 7th.

BIRKBECK INSTITUTION,

Bream's Buildings, Chancery Lane, E.C.

Principal: G. ARMITAGE-SMITH, M.A.

DAY AND EVENING CLASSES.

UNIVERSITY OF LONDON.—Complete Day Courses for all the Examinations in Science, and Complete Evening Courses for all the Examinations for the Science, Arts, and Law Degrees.

SCIENCE CLASSES in every Branch, with Practical Work. Well equipped Laboratories for CHEMISTRY, PHYSICS, and METALLURGY.

CONJOINT BOARD: Lectures and Practical Work in Chemistry, Physics, Biology, and Practical Pharmacy.

Prospectus free. Calendar 6d. (by post 8d.) on application to Secretary.

THE CHEMICAL NEWS.

VOL. LXXXIII., No. 2149.

TOTAL ECLIPSE OF THE SUN, JANUARY 22ND, 1898.

OBSERVATIONS AT VIZIADRUG. PART IV. THE PRISMATIC CAMERAS.*

By Sir NORMAN LOCKYER, K.C.B., F.R.S.

THE report gives full particulars concerning the 6-inch and 9-inch prismatic cameras which were used during the eclipse, and the results obtained. Twenty-four of the photographs are reproduced. A table is given indicating the wave-lengths and probable origins of the 856 lines which have been measured between D and λ 3663.

The investigation shows the probable presence of both arc and enhanced lines of calcium, chromium, iron, manganese, nickel, strontium, titanium, and possibly cobalt, copper, indium, lead, molybdenum, potassium, and rubidium; arc lines of aluminium, barium, carbon, magnesium, sodium, scandium, and possibly cerium, lanthanum, lithium, rhodium, and tantalum; enhanced lines of vanadium, and possibly of bismuth, cæsium, gold, ruthenium, selenium, silicium, thallium, tin, tungsten, yttrium, zinc, and zirconium. Hydrogen, helium, and asterium are also present.

No evidence has been found of the presence of antimony, arsenic, cadmium, iridium, mercury, osmium, palladium, platinum, silver, or thorium. Further investigations of the coronal rings have led to no definite results regarding their origins.

THE THERMO-CHEMISTRY OF THE ALLOYS OF COPPER AND ZINC.*

By T. J. BAKER, B.Sc., King Edward's School, Birmingham.

THE heats of formation of a number of alloys of copper and zinc, containing those metals in very diverse proportions, have been ascertained.

The method consists in finding the difference between the heats of dissolution, in suitable solvents, of an alloy, and of an equal weight of a mere mixture containing the metals in the same proportion.

The first series of experiments was made with an aqueous solution of chlorine as solvent. Its application was limited to those alloys containing less than 40 per cent of copper, as it was impossible to obtain those richer in copper in a sufficiently fine state of division to enable them to dissolve.

The results, though not altogether satisfactory, showed that the heat of dissolution of an alloy was sensibly less than that of the merely mixed metals.

Incidentally it was found that the equation $Cl_2.Aq = 2600$ (Thomsen's "Thermochemische Untersuchungen"), is erroneous, and on inquiry, Professor Thomsen gave a corrected value, 4870. The author finds $Cl_2.Aq = 4970$.

The most suitable solvents of the alloys are—

(*a*). Mixture of ammonium chloride and ferric chloride solutions.

(*b*). Mixture of ammonium chloride and cupric chloride solutions.

The chemical actions involved are simple reductions, and no gases are evolved.

Two series of experiments made on twenty-one alloys yielded very concordant results. They show that heat is evolved in the formation of every alloy of copper and zinc yet tested.

A sharply defined maximum heat of formation is found in the alloy containing 32 per cent of copper, *i.e.*, corresponding to the formula $CuZn_2$. It amounts to 52·5 calories per grm. of alloy, or 10,143 calories per grm.-molecule. There is some evidence of a sub-maximum in the alloy nearly corresponding to CuZn.

From these points there is a steady decrease in the heat of formation, both in the case of alloys containing less than 32 per cent of copper as the amount of copper decreases, and also in the case of those containing more than 50 per cent of copper as the quantity of copper increases.

The results, in general, confirm the existence of intermetallic compounds, and the values obtained are in accordance with those demanded by Lord Kelvin's calculation of the molecular dimensions of copper and zinc.

THE PREPARATION OF ZINC ETHYL.*

By ARTHUR LACHMAN.

ABOUT three years ago I published a brief outline of a method of preparing zinc ethyl (*Am. Chem. Journ.*, 1897, xix., 410). As is well known, the chief difficulty in this preparation is to secure a suitable form of zinc; and this difficulty was overcome by the use of zinc dust, which is both cheap and plentiful. My note, though brief, contained all the information needed for the immediate application of the process; and a more detailed description would be entirely unnecessary, were it not that a zinc-dust method (Simonowitsch, *Chem. Centrbl.*, 1899, i., 1066) has since then been published which does not appear to offer any advantages over the older one. The two methods differ in that Simonowitsch uses zinc-dust mixed with filings, whereas my process is to be regarded as a modification of the Gladstone-Tribe method (*Journ. Chem. Soc.*, xxxv., 569) in that it uses an alloy of zinc-dust with copper. The method of Gladstone and Tribe has long been recognised as yielding by far the best results; and the only obstacle to its universal employment would seem to be the great difficulty of preparing their "zinc-copper couple" in large quantities. Part of this difficulty lies in the fact that they use zinc filings for this purpose—for filings are hard to procure in quantity; the chief obstacle, however, is that great manual dexterity is required for the successful alloying of the two metals. Moreover, a number of operations are called for; the filings must be freed from oil, they must be cleaned with acid if appreciably oxidised, and then carefully dried; the copper must be prepared by careful reduction of its oxide, and finally the two metals must be alloyed with such care that only small amounts can be taken at one time. As my method yields unlimited quantities of alloy in a single operation, which is automatic and does not occupy more than twenty minutes' time, and as it furnishes an excellent yield of zinc ethyl, it may fairly claim to be an improvement upon its progenitor. The details of the new method proposed by Simonowitsch will be considered by the side of the corresponding details of my own.

1. *The Zinc Dust-copper Couple.*

Gladstone and Tribe have shown that the best yields are obtained when zinc and copper are alloyed in the proportions of about 9 to 1. Zinc dust contains an average of 90 per cent of metal, so that the above proportions are approximated if 100 parts of zinc dust are mixed with 12 parts of copper oxide, and then reduced by heating in a current of hydrogen.

* Abstract of a Paper read before the Royal Society, January 17, 1901.

* Contributions from the Chemical Laboratory of the University of Oregon. From the *American Chemical Journal*, XXIV., No. 1

100 parts zinc dust and 12 parts copper oxide (in the finest possible powder*) are thoroughly mixed and placed in a long glass tube. This tube, which may be of soft glass, should be as wide as the channel of a combustion furnace will permit; at distances corresponding to the length of the channel it should be narrowed to about half its diameter. A plug of glass-wool is fitted into one constriction, the tube then filled about one-half full, and a plug inserted into the other end. The tube is now shaken and rotated in a horizontal position until the mixture spreads out in an even layer. A moderate current of dry hydrogen is then passed through the tube, and the latter heated in the furnace. It is not a difficult matter to properly regulate the heating, a flame of about 5 to 10 c.m. being needed according to the construction of the furnace. The only essentials are to heat the whole tube at once, to rotate the tube one-quarter turn at an interval of a few minutes, and not to be afraid of heating too strongly. It has succeeded best when the powder has slightly baked together, and must be dislodged by a stout wire. Reduction is complete within twenty minutes from the start. The alloy looks much lighter than the mixture, and is considerably coarser, though still a fine powder, The contents are allowed to cool in hydrogen (best by removing the tube from the furnace), and are shaken out when no longer hot to the touch. It is advisable to use as soon as possible, though I have kept the alloy several days in an ordinary glass-stoppered bottle without noticeable deterioration.

It will be seen that this method is much more expeditious than the one given by Simonowitsch. The latter first cleans the zinc dust with dilute acid, washes, and finally dries it in a current of carbon dioxide at a definite temperature. This prepared dust must then be mixed with a considerable proportion of dry, clean filings. It has already been pointed out that filings are hard to obtain.

2. *First Stage of the Zinc Ethyl Synthesis.*

The action of zinc upon ethyl iodide, as is well known, proceeds in two entirely distinct phases. The first consists in a direct addition of ethyl iodide to zinc:—

$$Zn + C_2H_5I = Zn\begin{matrix} I \\ C_2H_5. \end{matrix}$$

It is carried out at the temperature of the water-bath, and its completion becomes manifest by the disappearance of the ethyl iodide. It is customary to carry out this reaction with a great number of complications, such as a mercury valve for increasing the pressure as well as the boiling-point of the liquid (Simonowitsch uses this device), a current of dry hydrogen for keeping out the air, &c. But these are all unnecessary. Equal parts of alloy and ethyl iodide are simply placed in a flask connected with a long reflux condenser, and the mixture kept *gently* boiling on the water-bath until no more ethyl iodide drops back. Violent boiling may drive some of the liquid through the condenser. The time varies from thirty to sixty minutes, according to circumstances that cannot be rigorously defined. I have found it preferable to work with small quantities at a time (from 150 to 250 grms. each of alloy and iodide), to use an Erlenmeyer flask of about 500 c.c. capacity, and to take pains to spread the alloy in a thin, even layer on the bottom. The speed of reaction seems to depend on the surface of metal exposed;† and this would appear to be the reason why Simonowitsch introduces zinc filings into his flasks.

It is a curious fact that the longer the time required for completing this reaction, the more does a secondary process take place resulting in the formation of butane and consequent loss of zinc ethiodide:—

$$2C_2H_5I + Zn = (C_2H_5)_2 + ZnI_2.$$

This is an additional reason for desiring rapid action. Once the ethyl iodide is all used up, the process can be indefinitely interrupted at this point, if not convenient to proceed to the final stage.

3. *Second Stage of the Synthesis.*

The conversion of zinc ethiodide into zinc ethyl according to the equation $2C_2H_5ZnI = Zn(C_2H_5)_2 + ZnI_2$, is accomplished by heating to 180—220°. The flask containing zinc ethiodide is fitted with a double-bored cork, through which connection is made with a condenser and with a generator furnishing dry carbon dioxide. The current of gas should be moderately rapid at first, very slow during distillation, and rapid again at the end in order to wash out the remaining few cubic centimetres in the flask. The zinc ethyl should be purified by re-distillation, as it invariably contains a small amount of unchanged ethyl iodide; for this reason a distilling flask of suitable size should serve as a receiver, to avoid subsequent transfer. The heating is best accomplished in an oil-bath. In my former note I recommended the use of asbestos air-baths as being cleaner and more expeditious; but this advantage is more than offset by the occasional bursting of a flask at the height of the distillation. Fifteen or twenty minutes suffice for this operation.*

The re-distillation of zinc ethyl may be conducted with little trouble as follows:—The distilling flask is carefully connected with a condenser; the receiver, which should be a stout Erlenmeyer flask, is filled with carbon dioxide, and fitted to the condenser with a cork from which a good sized wedge has been removed. A current of carbon dioxide is now delivered almost at the surface of the liquid, and continued until all of the air has been expelled from the apparatus. It is desirable to fit the tube into the flask with a cork, and make the gas escape at the receiver. The gas-jet is now replaced with a thermometer already fitted to a cork, and the distillation carried out as with ordinary liquids; a free flame may be used with perfect safety. All flasks to be used as receivers must be filled with carbon dioxide, and fitted with good sound corks. To change receivers, fasten the carbon dioxide jet used above so as to play a strong current upon the mouth of the first receiver; gently disengage this from the wedge-shaped cork, and then quickly change flasks, *devoting attention primarily to the new receiver*; the old one may be left with impunity for several minutes, if necessary, before being corked.

4. *The Preparation of Zinc Ethyl in Quantity.*

The process just outlined applies to a single flask of, say, 200 grms. charge, which will yield on an average 60 to 70 grms. zinc ethyl. The time required for all operations except re-distillation is at most one and one-half to two hours, usually not much more than one hour. The method is peculiarly advantageous, however, when it is desired to prepare several hundred grms. at one time. I have already mentioned that the yields are better if not more than 250 grms. be employed in a single operation; but by judicious planning it is not difficult to prepare practically unlimited quantities in a single working day. For this purpose select from three to six flasks of the same aperture, so that all fittings shall be interchangeable. Begin operation by preparing a tubeful of alloy (my tube will hold about 350 grms.). While this is heating, mount two condensers in connection with water-baths, and prepare the corks. As soon as the alloy is ready, charge two flasks and prepare more alloy. As these processes require almost no attention, employ the interval to fit up the condenser, oil-bath, and fittings for the second heating. As soon as a flask is ready, wipe it dry, and heat in the oil-bath (which may be warmed to about 110° or even more); then place a third charge upon the water-bath, &c. By

* This is a commercial article.

† During the boiling little or no liquid penetrates through a thick layer of the powder.

* The *total* time required is one and one-half hours. Simonowitsch needs two to two and one-half hours, not including the time needed for preparing the metal.

these alternations little or no time is lost, and, employing three condensers as described, about 75 grms. per hour will be obtained for each hour after the first (*i.e.*, 75 grms. in two hours, 150 grms. in three hours, &c.). Of course, any greater number of baths and condensers may be employed, if room and assistance permit. I have always worked alone, and have had plenty of spare time working as above.

5. *The Manipulation of Zinc Ethyl.*

The peculiar property possessed by zinc ethyl of rapidly heating itself to the kindling point in air, naturally renders caution necessary when making use of it. In the last few years I have had occasion to handle several kilos. of the substance, and have avoided all mishaps by very simple precautions. On the other hand, the very elaborate appliances which have been devised and recommended for this purpose are very likely to deter many from employing this classic synthetic reagent. I may therefore be permitted to summarise my experiences in this direction.

In the first place, all vessels which are to contain zinc ethyl must be filled with dry carbon dioxide. For drying purposes I use a long tube filled with calcium chloride, and two Muencke wash-bottles containing sulphuric acid. The vessels must be kept corked until used. Secondly, as has been demonstrated by Frankland, caoutchouc stoppers and connections must be avoided, and nothing but dry, sound corks exposed to the vapour of zinc ethyl. Thirdly, the transfer of zinc ethyl is greatly facilitated by pouring it from Erlenmeyer flasks which have perfectly straight sides; and these flasks must be strong enough to withstand sudden and energetic corking. It is inexpedient to attempt the isolation of definite quantities of the reagent; it is much better to pour out the amount needed approximately, and to suit the amounts of other substances to this. The amount taken is given by the loss in weight of the stock vessel; this is not a very accurate procedure, but answers all practical purposes. Fourthly, zinc ethyl may be poured from one vessel to another with perfect safety if the operation is carried out under an inverted funnel of from 4 to 6 inches in diameter, through the stem of which a rapid current of carbon dioxide is passing. After pouring, the first care belongs to the storage vessel; the other readily takes care of itself for some time. This simple expedient does away altogether with the "assistant" (Meyer-Jacobson, "Organic Chemistry," vol. i., p. 284), usually deemed indispensable when handling zinc ethyl. Finally, everything likely to be needed should be ready in advance, so that no time need be lost. It not infrequently happens that the carbon dioxide generator gives out at a critical moment. I make it an invariable practice to have two on hand, so that the second one may be coupled up without delay.

The chief inconvenience in the preparation of zinc ethyl is the cleaning of apparatus after it is all over. It therefore pays to make up as much as possible at one time. If not needed at once, I keep it in flasks of about 200 c.c. capacity, which are about half filled; these are tightly corked, and kept for safety in a large, lead-lined box with metal cover. The substance has been stored this way for months at a time, with no trouble and with practically no loss by oxidation.

6. *Experimental Results.*

The following tables will give the data for all the preparations of which I have kept a record; they are not selected, but include the poorest as well as the best I can find in my note-book.

Velocity of First Stage.

Amount of each reagent taken, in grms.	Time in minutes for disappearance of ethyl iodide.
150	50
150	48
200	45
300	65
75	30

Complete Data.

Iodide used in grms.	No. of separate charges.	Time for completion in hours.	Yield.	Theory.
650	7	4	216	256
300	2	2	95	108
1300	13	10	420	512
500	3	2·5	165	195

These experimental results bear out the claim that the method is quick, certain, and efficient. They correspond to a total yield of 84 per cent in the preparation of nearly 1 kilogrm. It should be remarked that in no case was an attempt made to hurry, and that usually I was at the same time busy with other work.

7. *The Recovery of Iodine.*

The recovery of the iodine which serves as a carrier of energy in this preparation is an exceedingly important affair from the standpoint of laboratory finance. The following method is the one I have found best after many trials:—

After heating in the oil-bath, the contents of the flasks form a solid cake. This is broken up with a sharp stick while still warm (it should be remembered that the contents are more valuable than the flask), and dropped into a bucket of water. After standing over night, the liquid is decanted, and the residue washed with water three or four times. A large bulk of liquid is an advantage. The solution is well mixed, and the amount of iodine determined either by analysis or by computation if the quantity of original ethyl iodide is known. After distributing the liquid among several large flasks, which should not be more than half full, add to each the calculated amount of potassium chlorate necessary to free all the iodine, and an excess of commercial hydrochloric acid. After an hour or more all the iodine will have settled; if the liquid should grow very warm, which happens when it is too concentrated, cool by standing in water. Decant the acid fluid, wash twice with water, and filter the iodine on a Buchner "nutsche." Press the pulp down hard with a pestle, and draw air through it for several hours.

The iodine thus prepared is by no means dry, but it can be easily used for making ethyl iodide. For this purpose, use as many c.c. of ordinary alcohol as there are grms. moist iodine, and take 1/20 the weight of the latter of red phosphorus.] From 2000 grms. iodine I obtained 1720 grms. distilled ethyl iodide in this manner. Thus it becomes possible to make a limited quantity of iodine furnish a practically unlimited amount of zinc ethyl.

THE TITRATION OF SALICYLIC ACID, SALICYLATES, AND PHENOL.

By FERNAND TELLE.

WHEN we add an excess of bromine to a solution of salicylic acid, or of a neutral salicylate, we obtain a precipitate of di-bromosalicylic acid. We have made quite certain that no matter what quantity of bromine may be used in proportion to the salicylic acid present, this is the only bromised derivative formed under the existing conditions:—

$$C_6H_4{<}^{CO_2H}_{OH} + Br = C_6H_2Br_2{<}^{CO_2H}_{OH} + 2HBr.$$

We see that one molecule of salicylic acid (138) requires four atoms of bromine (320). The amount of bromine absorbed by a salicylate is thus proportional to its richness in salicylic acid, and it is on the measurement of the quantity of bromine absorbed that the process we are about to describe rests.

Two methods are at present employed for measuring the amount of bromine absorbed by certain bodies under analogous conditions:—

1. To a solution of the material under examination, titrated bromine water is added until the slightest excess of the reagent is detected by an indicator, such as indigo, for example; this is the method adopted by M. François for the titration of aniline. In this manner the necessary volume of the reagent is determined directly.

2. A known quantity of bromine is added in such a manner that this metalloid will be in excess; the free bromine is then estimated by causing it to act on iodide of potassium, and then measuring the quantity of iodine displaced by a titrated solution of hyposulphite of soda. By difference we get the quantity of bromine that has been fixed. MM. Schlagdenhauffen and Braun determined the amount of bromine absorbed by fatty bodies in this manner.

We have endeavoured to avoid the use of titrated bromine water; this reagent, which is very disagreeable to use, so easily loses its strength, that, according to M. François, it ought to be standardised each time the burette is filled.

Since the application of the second process to the case in which we are concerned, we have observed another disadvantage; starch emulsion is used as an indicator at the end of the reaction, now the flocculent precipitate of dibromosalicylic acid retains the iodide of starch with such persistence that the blue colour which it takes does not disappear on the addition of hyposulphite.

It is for these reasons that, in order to produce the reaction, we prefer to use nascent bromine, given off by the action of a titrated solution of hypochlorite of sodium on a solution of bromide of potassium acidulated with hydrochloric acid.

The titrated solution of hypochlorite is prepared in such a manner as to give about 3·55 grms. of disposable chlorine per litre (a quantity corresponding with 8 grms. of bromine and 3·45 grms. of salicylic acid). This is obtained by diluting about 35 c.c. of commercial hypochlorite to 30 chlorometric degrees with distilled water so as to make one litre of solution.

The strength of this solution is maintained for at least a month if we take the precaution of keeping it away from the light. It is titrated by Gay-Lussac's method with the same author's chlorometric solution, or with a solution containing 4·95 grms. of arsenious anhydride per litre, a quantity corresponding to exactly 8 grms. of bromine, or to 3·45 grms. of salicylic acid. We use bromide of potassium as an indicator at the end of the reaction, as already recommended by M. Denigès; the yellow colouration communicated to the liquid by a slight excess of bromine, suffices to show the end of the reaction in the clear solution; but if the liquor contains a precipitate in suspension, we prefer to shake for some time with a few c.c. of chloroform, which concentrates the bromine set at liberty into a small volume.

We operate on 20 c.c. of arsenical solution, to which we add 5 c.c. of a solution of KBr at 10 per cent. We pour into this mixture, by means of a graduated burette, the hypochlorite solution, stopping when the last two drops added cause the appearance of a persistent faint yellow colour.

Let x be the number of cubic centimetres used; from this we deduce that 1 c.c. of this solution corresponds to $\frac{0{\cdot}0634}{x}$ grm. of Cl, $\frac{0{\cdot}1428}{x}$ grm. of Br, or $\frac{0{\cdot}0616}{x}$ grm. of salicyclic acid, if we have used Gay-Lussac's solution; if, on the other hand, we have made use of the arsenical solution described above, we get $\frac{0{\cdot}071}{x}$ grm. of Cl, $\frac{0{\cdot}160}{x}$ grm. of Br, or $\frac{0{\cdot}069}{x}$ grm. of salicylic acid.

Titration of Salicylic Acid.—1 grm. of the acid to be tested is dissolved in a mixture of 2 c.c. of soda-lye, and about 50 c.c. of water; when dissolved, the volume is made up to 500 c.c. with distilled water. About 25 c.c. of this solution (that is, 0·050 grm. of the substance) are taken, 5 c.c. of 10 per cent. KBr are added, and 10 to 15 drops of hydrochloric acid (too great an excess of HCl delays the absorption of the bromine). The graduated burette being filled with the titrated solution of hypochlorite; this latter is run, drop by drop, into the solution of salicylate with continuous stirring; the bromine is gradually absorbed as it is evolved, and soon a precipitate of bromosalicylic acid is formed. The addition of hypochlorite is continued until the mixture, after agitation, shows faint but evident yellow colouration, which is more apparent after the deposition of the precipitate; to prevent any error, we prefer to add 5 c.c. of chloroform, and the same quantity of alcohol, to prevent the formation of an emulsion, and then to shake vigorously. The precipitate dissolves in the chloroform; this latter is allowed to collect, which is accelerated by the addition of the alcohol, and the end of the operation is indicated by the yellowish tint which the solvent takes by reason of the presence of a trace of free bromine.

The operation can be easily carried out in an Erlenmeyer flask of 375 c.c. capacity; the separation of the chloroform is effected by inclining the flask at an angle of 45°, and giving it a rapid gyratory movement.

Knowing the strength of the hypochlorite solution, we can easily ascertain the richness of the substance under examination, from the number of c.c. used. In spite of the small amount of material operated upon, the estimation is exact because of the relatively large amount of bromine required by such a quantity of material.

A sample of commercial amorphous salicylic acid absorbs 2·305 grms. of bromine (theoretical quantity, 2·318 grms.) per grm., which corresponds to a richness of 99·47 per cent.

Salicylates of Soda, Lithia, and Magnesia.—We proceed as with salicylic acid; 1 grm. of the substance is dissolved in 500 c.c. of water (it appears to be unnecessary to use soda), and 25 c.c. of the solution are titrated as has been explained in the case of salicylic acid.

A sample of salicylate of soda has given the following result:—

Salicylic acid, per cent . .. 85·30 (theoretically, 86·25).

This quantity corresponds with 98·9 per cent of pure salicylate of soda.

A sample of salicylate of lithia gave—

Salicylic acid, per cent . .. 95·05 (theoretically, 95·83).

Which represents a richness of 99·18 per cent.

Two samples of salicylate of magnesia gave—

	I.	II.
Salicylic acid (per cent) ..	78·34	78·0
Magnesia (per cent)	11·2	11·3

by calcination and transformation of the residue into sulphate. At the same time we obtain by calculation—

	For $(C_7H_5O_3)_2Mg,H_2O$. Per cent.	For $(C_7H_5O_3)_2Mg,3H_2O$. Per cent.
Salicylic acid ..	87·34	78·40
Magnesia	12·65	11·36

We see that the quantity of salicylic acid obtained corresponds very closely with that of the magnesia, and that the commercial salt answers to the formula $(C_7H_5O_3)_2Mg,3H_2O$.

Salicylate of Bismuth.—1 grm. of salicylate of bismuth is rubbed up with 25 to 30 c.c. of water, 3 c.c. of soda-lye at 30° are added, and the whole boiled for ten minutes. After cooling, the volume is made up to 250 c.c., and the whole filtered; on 20 c.c. of the filtered solution (corresponding to 0·10 grm. of salicylate), the salicylic acid is estimated by means of the titrated solution of hypochlorite according to the method already described.

The following are the results obtained from two samples:—

	I.	II.	Calculated for $C_6H_4<^{CO_2Bi(OH)_2}_{OH}$
	Per cent.	Per cent.	Per cent.
Salicylic acid	31·79	33·88	36·22
Oxide of bismuth, Bi_2O_3	58·60	60·20	61·41

It is specially in the estimation of this salicylate that our method will be found applicable; the commercial salts are of very variable composition, and the estimation of salicylic acid by the gravimetric method takes rather a long time.

The "codex" shows that officially the salt should contain 61 per cent of the oxide, which can be very easily verified by calcining 1 grm. of the product with nitrate of ammonia, and weighing the residual oxide of bismuth, but this test does not throw much light on the composition of a product which, by the simple action of the water used to wash it, loses salicylic acid, and thus becomes richer in oxide of bismuth. It may also contain other salts of bismuth.

It should be further remarked that the two samples we have analysed contain a larger proportion of oxide of bismuth than that corresponding to the salicylic acid found.

To finish our remarks about salicylic acid and the salicylates, we may say that benzoic acid does not absorb bromine under the conditions described; this enables us to separate the two acids very easily.

On the other hand, for the determination of the purity of commercial salicylic acid there only exist, as far as we are aware, qualitative methods based on the colouration of the crystals resulting from the evaporation of the alcoholic solution of an impure material, or on the fact it communicates to its solution in concentrated sulphuric acid.

The Titration of Phenol.—A dilute solution of phenol, treated with bromine, under the same conditions as those described in the case of salicylic acid, also gives only one derivative, the tribromophenol—

$$\underset{94}{C_6H_5.OH} + \underset{6\times80=480}{6Br} = C_6H_2Br_3.OH + 3HBr.$$

From this it results that the same method of estimation can be applied to phenol. The titration of the hypochlorite solution can be made in the same manner, and x being the number of c.c. of this solution used in operating on 20 c.c. of arsenical solution, we know that 1 c.c. corresponds to $\frac{0{\cdot}0279}{x}$ grm. of phenol if we have used Gay-Lussac's solution, or to $\frac{0{\cdot}0313}{x}$ grm. of phenol if we have used the arsenical solution of which 1 litre corresponds to 8 grms. of bromine.

To make the estimation of a sample of phenol, we dissolve 1 grm. in a litre of water. We measure off 25 c.c. of this solution, and add 5 c.c. of 10 per cent KBr, and 10 drops of hydrochloric acid. By means of a graduated burette we run in the hypochlorite solution; the method of working is, as can be seen, identical with that used for the titration of salicylic acid, and the end of the operation is shown in the same manner by the yellow colouration that the excess of bromine gives to the solution; but it is not necessary in this case to shake up with chloroform, as the precipitate of tribromophenol formed becomes agglomerated on shaking, which enables us to observe the colour of the limpid solution between the flocks of precipitate. Knowing the strength of the hypochlorite solution we can easily calculate the richness of the material analysed. In this manner we obtained, with two samples examined, 99·07 and 99·65 per cent of pure phenol.

The titration of a phenic solution at 1/1000th can be similarly carried out on 25 c.c. of this solution, and that of a phenic solution at 1/100th on an equal volume of the same solution previously diluted with ten times its volume of water.

Salicylate of Phenol.—The method of estimation we have just described, which can be used both for salicylic acid and for phenol, necessarily applies also in the case of salol, if we do the titration on the product of saponification of this body. One molecule of salol then uses 10 atoms of bromine (of which 6 are for the phenol and 4 for the salicylic acid).

The titration of the hypochlorite solution being always effected in the same manner, we find that 1 c.c. of this solution is equivalent to $\frac{0{\cdot}0382}{x}$ grm. of salol if the titration is done with Gay-Lussac's solution, and to $\frac{0{\cdot}0428}{x}$ grm. if we use the arsenical solution corresponding to 8 grms. of bromine per litre.

The following is the method used for titrating a sample of salol:—We weigh out 0·25 grm. of salol, and place it in a 100 c.c. flask; we add 2 c.c. of soda-lye at 30° B. and about 20 c.c. of water, then boil for a few minutes. After cooling, the volume is made up to 100 c.c.; we shake well, and then take 10 c.c. of the solution, on which the titration with hypochlorite is done after the addition of 5 c.c. of KBr at $\frac{1}{10}$th, and 15 drops of hydrochloric acid, following the same manner of working as has been described for the estimation of phenol.—*Journ. de Pharm. et de Chim.*, Series 6, vol. xiii., No. 2.

A BIBLIOGRAPHY OF STEEL WORKS ANALYSIS.

PART VII.

By HARRY BREARLEY.

(Continued from p. 40).

CHROMIUM (*continued*).

III. VOLUMETRIC ESTIMATION OF CHROMIUM.

III.*a. With Ferrous Salts.*—

996. BRITTON (*C. N.*, xxi., 266).—Ignite ore with $KClO_3$ and soda-lime, dissolve in dilute HCl, and titrate with $FeSO_4$ and $KMnO_4$.

997. CLARK (*C. N.*, xxiv., 286). — Ignite ore with $NaHO + MgO$, and titrate sulphuric solution with $FeSO_4$ and $K_2Cr_2O_7$.

998. CLARK (*J. S. C. I.*, 1893, 340).—Dissolve steel in HCl, precipitate Cr with Na_3PO_4 and Na_2SO_3, oxidise ignited precipitate with MgO and NaHO. Chromic oxide may also be precipitated as basic sulphite and, if pure, ignited to Cr_2O_3.

999. SCHWARZ (*C. N.*, xlix., 201).—The CrO_3 formed by alkaline fusion is added to excess $FeSO_4$, and titrated with $KMnO_4$. Pouring $FeSO_4$ into K_2CrO_4 may cause error through formation of chromic chromate.

1000. MCKENNA ("Methods of Iron Analysis," p. 121, Pittsburg).—Dissolve in HCl, replace HCl with HNO_3, add $KClO_3$, boil to decompose it, and titrate CrO_3 with permanganate. Powalleck (*C. N.*, li., 83) also oxidises and titrates in this way.

1001. GALBRAITH (*C. N.*, xxxv., 151).—Dissolve steel in dilute H_2SO_4, oxidise with $KMnO_4$, and titrate filtered solution with $FeSO_4$, &c.

1002. PETERSON (*C. N.*, l., 210).—As 1001; add $KMnO_4$ to the H_2SO_4 solution until MnO_2 is plentifully formed.

1003. VIGNAL (*C. N.*, liii., 195).—A good account of the process depending on oxidation with permanganate. Dissolve iron by preference in HNO_3. The formation of MnO_2 roughly indicates the amount of Cr present.

1004. Arnold (*C. N.*, lxxi., 292).—In strong H_2SO_4 solutions, oxidation to CrO_3 with permanganate is impossible.

1005. Galbraith (*J. I. S. I.*, 1893, i., 146).—Presence of Fe favours accuracy of process 1001. Modifies process by adding NaHO, filtering off MnO_2, $Fe_2(HO)_6$, &c., and titrating the filtrate.

1006. Barba (*J. I. S. I.*, 1893, ii., 536).—Condemns process 1005. Dissolve in HNO_3, oxidise, precipitate Mn, Fe, &c., with AmHO, but re-dissolve the Fe in H_2SO_4, and titrate the filtrate.

1007. Brearley (*C. N.*, lxxvii., 131, 187, and 216).—Manganous salts precipitated with NaHO in presence of CrO_3 partly reduce it. Process 1005 subject to error on this account.

1008. Wahlberg (*J. I. S. I.*, 1889, i., 398).—Dissolve in HNO_3, ignite dried residue with Na_2CO_3, $KClO_3$, and MgO, and titrate the filtered CrO_3.

1009. Dittmar ("Quant. Chem. Anal.," p. 128).—Fuse chromite with borax-glass + $NaKCO_3$, and titrate the acid extract. Instructions for complete analysis of ore.

1010. Stead (*J. I. S. I.*, 1893, i., 153).—Examination of 1001. Avoid filtration of MnO_2 by dissolving in HCl and boiling off Cl. Or precipitate from ferrous solution as phosphate, ignite with $NaKCO_3$ + MgO, and titrate CrO_3. $BaCO_3$ does not precipitate Cr_2O_3 completely from ferrous solutions. Precautions against V. Chromeisen also oxidised by the above (tribasic) reagent, and extract titrated. Distribution of Cr in British irons.

1011. Leffler (*C. N.*, lxxvii., 156).—MnO_2 is soluble in strong H_2SO_4. Such a solution can oxidise $FeSO_4$, and may lead to error in processes like 1001.

1012. J. T. (*C. N.*, lxxix., 158).—When chromeisen is oxidised in the dry way and the frit dissolved in acid, some very fine portions of the alloy, having escaped oxidation, will exert a reducing action on the CrO_3.

1013. Schneider (*J. I. S. I.*, 1892, ii., 515).—Oxidise nitro-sulphuric solution of the steel with PbO_2; decompose any permanganate formed by making alkaline and boiling. Titrate with $FeSO_4$.

1014. Harvey (*C. N.*, xlvii., 86).—Heat CrO_3 compound with HCl + $SnCl_2$, add Fe_2Cl_6, and determine FeO with $K_2Cr_2O_7$.

1015. Schneider (*J. I. S. I.*, 1886, 399). — Dissolve chromeisen in H_2SO_4, oxidise solution of dried residue with Br, precipitate Fe with AmHO, and titrate the filtrate.

1016. Spüller and Kalmann (*J. I. S. I.*, 1893, ii., 537). —Fuse chromeisen with soda peroxide, decompose excess by passing CO_2, and titrate the acidulated filtrate.

1017. Spüller and Brenner (*J. I. S. I.*, 1897, i., 570).—Modified process for FeCr. Acid solution of steel dried, fuse as FeCr, and CrO_3 estimated iodometrically.

1018. Saniter (*J. I. S. I.*, 1895, ii., 153).—Fuse FeCr with mixture of Na and Ba peroxides, and boil acidified solution with permanganate according to Stead's modification (1010) of 1001.

1019. Rideal and Rosenblum (*J. S. C. I.*, 1895, 1017).—Severe criticism of 1018. Ni from fusion crucible interferes with the ferrocyanide indicator. Mn, Ni, and Fe separated before titration. The uses of Na_2O_2 in chrome-iron and steel analysis.

1020. Saniter (*J. S. C. I.*, 1896, 155).—Discusses the criticisms of 1019.

1021. Carnot and Goutal (*J. C. S.*, lxxii., ii., 521).—Treat with Cu solution (993), fuse residue with Na_2O_2, and titrate CrO_3.

1022. Kosmann (*J. I. S. I.*, 1889, ii., 479).—Oxidise the Fe solution with alkaline H_2O_2, and titrate a filtered fraction with $FeSO_4$.

III.*b. Iodometric Estimation of Chromium.*—

1023. Waller (*J. S. C. I.*, 1896, 436).—Decompose ore with Na_2O_2, and titrate CrO_3 with $Na_2S_2O_3$ and KI.

1024. O'Neill (*C. N.*, v., 199). — Fuse ore with $KHSO_4$, precipitate with Na_2CO_3, fuse with Na_2CO_3 + $KClO_3$, and titrate CrO_3 with $Na_2S_2O_3$, using KI and starch as spot indicator.

1025. Zulkowski (*C. N.*, xix., 238).—Add KI to an HCl solution of CrO_3, and titrate liberated I.

1026. Sell (*C. N.*, xxxix., 131).—Fuse chromite with bisulphate and soda fluoride, oxidise with $KMnO_4$, add Na_2CO_3 and alcohol, and estimate CrO_3 with KI.

1027. Sell (*C. N.*, liv., 299).—Oxidise with H_2O_2 in alkaline solution, and titrate CrO_3. Al and Zn are without influence; Fe (filtered off) causes low results.

1028. Browning (*J. C. S.*, lxxii., ii., 73).—Add excess As_2O_3 and $NaHCO_3$ to CrO_3 solution, and titrate with I. Ferric salts may be present. Also, Namias (*J. C. S.*, lxii., 1374) and Bialobrzeski (*J. C. S.*, lxxiv., ii., 184.—In like manner in the presence of acetates and acetic acid.

1029. Donath (*J. I. S. I.*, 1894, ii., 493).—Pour ferric solution into alkaline permanganate, and estimate the iodine liberated by the CrO_3. $FeSO_4$ not suitable for estimating small amounts of chromic acid.

III.*c. Miscellaneous Volumetric Processes.*—

1030. Davy (*C. N.*, iii., 274) and Rube (*C. N.*, xii., 82).—Titrate acid solution of CrO_3 with ferrocyanide, using Fe_2Cl_6 spot indicator.

1031. Donath (*C. N.*, xliii., 253).—The neutral Cr_2O_3 solution is run into hot alkaline standard $KMnO_4$ until a yellow colour is obtained. Fe and Al do not interfere; Mn does (see 100).

1032. Giorgis (*J. C. S.*, lxiv., ii., 554).—Oxidise alkaline ferric solution with $KMnO_4$, destroy excess with H_2O_2, reduce filtered CrO_3, and run into $KMnO_4$ as in 1031.

1033. Giorgis (*J. C. S.*, lxxii., ii., 350).—Add standard $KMnO_4$ to Cr_2O_3 solution, boil, and titrate excess $KMnO_4$ with N/20 $Cr_2(SO_4)_3$ solution.

1034. Carnot (*J. I. S. I.*, 1889, i., 399) and Perrault (*J. I. S. I.*, 1893, i., 413).—Oxidise to CrO_3 with AmHO + H_2O_2, boil off excess, and titrate with H_2O_2 in acid solution.

1035. Berthelot (*J. C. S.*, lvi., 350 and 468).—The H_2O_2 + CrO_3 reaction varies with the mode of admixture, temperature, and concentration.

1036. Jean and Pellet (*C. N.*, xxxv., 213).—Decompose ore by fusion. To CrO_3 add baryta-water and CO_2 to precipitate excess thereof. The free alkali equivalent to the CrO_3 is titrated with H_2SO_4.

1037. Ruoss (*J. C. S.*, lxxiv., ii., 644).—Add lead salt to CrO_3 solution, and estimate the excess in a fraction of the filtrate.

1038. Soltsein (*J. C. S.*, lx., 118).—CrO_3 titrated with $BaCl_2$, using hæmatoxylin or logwood indicator.

1039. Purgotti (*J. C. S.*, lxxii., ii., 349).—Acidified hydrazine sulphate acts quantitatively with $K_2Cr_2O_7$, liberating N. The N is measured at normal temperature and pressure. Similar process for Cu.

1040. Baumann (*C. N.*, lxvi., 181, &c.).—In acid solutions, H_2O_2 oxidises CrO_3 to perchromic acid and then reduces it to Cr_2O_3. Liberated O gasometrically estimated. CrO_3 formed by H_2O_2 in alkaline liquids. These facts applied extensively to quantitative analysis.

1041. Hillebrand (*C. N.*, lxxviii., 227).—Traces of Cr in rocks, ores, &c., estimated by comparing as mono chromate with standard solutions.

1042. Neumann (*J. C. S.*, lxviii., ii., 64).—By titrating neutral Cr_2O_3 solution with soda sulphide.

(To be continued).

THE DETECTION OF METHYL ALCOHOL IN MIXTURES.*

By S. P. MULLIKEN and HEYWARD SCUDDER.

In a recent article by E. Jandrier (*Ann. Chim. Anal. App.*, iv., 156; *Centrbl.*, 1899, i., 1296, Abstract), it is stated that a test for methyl alcohol described by us in an earlier number of the *American Chemical Journal* (xxi., 266), and based on the oxidation of the alcohol to formic aldehyde, followed by condensation of the latter to a coloured derivative of resorcine, is unreliable, because it is also given by acrolein, and is interfered with by the presence of furfurol. To remedy these defects in our method Jandrier recommends that gallic acid be employed instead of resorcine as the reagent for formic aldehyde, he having found in an earlier investigation (Barbier and Jandrier, *Ann. Chim. Anal. App.*, i. 325; *Analyst*, xxi., 295, Abstract), that the colour reaction obtained by the use of gallic acid is much more delicate and less likely to be obscured by colourations occasioned by the simultaneous presence of other aldehydes.

A careful examination by the authors of this modification of their test soon proved that its use for the purpose proposed is entirely inadmissible, and this despite the fact that gallic acid is actually, as claimed, a better reagent for the detection of formic aldehyde than is resorcine! The explanation of this paradox will be made apparent by a consideration of certain facts that have lately come to our knowledge while studying the partial oxidation by hot copper oxide of a considerable number of organic compounds.

The means chosen for oxidising methyl alcohol to formic aldehyde detailed in our first paper, was the very simple one of plunging a short, closely-wound spiral of light copper wire, previously heated to redness, and superficially oxidised, into the solution to be tested. Special emphasis was placed on the condition that: "A concentrated spirit should always be diluted with at least three or four volumes of water before oxidation." It was also particularly noted that 1 drop of 0·5 per cent resorcine solution was the quantity of reagent that should be added for every 3 c.c. of all solutions originally containing more than 0·1 per cent of methyl alcohol. These minute specifications were necessary, partly because it had been found that absolute ethyl alcohol, when directly oxidised without previous dilution, would, if afterwards largely diluted with water, give a very faint colour reaction resembling that caused by formic aldehyde. This colour was, however, noticed only when the weight of resorcine added to a given volume of solution was many times less than that usually employed, and it first made its appearance after several hours instead of within a few minutes, as usually happened with solutions that really contained methyl alcohol. The conditions necessary for the production of this colour from ethyl alcohol were so unusual, its intensity was so slight, and its course so obscure, that no account of it was included in our first paper. A more suggestive observation was made by us at the same time with reference to the use of caseine, of which we wrote (*loc. cit.*):—"Caseine is not a suitable reagent for methyl alcohol tests, because the oxidation-products of ethyl alcohol yield with it the same blue colour as formic aldehyde; though singularly enough solutions of pure acetaldehyde do not give this result."

After the gallic acid reaction for formic aldehyde had been brought to our attention, we endeavoured to verify the advantages claimed for it in the detection of methyl alcohol. For our purpose it was found best to employ the reagent very nearly in the manner recommended by Istrati.† 0·2 c.c. of a saturated solution of gallic acid in pure ethyl alcohol was mixed with a few drops of the oxidised alcoholic solution to be tested, diluted to 2 c.c., and the mixture carefully run down the side of an inclined test-tube containing a few c.c. of concentrated sulphuric acid. At the line of contact between the two liquids a yellow zone, almost immediately turning green, makes its appearance, if the solution contains formic aldehyde. Above and below the green zone, blue rings then rapidly develope. If other substances which give colour reactions are also present, the upper layer will vary in colour, but the green and the lower blue ring will still appear beneath. The colours are pure and characteristic, and are not obscured by the presence of other aldehydes. Having familiarised ourselves with these phenomena, it was with considerable surprise that we found the oxidation-products obtained in the usual way from the purest procurable ethyl, propyl, isopropyl, secondary butyl, tertiary butyl, and normal butyl alcohols, ethylene glycol, glycerin, acetaldehyde, paraldehyde, ethyl ether, acetone, pinacone, and acetic acid, all gave distinct green and blue rings with gallic acid.

The total failure of the gallic acid test to distinguish the substances enumerated from methyl alcohol, as well as the anomalous results noted in our earlier experiments with the oxidation-products from concentrated ethyl alcohol when tested with a trace of resorcine or with caseine, are susceptible of only two simple explanations. Either all the apparently pure compounds oxidised must have contained methyl alcohol or methyl derivatives as impurities, or the list of compounds which may give traces of formic aldehyde, upon oxidation with copper oxide, is a very much longer one than has hitherto been suspected. The hypothesis that methyl alcohol in small quantities may be formed along with ethyl alcohol in alcoholic fermentations is perhaps not unworthy of a more thorough investigation than it has received. Trillat claims to have detected traces of it in some genuine brandies. But it is, nevertheless, highly improbable that all the cases which have been noted by us in which formic aldehyde reactions were obtained from the oxidation-products of the many presumably pure substances taken for our experiments can be explained in this way, and we inclined strongly, from the first, to the acceptance of the second explanation, the probability of which has since become a certainty in consequence of a supplementary quantitative investigation conducted by one of the authors, with the assistance of Messrs. Brown and French, an account of which will follow later in the *American Chemical Journal*.

The logical justification for adhering to the use of resorcine in the test for methyl alcohol lies, then, in the presumption that no common organic compound that could occur in such solutions as are provided for by the method (with the exception of methyl esters or ethers), will furnish enough formic aldehyde, or other substance, exhibiting a similar behaviour, when treated with due regard to the detailed directions, to give a rose-red ring and flocks. This presumption is a sufficiently well-founded one, when all the precautions that will be given further on in this paper are observed. The gallic acid and caseine tests, on the contrary, must be rejected, because they are so delicate that formic aldehyde may be detected by their use in nearly any organic solution that has been partially oxidised by means of a copper spiral.

Since the publication of our first paper we have had occasion to apply the resorcine test for methyl alcohol to a great variety of mixtures, and as a consequence of the fuller knowledge of the imperfections of the method thus gained, we are now in a position to suggest certain improvements in the original procedure, which, we believe, will considerably augment its practical usefulness. Analysts are, as a rule, too prone to ignore the fact, that the *absolute*

* Contribution from the Chemical Laboratory of the Massachusetts Institute of Technology. From the *American Chemical Journal*, xxiv., No. 5.

† *Analyst*, 1898, xxiii., 230, Abstract, Istrati's original memoir on the colour reactions between aldehydes and phenols (*Buletinul Societatei de Sciinte, Bucuresci*, vii., [2]. 163—170), which was made accessible to us through the kindness of M. Jandrier, forms a continuation of the earlier studies of Barbier and Jandrier. Another still earlier research on the value of phenols for the detection of aldehydes, mention of which was also unintentionally omitted in our first paper, is by Nickel (*Fres. Zeit.*, 1889, 249).

identification of any compound by the use of some single specific reaction is an unattainable end when really unknown mixtures are dealt with. Specific qualitative tests are of great value when judiciously employed; but each new mixture must be considered by itself, and whenever there is reason to suspect the presence of substances which may interfere with the test selected, means for their removal must first be devised. The list of compounds whose presence may mask the colour reactions given by phenols with formic aldehyde is a long one, and includes bodies which are likely to be met with in such important mixtures as the commercial tinctures, extracts, varnishes, alcoholic beverages, and solvents. While it would be feasible to formulate quite definite rules of procedure for the detection of methyl alcohol in any limited group of mixtures, it will be more profitable here to make certain general suggestions that will be of service in the solution of a variety of special problems.

The following precautions should always be observed:

(*a*). Use for the test only that part of any mixture that can be completely distilled at a temperature between 50° and 100°, and which, after distillation, gives a clear colourless solution when shaken with two or three volumes of water.

(*b*). Make a blank experiment, before oxidation with the copper spiral, by pouring 2 c.c. of a clear aqueous solution of the distillate of proper boiling-point, to which 1 drop of 0·5 per cent resorcine solution has been added, so as to form a layer upon concentrated sulphuric acid in a test-tube. If a precipitate or a coloured ring make its appearance, the solution requires further preliminary treatment.

(*c*). Do not test without preliminary treatment any solution that is known or suspected to contain phenols, alkaloids, or organic bases.

The reasons for these precautions are obvious. Many organic compounds give colourations with sulphuric acid alone; others, including nearly all aldehydes and many bases, condense easily with resorcine under the conditions of the test to insoluble or intensely coloured products. Other phenols besides resorcine, and many bases, will, if present, react with any formic aldehyde that may arise by oxidation with the wire, and thus prevent or obscure the appearance of the characteristic rose-red ring.

Methyl alcohol may be separated easily from most colouring-matters, oils, resins, sugars, glycerin, and glycols, by a simple distillation; from phenols and acids by distillation from an aqueous solution containing caustic alkali; from bases by distillation from aqueous solutions strongly acidified with a dilute mineral acid. When small quantities of methyl alcohol are extracted from insoluble organic mixtures by shaking out with water, it is to be remembered that the methyl alcohol will tend to concentrate in the first part of the aqueous distillates obtained from such solutions, and that various aldehydes, phenols, and bases may pass over with it on account of their volatility with steam, and will have to be removed afterwards.

When the preliminary blank experiment (*b*) gives a colouration or precipitate, and the solution gives aldehydic reactions with ammoniacal silver nitrate, and with Schiff's rosaniline-aldehyde reagent, take 12 c.c. of the alcoholic distillate, which, if concentrated, must first have been diluted so as to contain at least 75 per cent of water; place in a small firmly stoppered bottle with 3 grms. of resorcine, and 1 c.c. strong sulphuric acid, and heat for two hours in a water-bath at 70—80°. Cool, dilute the solution to 50 c.c. with water, distil off 5 c.c., and test the distillate for methyl alcohol in the usual manner. Large quantities of aldehydes may be held back by resorcine in this way, though, when the mixture consists mainly of aldehydes, more resorcine and longer heating will be required. An analogous method for accomplishing this same result, which employs aniline and phosphoric acid instead of resorcine and sulphuric acid, was proposed by Allen and Chattaway (*Analyst*, xvi., 102), for use in the analysis of whiskies. We have used both these methods with success upon mixtures containing as high as 50 per cent of furfurol and other aldehydes, thus meeting the chief objection which Jandrier has raised against our procedure.

A more difficult, but practically far more important, problem than that of removing aldehydes from the original mixtures, had to be faced, when we sought to discover some simple means for taking away the acetaldehyde which is always formed together with formic aldehyde when mixtures containing both ethyl and methyl alcohols are oxidised. The most that could be previously claimed for the test with resorcine in such mixtures was that:—"One part of methyl alcohol may be detected without great difficulty in the presence of five parts of ethyl alcohol." A simple and fairly satisfactory way out of this difficulty was, however, found.

Acetaldehyde is easily and completely expelled from aqueous solutions by persistent boiling in a vessel provided with some condensing arrangement that will prevent too rapid loss of water vapour. Dilute solutions of formic aldehyde, on the contrary, lose their aldehyde very slowly under this treatment, it being firmly held, partly in a polymerised condition, by the hot water. Such solutions will, however, lose all their formic aldehyde when the distillation is rapid and is pushed too far. The improved test for methyl alcohol now to be described takes advantage of these facts, and as the procedure not only removes acetaldehyde, but also traces of many other higher boiling substances that exert an injurious influence on the final colour reaction, its employment is generally to be preferred to the somewhat simpler method earlier described by us.

When entirely unknown mixtures are under examination they must, of course, always receive in addition a suitable preliminary treatment, though it has been found that a previous digestion with resorcine and acid for the removal of aldehydes, will seldom be required when these substances are not present in larger quantities than are usually found in the distillates from fermented and distilled liquors.

Unless the mixture to be examined, after receiving what ever preliminary treatment may have been found necessary, already contains much water, dilute 2 c.c. with water until it measures 6 c.c. Treat with the oxidised copper spiral as elsewhere described, six times, cooling the tube with running water after each treatment. Next fit the test-tube, which should have a length of 6—7 inches, with a doubly perforated rubber stopper. One perforation of the stopper is to be fitted with a piece of glass tubing drawn out to a *very fine capillary* whose end is forced down so as nearly to touch the bottom of the tube. Let the wide end of the tube, on which the capillary has been drawn, project an inch above the stopper, and attach to the projecting end a bit of rubber connector which can be closed by a small screw clamp. Fit the second perforation of the stopper with a bit of glass tubing which is placed in connection with a good water-suction pump capable of giving a vacuum of about 20 m.m. Support the test-tube by a clamp, so that it will be two-thirds immersed in water in a beaker maintained at 25—30°. Partially close the screw clamp, and apply gentle suction for a few moments so as thoroughly to saturate the liquid with air. Then screw the clamp tight, and apply suction with the full power of the pump. A rapid stream of gas bubbles, at first principally air, but later consisting of acetaldehyde, alcohol, and water vapour, will rise from the fine capillary point, the liquid boiling under the diminished pressure. Continue this distillation *in vacuo* until just one-half of the liquid has evaporated. This requires about ten minutes. By judiciously regulating the action of the pump, and in some cases admitting a very little air through the capillary, the boiling, though accompanied by some frothing, is easily controlled, and bumping prevented.*

* An experienced operator may often obtain equally satisfactory results by simply boiling down the oxidised aqueous solution in an open test-tube until the moment when the odour of acetaldehyde disappears. The method of boiling down *in vacuo* is, however, in general, much more reliable.

Next add 1 drop of a solution, containing 1 part of resorcine in 200 parts of water to the residual solution, and pour it cautiously into a second tube held in an inclined position in such a way that the two liquids shall not mix. Allow it to stand three minutes; then, holding the tube by its upper end, sway it slowly from side to side in such a manner as to produce a very gentle rotary motion between the two layers. This operation must be persisted in, if necessary, for a minute or more, using a piece of white paper for a background; but must be conducted so gently that only a very gradual and partial mixing of the water and acid shall be caused. Nearly half of the acid should remain as a distinct unmixed layer at the end. When methyl alcohol is present, the shaking causes the separation of more or less voluminous flocks of a very characteristic rose-red colour. The appearance of coloured zones or flocks of other hues, even when tinged with red, or of a rose-red solution without the flocks, should never be considered proof of the presence of methyl alcohol. However, if the flocks are reddish-brown, or if the upper layer has a pronounced red colour, it is often well to repeat the test. Too hasty or careless mixing of the aqueous and acid layers spoils the reaction, which will also fail or give unsatisfactory results if the evaporation *in vacuo* is too long continued, or if it is stopped before the complete removal of all acetaldehyde.

The delicacy of the test as here described is sufficient to permit the detection of 1 part of methyl alcohol in 2000 parts of the solution as prepared for oxidation. If, in a solution of moderate concentration, the proportion of ethyl to methyl alcohol does not exceed 100 parts to 3, entirely satisfactory tests for the latter are obtained without difficulty. When the ratio between the alcohols is 100 : 2, the test is occasionally successful, but cannot be depended upon.

Besides methyl alcohol, the only substances which are known to give the same reaction with the improved resorcine test are the methyl esters and ethers (including methylal), and secondary and butyl alcohols (compounds which are rarely met with except in quantities too small to be readily detected). Acetone and dimethylethyl carbinol give red rings at first, but on shaking, the aqueous layer becomes red-brown without yielding the rose-coloured flocks.

As compared with other qualitative tests for methyl alcohol known at the time of writing, the one just presented is without question the simplest, the most rapid, and the most convenient. Its delicacy, while not great, is sufficient for most practical purposes, and its most serious imperfections are so well defined as to be rendered comparatively harmless.

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Ordinary Meeting, January 17th, 1901.

Professor THORPE, C.B., F.R.S., President, in the Chair.

MESSRS. E. F. Hudson, H. A. Auden, and A. H. Mitchell were formally admitted Fellows of the Society.

The following certificates were read for the first time:—Percival James Burgess, Singapore; Raymond Dubois, Rutherglen, Victoria; Oscar Loewenthal, Mill Hill Park, London, W.; Walter Stevens Crocker, 25, Upper Parliament Street, Liverpool; Herbert Ackerman Tozer, 113, Stepney green, London, E.

The following letter has been sent, at the direction of the Council, to Professor Markownikoff of the University of Moscow, a Foreign Member of the Society, on the occasion of the commemoration of the fortieth year of his Doctorate:—

DEAR SIR,—At the last meeting of the Council of the Chemical Society I had the pleasure of submitting your letter of December 8th, concerning the proposed celebration in honour of Prof. Dr. Wladimir Markownikoff. I am instructed by the Council to inform you that it will not be possible for any of our Fellows to be present personally on February 25th, but I am to ask you to be so good as to convey to Prof. Markownikoff the hearty congratulations of our Society, and to express the wish that he may be spared to carry on his valuable and important investigations for many more years. We rejoice that your distinguished countryman's name appears in our list of Foreign Members, and I beg you to convey to him the assurance that his long devotion to that science which he has done so much to advance by his researches is most highly appreciated by English chemists.

Yours obediently,

RAPHAEL MELDOLA,
Foreign Secretary.

Dr. H. DECKER.

Of the following papers, those marked * were read:—

*1. "*The Preparation of Iodic Acid.*" By A. SCOTT and W. ARBUCKLE.

The usual method of preparing iodic acid by gently boiling iodine with nitric acid in a flask with a long neck, is tedious when any quantity is required, and liable to great loss of iodine unless the source of heat is very carefully regulated. By using, first the ordinary form, and later a modified form, of Soxhlet's fat extraction apparatus to contain the iodine, almost theoretical yields of iodic acid were obtained after a very short treatment with the boiling nitric acid. The liability, however, of the syphon-tube to become choked with crystals of iodic acid led to the abandonment of this type of apparatus. After many trials with various forms of apparatus, the authors recommend the use of a round-bottomed flask having a ground-in neck carrying two tubes, to one of which is sealed a reflux condenser, and through the other is fitted a tube by means of which a current of oxygen is passed through the boiling liquid. With this apparatus *finely powdered* iodine boiled with ten times its weight of fuming nitric acid may be completely oxidised in twenty to thirty minutes.

*2. "*Note on Isomeric Change and Meta-substitution in Benzenoid Amines.*" By A. LAPWORTH.

The rules deduced from the two simplest change forms (*Trans.*, 1898, lxxiii., 457) depend on the assumption made implicitly throughout the paper, that only one group can "migrate" along any chain of atoms at any instant; that is, that exchange of groups is, as a rule, the result of the successive migration of the two groups in reverse directions. This view appears in general to be well founded, and it is easily demonstrated that if it holds true, the rules deduced are necessarily correct, the second being used where the valency of an atom alters. It is of no consequence whatever how the migration is effected, so far as the applicability of the rules is concerned.

Although in applying the rules it is sometimes convenient to assign successive positions of attachment of a labile group in its migration, it is not imagined that these are actually occupied, at least in the ordinary sense of the term. It may be supposed, for example, that the group is handed on in a still dissociated state from its initial to its final position, the others merely representing the possible places of attachment.

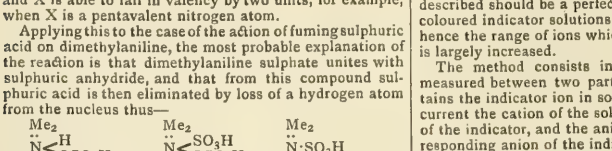
The author has advanced the view that *meta*-substitution is the result of elimination of a hydrogen atom in the benzenoid nucleus (necessarily from the *meta*-position) with a group in the complex formed by union of the side chain with the acting agent. Armstrong has recently used a similar conception in explaining the formation of chloracetanilides from phenylacetylchloramines; in the author's opinion, this would lead to the production of the *meta*-derivative, instead of, as is the case, the *ortho*- and *para*-derivatives (compare *Trans.*, 1900, lxxvii., 1051).

In alluding to the formation of *meta*-sulphonic acids from benzenoid amines (*loc. cit.*, p. 457), the author suggested that it was the result of the migration of the $-SO_3H$ group in aniline sulphates; this view must be rejected as impossible, as the necessary grouping is not present. The statement that *meta*-derivatives are formed when the labile group M is separated from the benzene ring by two atoms only holds true when the grouping—

is present or can be formed as an intermediate step. M will migrate to the *meta*-position when separated by one atom only, from the nucleus if the intermediate compound is of the type—

and X is able to fall in valency by two units, for example, when X is a pentavalent nitrogen atom.

Applying this to the case of the action of fuming sulphuric acid on dimethylaniline, the most probable explanation of the reaction is that dimethylaniline sulphate unites with sulphuric anhydride, and that from this compound sulphuric acid is then eliminated by loss of a hydrogen atom from the nucleus thus—



The latter substance must yield the meta-sulphonic acid if the sulpho-group then migrates, assuming, as usual, that the other atoms retain their positions until this migration has ended. Or, expressing it in terms of the author's rules, as the sulpho-group migrates the valency of the nitrogen must fall, since it cannot become attached to the nucleus by a treble binding; the nearest possible position of attachment for the labile group is, therefore the β-position; hence, as the valencies of the carbon atoms remain constant, the next position must be imagined to be reached by an $\alpha\gamma$-change. This process can also be followed by using Thiele's rule, but, in this case, it must be assumed that sulphuric acid is added in one way and eliminated in another, and as for this purpose it must be supposed that before addition it breaks up into HO and $\cdot SO_3H$ instead of into H and OSO_3H, the objection to this hypothesis is obvious,

3. "*The Preparation of Esters from other Esters of the same Acid.*" By T. S. PATTERSON and C. DICKINSON.

Experiments were described which had for their object the preparation of methyl ethyl tartrate. A substance was obtained having the observed rotation $+11\cdot14°$ at 18° (l=200 m.m.), which probably consisted chiefly of the compound sought. It showed no tendency to crystallise, and as no method of purification, other than crystallisation, was likely to be suitable, these attempts to obtain a pure compound were abandoned. They had shown, however, that ethyl tartrate is largely converted into methyl tartrate by the action of methyl alcohol and hydrochloric acid. Experiments were then described showing that pure ethyl tartrate can be obtained from methyl tartrate and pure methyl tartrate from ethyl tartrate, by Fischer's method; hence it is probable that any other ester may be prepared by an analogous process; under certain circumstances this might prove useful.

Finally, determinations of the rotation of methyl tartrate at temperatures between 20° and 100° were given.

4. "*Tecomin: a Colouring-matter derived from 'Bignonia tecoma.'*" By T. H. LEE.

The new colouring-matter is a yellow crystalline substance soluble in alcohol with an orange colour, insoluble or very slightly soluble in water; the solution becomes rose-red with alkalis and clear yellow with acids; 2 c.c. N/100 alkali or acid causes the colour change; it is not affected by any but the strong mineral acids, but the presence of organic acids renders the end-reaction indistinct. The wood contains a reddish brown resin soluble in alcohol, from which it is difficult to free the tecomin; also a deep brown colouring-matter which dissolves in aqueous alkalis and is precipitated by acids. It is used locally as a dye for cotton and as a stain for wood.

5. "*A New Method for the Measurement of Ionic Velocities in Aqueous Solution.*" By B. D. STEELE, B.Sc.

The author described a new method for the direct measurement of ionic velocities in aqueous solution. Masson (*Phil. Trans.*, 1899, cxcii., A, 331), has succeeded in obtaining satisfactory measurements in gelatin, and for a few ions; Whetham (*Phil. Trans.*, 1893, clxxxiv., A, 337) has made measurements in water. The method now described should be a perfectly general one, as the use of coloured indicator solutions is no longer necessary, and hence the range of ions which may be used as indicators is largely increased.

The method consists in enclosing the liquid to be measured between two partitions of gelatin, which contains the indicator ion in solution; on the passage of the current the cation of the solution is followed by the cation of the indicator, and the anion of the solution by the corresponding anion of the indicator. It is necessary in all cases that these indicator ions should move more slowly than the measured ion.

The position of the boundary between the two solutions is easily seen, on account of the difference in refraction, and the motion is measured by means of a cathetometer. If the above-mentioned condition is fulfilled, the relative velocity of the boundary is not influenced by changing the indicators; thus ($CuSO_4$ and K_2CrO_4), $CuSO_4$ and $NaC_2H_3O_2$), and ($CdSO_4$ and $NaC_2H_3O_2$) all gave the same value for the transport number of $MgSO_4$.

The absolute velocity of a few ions has also been calculated and compared with the velocities found by Kohlrausch, and a very fair agreement is shown to exist between the two sets of measurements.

6. "*Metal-ammonia Compounds in Aqueous Solution.* Part II. *The Absorptive Powers of Dilute Solutions of Salts of the Alkali Metals.*" By H. M. DAWSON and J. MCCRAE.

The influence exerted by the addition of salts of the alkali metals on the distribution of ammonia between water and chloroform at 20° has been investigated. It has been found that so long as the ammonia concentration in the aqueous phase is less than 0·5 normal, the alteration of the distribution coefficient is proportional to the salt concentration; that is, the expression $\frac{k-k'}{n}$ is constant; where k is the distribution coefficient with pure water (26·28), and k' is the observed distribution coefficient with salt solution of normality n. This constant it is proposed to call the "equivalent alteration of the distribution coefficient."

The alteration for each salt is composed additively of two values, one dependent upon the cation, the other upon the anion. Since, according to the views of Abegg and Bodländer, "ammonia-complex formation takes place only with the cation, the differences in the values of the alteration for salts of one metal express the differences in the physical actions of the anions; but differences in the values for salts containing the same anion do not measure the differences in the physical actions of the cations because of the complicating influence of complex formation. The lithium salts show the greatest tendency to form ammonia addition compounds, ammonium salts show it to a less degree, whilst for sodium salts it is probably very small, but greater than for potassium salts.

When the ammonia concentration is greater than 0·5 normal, irregularities occur, and it has been found that

for increasing salt concentration and constant ammonia concentration the value of $\frac{k-k'}{n}$ decreases, whilst for constant salt concentration and increasing ammonia concentration it increases.

Non-electrolytes (urea and cane-sugar) also considerably affect the distribution coefficient, so that Dalton's law is not obeyed.

These results indicate that the solvent power of water is changed to a varying extent by the different ions. The intrinsic property of the ion which is the cause of this difference is not deducible from the ionic theory as it stands at present.

7. "*The Amide, Anilide, and Toluidides (Ortho- and Para-) of Glyceric Acid.*" By P. F. Frankland, F. M. Wharton, and H. Aston.

These compounds have been prepared by the authors with the object of investigating the influence on the rotation produced by replacing the alkoxyl group by the amido-group and its substituted derivatives. After a review of the limited number of cases at present available for ascertaining these relations, the authors pointed out that so far it was observable that if in an homologous series of ethereal salts the rotation is raised by successive additions of CH_2, then the amide has a similar but still higher rotation than the ethereal salts, but that if the successive additions of CH_2 lead to diminished rotation, then the corresponding amide has a lower rotation than the ethereal salts. The first of these relations is exhibited by the derivatives of tartaric, malic, and glyceric acids, whilst the only hitherto known example of the second is furnished by the corresponding derivatives of mandelic acid.

The result of substituting in the amido-group appears in all cases to be an increase in the rotatory effect of the latter. In the case of malic acid, the anilide has a greater molecular rotation than the amide, the *o*-toluidide greater still, and the *p*-toluidide the greatest of all. In the case of glyceric acid, on the other hand, although the anilide has a greater molecular rotation than the amide, the rotation of the *p*-toluidide is less than that of the anilide, and the rotation of the *o*-toluidide is about the same as that of the amide.

The amido-compounds prepared by the authors appear to be the only ones which have hitherto had their rotation determined in the liquid state; in the case of the *o*-toluidide, however, this could unfortunately not be effected, as this, on fusion, at once acquired a strong colour. In consequence of this, the rotation of all the compounds in question was determined also in methyl alcohol solution.

The corresponding compounds of inactive glyceric acid were also prepared, and their melting-points compared with those of the active substances.

Anniversary Dinner.

It has been decided by the Council to arrange for a Dinner of the Fellows of the Society and their friends on Wednesday, March 27th, 1901, the day preceding that fixed for the Annual General Meeting. Further particulars will shortly be announced.

PHYSICAL SOCIETY.

Ordinary Meeting, January 25th, 1901.

Mr. T. H. Blakesley, Vice-President, in the Chair.

It was decided to forward a vote of condolence to His Majesty the King.

The ordinary business of the meeting was postponed.

East London Technical College, People's Palace, E.—Dr. R. A. Lehfeldt will read a paper on "Electro-Chemistry" before the Chemical and Electrical Societies of this Institution, on Wednesday, February 13th, at 6 p.m. Visitors are invited.

CORRESPONDENCE.

THE BRITISH FOOD CONTROL.

To the Editor of the Chemical News.

Sir,—The *British Food Journal*, received on January 26th, contains a list of twelve gentlemen composing the Consulting Scientific Staff of the Austrian Chemical Control.

In the Austrian *Chemiker Zeitung*, No. 2, 1901, published on January 15th, there are two paragraphs relating to the Control. No. 1: "In consequence of well-known events, Dr. Mansfeld (the Secretary) has, on December 10th, 1900, broken off his connection with the European Federation of Permanent Chemical Control, and has dissolved the Austrian Chemical Control." And No. 2: A letter dated January 5th, 1901, signed by Dr. F. W. Dafert, Dr. Max Gruber, T. F. Hanausek, H. Kratschmer, E. Ludwig, Prof. E. Meissl, L. Roesler, F. Strohmer, and A. R. von Vogl, stating that their names have been used in connection with the Chemical Control without their knowledge and consent.

The English organ continues to use the names of these gentlemen in spite of their protest.—I am, &c.,

Hydroxyl.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Note.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, del'Académie des Sciences. Vol. cxxxii., No. 1, January 7, 1901.

A New Phosphide of Tungsten.—Ed. Defaçoz.—When copper phosphide is heated with tungsten biphosphide to a temperature of about 1200°, a new crystallised phosphide is obtained. This substance can be easily isolated by treating the mass obtained with dilute nitric acid. The new phosphide is separated in the form of prismatic crystals of a greyish metallic lustre. These have a density of 8·5, and are not attacked by air at ordinary temperatures, but at a red heat are transformed without incandescence into greenish tungstic acid. Analysis shows this substance to have the formula WP.

Some Properties of Sodium Peroxide.—George F. Jaubert.—The author's experiments, described in this paper, are intended to show the inaccuracy of various statements appearing in "Wurtz's Dictionary," with regard to the properties of sodium peroxide. (1). Peroxide of sodium is not pure white in colour, but is of a clear yellow. Many specimens were examined by the author, who found that those which were pure white in colour contained a greater proportion of hydrate or carbonate. Also pure sodium perioxide was prepared by oxidising redistilled metallic sodium in a current of pure dry oxygen. The resulting peroxide was in the form of a yellow powder. The yellow colour darkens on heating. (2). Peroxide of sodium does not deliquesce in the air. In the author's laboratory some peroxide was freely exposed to air for several years without deliquescing. The yellow colour which it possessed at first changed to white, owing to the transformation of the peroxide into carbonate.

Composition of the Hydrate and Nitride of Thorium.—C. Matignon and M. Delépine.—Chydenius announced the existence of a nitride of thorium, produced when ammonia acts on the chloride. M. Moissan obtained this same body by the action of ammonia on the carbide, and one of the authors of the present paper showed that thorium metal combines directly with nitrogen. Finally, Winkler has shown the existence of a hydride of thorium.

The authors now examine these two compounds of thorium with a view to fixing their composition. They are prepared directly from the metal. The results of these experiments show that the hydride has the composition ThH_4 The nitride, which has to be prepared at a somewhat higher temperature, has the formula Th_3N_4. This latter substance is decomposed by water, even in the cold, according to the equation, $Th_3N_4+6H_2O=3ThO_2+4NH_3$.

New Reactions of Organo-metallic Derivatives.—E. E. Blaise.—The author's experiments were performed on zinc compounds for all condensations where ethers of the bromated fatty acids entered into the reaction. In other cases magnesium was used. The reaction of organo-metallic derivatives on the nitriles can be expressed by the general scheme—

$$R-C\equiv N+Br-Mg-R'=R-C\begin{matrix}=N-Mg-Br\\ \diagdown R'\end{matrix}.$$

The ethers of the α-bromated fatty acids react in the same way on the nitriles in presence of zinc—β ketonic ethers being obtained in this case.

$$R=CN+Zn+R'-CHBr-CO_2C_2H_5=$$
$$=R-C\begin{matrix}=N-Zn-Br\\ \diagdown CH(R')-CO_2-C_2H_5\end{matrix}$$
$$\rightarrow R-CO-CH(R)-CO_2C_2H_5.$$

The researches described in this paper lead to new methods of synthesis for ketones, β-ketonic ethers and acids, and perhaps also for α-ketonic acids and bibasic acids. The author is further investigating this matter.

Action of Methylacetylacetone and Ethylacetylacetone on Diazoic Chlorides.—G. Favrel.—Diazoic chlorides react on methylacetylacetone or on ethylacetylacetone with elimination of a molecule of acetic acid and formation of a hydrazone, on account of the union of the diazoic radicle with the remainder of the acetylacetone and subsequent molecular transposition. This reaction is similar to that of cyanacetic ethers with substituted acid radicles and alcoyl acetyl acetic ethers on diazoic chlorides. In all cases the diazoic chlorides behave with regard to these ethers and substituted acetylacetones, in such a manner as to form strong bases which remove the acetyl group.

MISCELLANEOUS.

Messrs. Geo. G. Blackwell, Sons, and Co., Limited, have just issued a small pamphlet on their special refractory bricks and furnace linings. These bricks are particularly advantageous for use in the linings of open hearth and re-heating furnaces for steel, and also for smelting works where lead, copper, silver, spelter, zinc, and other metals are treated. The finest silica bricks will run at a very high temperature, whereas it is claimed that these "refractory" bricks will stand a much higher temperature, and last four or five times as long as the best silica brick made.

The Chemical Composition of Norwegian Tar.—K. Ström.—The tar extracted from the roots of the *Pinus silvestris* is syrupy, with a very acid reaction, reddish-brown in colour, soluble in alcohol, acetone, ether, $CHCl_3$, and C_6H_6; it holds crystals of pimaric acid in suspension. Its density at 15° = 1·0680. It contains 4·70 per cent of volatile acids, 10·94 per cent of phenols, and 60·80 per cent of hydrocarbides. Among the acids may be found formic, acetic, propionic, butyric, valerianic, methylpropylacetic, normal caproïc, œnanthylic, and normal caprylic acid, and probably pelargonic, caprinic, and inactive pimaric acids. Among the phenols are cresol, gaiacol, creosol, ethylgaiacol, propylgaiacol, the two phenols, $C_{11}H_{16}O_2$ and $C_{12}H_{14}O_2$. We find, in fact, 14 per cent of the hydrocarbides in the solid state, and 86 per cent in the liquid state.—*Arch. de Pharm.*, vol. ccxxxvii., p. 525.

NOTES AND QUERIES.

** Our Notes and Queries column was opened for the purpose of giving and obtaining information likely to be of use to our readers generally. We cannot undertake to let this column be the means of transmitting merely private information, or such trade notices as should legitimately come in the advertisement columns.

Bitumen Compounds.—Can any reader instruct the writer as to finding a suitable place in which to conduct experiments in bitumen compounds? There was a place somewhere in Lambeth that seemed to follow under these lines, but the writer can find no trace of same up to the present time.—W. Macdonald.

MEETINGS FOR THE WEEK.

Monday, 4th.—Society of Arts, 8. (Cantor Lectures). "Elementary Art Education," by J. Liberty Tadd.
—— Royal Institution, 5. General Monthly Meeting.
Tuesday, 5th.—Royal Institution, 3. "Practical Mechanics" (Experimentally treated), by Prof. J. A. Ewing, M.A., F.R.S., M.Inst.C.E.
Wednesday, 6th.—Society of Arts, 8. "Some Experiences of Motor Bicycles," by Joseph Pennell.
—— Royal Institution, 3. "The Government and People of China," by Prof. R. K. Douglas.
Thursday, 7th.—Chemical, 8. Ballot for the election of Fellows. "The Action of Hydrogen Bromide on Carbohydrates," by H. J. H. Fenton and Mildred Gostling. "Note on a Method of Comparing the Affinity-Values of Acids," by H. J. H. Fenton and H. O. Jones. "Organic Derivatives of Phosphoryl Chloride, and the Space Configuration of the Valencies of Phosphorus," by R. M. Caven. "Synthetical Work with Sodamide Derivatives," "Note on Two Molecular Compounds of Acetamide," and "Diacetamide—a New Method of Preparation," by A. W. Titherley, M.Sc., Ph.D.
—— Royal Institution, 3. "Society in France before before the Revolution," by the Rev. Henry Grey Graham.
Friday, 8th.—Royal Institution, 9. "History and Progress of Aerial Locomotion," by Prof. G. H. Bryan, F.R.S.
—— Physical, 5. (Annual General Meeting). Address by the President. "A Mica Echelon Grating," by Prof. R. W. Wood.
Saturday, 9th.—Royal Institution, 3. "Vocal Music, its Growth and Decay," by F. Corder, F.R.A.M.

THE CHEMICAL NEWS.

VOL. LXXXIII., No. 2150.

ON THE PRESENCE OF ARSENIC IN VARIOUS COMMERCIAL PRODUCTS.

By Dr. T. L. PHIPSON.

As early as 1862 I found notable amounts of arsenic and selenium in the sulphur of the Solfatare, near Naples (*Comptes Rendus*, 1862). This sulphur was purchased for pharmaceutical use in Belgium.

Since then I have examined some specimens of Sicilian sulphur and artificial English sulphur (from soda refuse), which were quite exempt from arsenic.

The volcanic sulphur of Hecla, which I examined in 1870, gave mere traces of arsenic.

Many phosphates used in pharmacy will be found to yield arsenic when carefully examined, and doubtless arsenic thus finds its way into phosphatic syrups and other medicaments.

The pyrites used in the manufacture of sulphuric acid almost invariably yield a certain quantity of arsenic (often 0·1 per cent, or more), and chamber acid in which impurities of various kinds, such as lead, mercury, thallium, selenium, and arsenic, are concentrated, is, of course, quite unfit for the production of phosphoric acid or glucose, or for any use connected with food or medicaments. Some specimens of this chamber acid have yielded as much as 1·44 per cent of arsenious acid.

M. Herz, an apothecary of Berlin, detected arsenic in the phosphoric acid used in pharmacy as early as 1834. This phosphoric acid was prepared by acting upon phosphorus by nitric acid. Its solution, treated by sulphuretted hydrogen, gave a deposit of the yellow sulphide of arsenic after being allowed to stand for some days. The same result was obtained at the same time by Mr. Barwald, who got 8 grains of sulphide of arsenic from 1 pound of phosphoric acid; isolated the arsenic itself, proved that the latter did not come from the vessels used, nor the nitric acid, nor the sulphuretted hydrogen, but from the phosphorus. He then examined the phosphorus purchased at several other pharmacies in Berlin with the same results.

About the same time Justus von Liebig obtained similar results with specimens of phosphorus purchased at several drug-stores in Frankfurt-a-M.

ARSENIC IN BEER.

By JOHN RYDER and ALFRED GREENWOOD, M.D., D.P.H.

HAVING had occasion during the last two months to examine a number of samples of beer for arsenic, the following method was used in those cases in which the quantity of arsenic present was determined:—

Take 2 litres of beer (or less, according to the sublimate of crystals obtained in the qualitative test), and boil down to 1000 c.c. Then add 3 or 4 grms. of bright copper foil in small pieces (about ½ inch square) and one-sixth litre of pure re-distilled HCl (sp. gr. 1·16). Boil for one hour. Pour beer into another beaker containing about 1 grm. bright copper foil, and boil for a quarter of an hour longer. If no stain on this copper, the beer may be put aside. Wash the copper from the two treatments with distilled water, transfer to porcelain basin, dissolve in 20 c.c. HNO_3 (sp. gr. 1·42), evaporate off excess of acid.

(From this stage the method is that described in Blair's "Chemical Analysis of Iron" (Second Edition, p. 189) for the determination of small quantities of arsenic in iron and steel).

Add 20 c.c. H_2SO_4 (sp. gr. 1·84), heat to dryness on sand-bath until H_2SO_4 fumes come off, transfer residue to distillation flask, add 7½ grms. pure $FeSO_4$ cryst. (B.P. granulats), and fit cork with tubes attached.

Now add down funnel 75 c.c. pure re-distilled HCl (sp. gr. 1·16), and distil into 150 c.c. distilled H_2O until delivery tube is too hot to bear the hand; then change receiver for beaker containing 50 c.c. distilled H_2O, and continue distillation for five minutes.*

Heat the two receivers to about 70° C., pass brisk current of H_2S through each for ten minutes, digest on water-bath for ten minutes, and then pass H_2S through again for ten minutes. Place on water-bath. After a while the As_2S_3 will settle well, leaving the supernatant liquid clear and colourless. Now bubble CO_2 through to dispel H_2S, filter off As_2S_3, wash with H_2O, then alcohol, CS_2—to dissolve out any free S—alcohol, and H_2O.

Dissolve the As_2S_3 in cold dilute AmHO (1 : 4), letting the ammoniacal solution run into a weighed porcelain crucible. Evaporate to dryness on water-bath, and dry in oven (until constant) at 100° C.

In iron and steel analysis, when taking 5 grms. sample and using above quantities, 0·016 per cent As may be determined, so that when taking 2 litres of beer the same weight of precipitate would represent 0·00004 per cent arsenic.

Health Department, Municipal Offices,
Earle Street, Crewe, Feb. 1, 1901.

SULPHOCYANIDES OF POTASSIUM AND SODIUM.
ON A PECULIAR BLUE COLOUR PRODUCED WHEN THESE SALTS ARE HEATED.

By W. B. GILES, F.I.C.

SOME time ago when making experiments on the reducing action of cyanide of potassium on titanic acid, and some other oxides, it occurred to me to see what would happen if sulphocyanide of potassium was substituted for the cyanide. On fusing small quantities of the sulphocyanide with the oxides in porcelain crucibles I noticed that a very intense blue colour was produced at a red heat, and I conceived at first that this was due to some reduction of the oxides, and that it might afford a good means for their detection. On pursuing the matter further I found, however, that pure silica yielded just the same intense blue colour with the sulphocyanide when they were heated to redness together. Then I tried heating the sulphocyanide by itself, and found that without any addition whatever it also yielded this colouration. Not being able to find any account of this peculiar behaviour of the salt, I thought possibly that there might be something unusual in the sample of sulphocyanide of potassium I was using. To settle this question I obtained five more samples of pure sulphocyanide of potassium, and three samples of pure sulphocyanide of sodium, from different sources. The whole of these eight samples with one exception (which is referred to later on), gave the blue colouration on heating in a very marked manner. In order to obtain this curious result it is merely necessary to heat in a porcelain crucible over a Bunsen burner a small amount of the *pure* salts, using a gentle heat till all the adherent moisture is expelled; then on raising the heat slowly the salt becomes slightly pink or yellow, and when an incipient red heat is reached begins to darken, and a very bright blue colour is produced, which becomes more intense as the heat is

* This second receiver very seldom contains even a trace of arsenic, but it is best to use it as a safeguard.

raised, till sometimes it appears nearly black. A remarkable feature is that the colour only persists at a strong heat; directly the lamp is withdrawn the colour begins to fade, and if the salt has not been heated too strongly, long before solidification takes place, the mass is quite white again. On re-heating the salt the colour again appears, and with care this can be repeated a great number of times. As, however, heating in crucibles entails oxidation, and the salt often takes fire, small test-tubes made of hard combustion glass are substituted with advantage. On heating the sulphocyanide in tubes it is seen that small quantities of sulphur sublime. Yet after eight or ten careful reproductions of the colour by alternate heating and cooling have been made on a small quantity, the residue on examination appears to consist principally of unaltered sulphocyanide. The cause of the colouration is evidently connected with sulphur, for if some of the salt is heated to such a point that the blue colouration is just perceptible, and a small chip of sulphur is introduced, a very marked increase of the colour is noticed. If, however, too much sulphur is added the colour is destroyed. When pure sulphocyanide of potassium or sodium is heated in a current of dry hydrogen it does not prevent the formation of the blue colour, but after the current of gas has been passed for a long time, the colour fades away gradually, and the salt becomes white again, or nearly so. If the sulphocyanides are pure the escaping gas contains a large amount of hydric sulphide, and the residue in the tube consists principally, if not wholly, of potassium cyanide, $KCyS + H_2 = KCy + H_2S$. If, however, the sulphocyanides contain certain impurities, such as carbonate or hydrate of potassium, the formation of the blue colour is entirely prevented, and, on heating in hydrogen, ammonia is given off as well as hydric sulphide. I have mentioned previously that one sample of the sulphocyanide of potassium, though marked as "pure," did not yield any blue colour on heating, either in a test-tube or in dry hydrogen. The cause of this was found to be that it was strongly contaminated with carbonate of potassium. This sample gave a deep yellow or orange-colour on heating it, and behaved quite differently to the pure samples. Pure sulphocyanides are perfectly indifferent to phenolphthalein, whereas this sample was strongly alkaline. If instead of starting with the sulphocyanides themselves, *pure* cyanide of potassium is fused in a tube of hard glass and small quantities at a time of sulphur are added, by careful manipulation it is possible to produce the blue colouration in a very distinct manner. But if the cyanide is impure (and what has been kept for any time almost always contains carbonate), or if too much sulphur is added, the colour is not obtained. It is difficult to explain the formation of this blue compound; the sulphocyanides on heating seem to be (at least in part) dissociated, as appears from the slight sublimation of free sulphur, and while the blue colour is clearly due in some way to sulphur an excess destroys it. In this connection it may be of interest to note that the temperature at which the blue colouration manifests itself (a dull red heat) is about the point at which the vapour density of sulphur changes from 96 to 32 as referred to hydrogen, or from a six atom molecule to a two atom molecule, according to Mendeleeff.

It would be of interest to know whether Sir William Crookes, who has worked so much with the seleniocyanides, has ever noticed any analogous colouration when seleniocyanide of potassium, for instance, is heated.

Compounds of Boron Bromide with Phosphorus Chlorides.—M. Tarible.—Boron bromide in presence of chloride of phosphorus reacts very easily, giving double compounds. The substances thus obtained are perfectly crystalline, and are decomposed by water in the cold, chlorine and ammonia gas being produced. In all cases their formulæ are different from those compounds which are obtained with phosphorus bromide.—*Comptes Rendus*, cxxxii., No. 2.

NEW METHOD FOR THE ESTIMATION OF TANNING MATERIALS.

By L. SPECHT and F. LORENZ.

This method depends on the precipitation of safranine in the form of ammonio-tannic lake, and on the reducing action exercised by hyposulphite on safranine. The tanning material is precipitated by tartar emetic and safranine, the excess of which is titrated with hyposulphite. The strength of this latter is found by means of pure safranine. The number of c.c. used indicates the amount of safranine that has not taken part in the reaction, and the difference between this figure and that obtained with the amount originally required enables us to estimate the quantity of safranine necessary to form the lake, and, consequently, the strength of the tanning material. To be able to express this relative value in figures, it is necessary to titrate a tannin of well-known composition, under the same conditions.

The large number of experiments we have carried out to test the value of our process have given results of an entirely satisfactory character.

As a standard tannin of 100 per cent we used tannic acid dried at 100°, Ph. G. III., supplied by Schering and Co., Berlin.

The T safranine, from the Badische Anilin und Soda Fabrik, of which we made use, was first purified by repeated crystallisations in alcohol. To diminish the oxidising action of the oxygen dissolved in the water as much as possible, we always used boiled water. Instead of hyposulphite of sodium, we used hyposulphite of ammonium, which is much more stable. To prepare this reagent we made a mixture of 50 grms. of zinc powder and 100 grms. of water, and added to this 600 c.c. of a solution of bisulphite of ammonium at 20° B., and neutralised with ammonia. During this operation it is important that the temperature should not exceed 36°.

After standing, 75 c.c. of the clear liquid were taken and poured into 2 litres of water. A flocculent precipitate separates, which is allowed to settle, and the liquid is then covered with a layer of mineral oil, to protect it from the oxygen of the air.

The end of the titration is taken as the moment when complete decolouration takes place.—*Chemiker Zeitung*, 1900, p. 170.

ON THE COMPOUNDS OF TELLURIC ACID WITH THE IODATES.

By R. F. WEINLAND and H. PRAUSE.

Among the compounds of the iodates and the acids of the sixth group of elements, we know up to the present only those of sulphuric acid, chromic acid, molybdic acid, and tungstic acid. Taking the first of these acids as an example, the different forms which exist are as follows:—$I_2O_5.2SO_3.2K_2O.H_2O$; $I_2O_5.SO_3.K_2O$; $2I_2O_5.8SO_3.5K_2O$. In this paper the authors examine a series of new salts formed by the union of telluric acid with the iodates.

Monoiodotellurate of Potassium, $I_2O_5.2TeO_3.K_2O.6H_2O$. —This salt is formed when we allow an aqueous solution of the three oxides to evaporate slowly at the ordinary temperature. It crystallises in flattened colourless prisms. The solutions it gives with water have an acid reaction; when submitted to the action of heat this body loses the greater part of its water of crystallisation at 100°, but the remainder only at 250°.

Monoiodotellurate of Rubidium, $I_2O_5.2TeO_3.Rb_2O.6H_2O$. —This salt is obtained by the evaporation of solutions containing a quantity of telluric acid, slightly higher than that required by the formula. This salt crystallises in prisms analogous to those of the above mentioned potassium salt.

Monoiodotellurate of Ammonium,—

$I_2O_5.2TeO_3.(NH_4)_2O.8H_2O$.

—This body consists of colourless flattened crystals, which attain a diameter of 1·5 c.m. They contain 8 molecules of water of crystallisation.

Di-iodotellurate of Potassium, $I_2O_5.TeO_3.K_2O.8H_2O$.—This body is prepared from an aqueous solution of 2 molecules of IO_3H, 1 molecule of TeO_4H_2, and 2 molecules of KOH. The liquor should have a slightly acid reaction. The di-iodotellurate is also formed in good proportion, by evaporating aqueous solutions of iodic acid, telluric acid, and potash mixed together in the proportions of 3 : 1 : 3·2. This salt occurs in the form of rhombohedric crystals having a vitreous lustre. Like the monoiodotellurate, it loses the whole of its water at 250°. —*Berichte*, vol. xxxiii., p. 1015.

A BIBLIOGRAPHY OF STEEL WORKS ANALYSIS.

PART VII.

By HARRY BREARLEY.

(Continued from p. 54).

CHROMIUM (*continued*).

IV. Means of Converting to Chromic Acid.

IV.*a*. *In the Dry Way*.—

1043. Clarke (*C. N.*, xvii., 232).—Chromite (and other refractory materials) is fused with soda fluoride and bisulphate, and oxidised with hypochlorite; or at once by including KNO_3 in the fusion. CrO_3 not completely separated from Fe and Al by Na_2CO_3.

1044. Namias (*J. S. C. I.*, 1891, 486).—Fuse ore with $KHSO_4$, precipitate water extract with MgO, and fuse with $KClO_3+NaKCO_3$.

1045. Moissan (*C. N.*, lxvii., 137).—Powdered chromeisen is converted to CrO_3 by melting with KNO_3.

1046. Kayser (*C. N.*, xxxvi., 153).—Heat chrome-iron with a mixture of Na_2CO_3 and CaO.

1047. Pemberton (*C. N.*, lxiii., 241).—Chromite and Na_2CO_3 are heated over night by a Bunsen, and next morning over the blast. Decomposition is complete.

1048. Haussermann (*J. S. C. I.*, 1892, 182).—Fuse powdered ore with K_2CO_3 and NaHO.

1049. Massignon and Vatel (*C. N.*, lxiii., 273).—Heat ore mixed with $CaCl_2$ and CaO (or $CaCO_3$).

1050. Clark (*J. S. C. I.*, 1892, 501).—Ferro-chromium is not completely dissolved by H_2SO_4 (1073). Oxidise with MgO or CaO+NaHO. FeCr is decomposed by heating with $Ca(HO)_2$, or in the vapour of S or CS_2. Latter process available for steels.

1051. Donath (*J. I. S. I.*, 1887, ii., 371).—Heat with barium peroxide, and extract CrO_3 with acidulated water.

1052. Kennicut and Patterson (*J. C. S.*, lx., 366).—Fuse with barium peroxide and Na_2CO_3, dissolve in HCl, re-oxidise with alkaline H_2O_2, acidify, and titrate.

1053. Clark (*J. C. S.*, lxiii., 1081).—FeCr and chromite are completely decomposed by Na_2O_2. Heat to make pasty, not to liquefy. Na_2O_2 does not separate Fe and Cr.

1054. Reinhardt (*J. I. S. I.*, 1890, i., 375).—Fuse with soda-lime and $KClO_3$. Titrate with $FeSO_4$.

1055. Smith (*C. N.*, lxiv., 44 and 218).—An electric current passed through molten potash containing chromiferous material completely oxidises it to CrO_3. Titrate with $FeSO_4$.

IV.*b*. *Conversion to* CrO_3 *in the Wet Way*.—

1056. Storer (*C. N.*, xxi., 198).—Strongly ignited Cr_2O_3 and chromite are converted to CrO_3 by boiling with HNO_3+KClO_3. Precipitated as $BaCrO_4$.

1057. Stoddart (*C. N.*, xxiii., 284).—Storer's process does not completely decompose chromite.

1058. Phillips (*C. N.*, xxix., 28).—Decompose chromeisen with H_2SO_4 in closed tubes, oxidise with Na_2CO_3 and Br. Zn, Mn, Fe, and Al are completely separated (see 1043).

1059. Marchal and Wiernich (*J. S. C. I.*, 1891, 1034).—To nearly neutral H_2SO_4 solution, add MnO_2 and boil; Fe is precipitated. Precipitate Al with AmHO, reduce CrO_3, and precipitate.

1060. Matignon (*J. C. S.*, l., 984).—In alkaline solutions H_2O_2 immediately converts Cr_2O_3 to CrO_3; in acid solutions the easily decomposable perchromic acid is formed.

V. Detection of Chromium.

1061. Storer (*C. N.*, i., 253, &c.).—PbO_2 best reagent for effecting oxidation. PbO_2, MnO_2, and $KMnO_4$ form CrO_3 in cold acid solutions; PbO_2 (not Pb_3O_4), MnO_2, $KMnO_4$, Br, I, HgO, and hypochlorite in alkaline solutions. Formation of perchromic acid with H_2O_2 the most delicate reaction.

1062. Neville (*C. N.*, xxxiv., 19).—Add ether and H_2O_2 to CrO_3 solution; a blue colour = Cr. Ni, Co, Fe, Mn, and Al do not interfere; acetates do. The blue colour in ether is used as indicator (McCulloch, *C. N.*, lv., 2) in estimating acidimetrically K_2CrO_4 in the presence of $K_2Cr_2O_7$.

1063. Donath (*C. N.*, lix., 109).—Similar to 1029. Use KI and starch. Small quantities are estimated by precipitating with Am_2S.

1064. McCay (*C. N.*, lxv., 221).—After fusing with $Na_2CO_3+KNO_3$ the yellow colour of the acidified extract looked for may have been destroyed by the nitrous acid present (see 971).

1065. Terriel (*C. N.*, xi., 136).—Precipitate the ferric solution with KHO, oxidise with permanganate, and add lead acetate and acetic acid to the filtrate. Traces of W, Mo, and Va in steel are similarly detected.

1066. Walden (*J. C. S.*, liv., 321).—Diphenylamine in concentrated H_2SO_4 detects 1 part $K_2Cr_2O_7$ in 700,000.

VI. Miscellaneous Notes.

1067. Fresenius and Hintz (*C. N.*, lxi., 65).—Scheme for very elaborate analysis of chrome-iron. The material is decomposed in a current of chlorine.

1068. Clark (*J. S. C. I.*, 1895, 510).—Decompose ore with $KHSO_4$ preparatory to estimation of SiO_2, CaO, MgO, Fe_2O_3, Al_2O_3, and Cr_2O_3.

1069. Moissan (*C. N.*, lxx., 93).—Preparation, physical and chemical properties of metallic Cr.

1070. Jannasch and Vogtherr (*C. N.*, lxiv., 293).—Chromite decomposed with HCl in sealed tube.

1071. Schneider (*J. I. S. I.*, 1886, 399).—Fifty per cent FeCr would dissolve in HCl if it were not for a protective coating of oily hydrocarbon.

1072. Rideal and Rosenblum (*C. N.*, lxxiii., 1).—Give prominence to Na_2O_2 in a review of the means proposed for decomposing chromite, ferro-chromium, &c. A bibliography of forty items.

1073. Warren (*C. N.*, lxv., 186).—Ferro-chromium is completely dissolved by hot concentrated H_2SO_4 (see 1050). Borax in fusion mixtures contaminates the precipitates of the subsequent analysis.

1074. Carnot and Goutal (*J. C. S.*, lxxii., ii., 555).—Chromium exists in steel as a Cr-Fe carbide.

1075. ZIEGLER (*J. S. C. I.*, 1893, 377) —Describes the following processes for steel :—Fusion of the dried residue; removal of the iron with cupram-monium chloride; fusion with $NaHSO_4$, or oxidation with $KMnO_4$; and dissolving out other chlorides than Cr from the dried residue with alcohol.

1076. PROCTOR (*J. S. C. I.*, 1897, 413).—A review of the processes for estimating CrO_3 and some mixtures of Cr salts.

1077. JERVIS (*C. N.*, lxxvii., 133).—Either acid or alkaline chromate solutions are reduced by filter-paper (see 987).

1078. PARRY and MORGAN (*C. N.*, lxvii., 307).—There is no satisfactory process for estimating Cr in steel. Describe some processes the like of which are otherwise noticed.

(END OF PART VII.).

CONCERNING LIPASE, THE FAT-SPLITTING ENZYME, AND THE REVERSIBILITY OF ITS ACTION.*

By J. H. KASTLE and A. S. LOEVENHART.

IT was suggested by one of us (Loevenhart), that possibly lipase might be capable of effecting the synthesis of fats from fatty acid and glycerin as well as their hydrolysis into these products. It was with the view of making an experimental study of this question that this investigation was first undertaken. An examination of the literature of the subject revealed that but comparatively little was known concerning the fat-splitting enzyme. It was therefore deemed advisable to extend the original scope of the investigation. The most convenient source of the enzyme to us was the pancreas of the pig. In the preparation of our extracts, the organ was removed from the animal within thirty minutes after death, dissected as free as possible from fat, thoroughly macerated with coarse white sand, and extracted with water or glycerin. It was afterwards found more convenient, however, to cut up the pancreas in small pieces upon its removal from the animal, and preserve it in chloroform water in cold storage until required for use. At first the activity of the enzyme was tested upon pure butter-fat, litmus being used as the indicator, and the time being noted that was required to pass from the blue colour to a definite shade of red. Under the best conditions, however, lipase hydrolyses the fats but slowly, and hence they are by no means convenient substances with which to follow the change in question. In testing the activity of the pancreas extract on other ethereal salts, it was observed that it hydrolysed ethyl butyrate comparatively rapidly, and, except where expressly stated to the contrary, this ethereal salt was employed in all of our experiments. Ethyl butyrate further possesses the advantage that the amount split by water alone at the temperature at which we worked, is not measurable within the duration of our experiments. The experiments were carried out in test-tubes usually in the following manner :—4 c.c. of water, 0·1 c.c. toluene (as antiseptic), and 0·26 c.c. ethyl butyrate† were placed in test-tubes. The tubes were then tightly corked and heated to the desired temperature, usually 40°, for five minutes, to bring their contents to the temperature of the bath, at the end of which time 1 c.c. of the enzyme solution was added to each. The tube was then heated for the desired time, usually for fifteen minutes, when it was removed from the bath, plunged into ice-water, and titrated with N/20 KOH, neutral litmus being used as the indicator. In what follows, the initial acidity of the enzyme solution, usually amounting to 0·1 to 0·2 c.c. N/20 KOH, has in every case been deducted from the c.c. KOH required.

That the hydrolysis of ethyl butyrate and other ethereal salts was in reality brought about by the action of an enzyme, and not by other agents, was proved by numerous control experiments in which the solution of the enzyme was boiled before it was used. It may be of interest to note in this connection that in not a single instance did the control experiment show any hydrolysis of the ethereal salt.

The action of fat-splitting bacteria was prevented by antiseptics, usually toluene or thymol.

In our early experiments no special attention was paid to the amount of pancreas employed in the preparation of the extracts. It soon became manifest, however, that it would be far better, for purposes of comparison at least, to employ definite amounts of the gland, and hence it will be observed in what follows that 10, 20, and even 50 per cent extracts were used. By this is meant that 10, 20, or 50 grms. of gland were extracted with water, and made up to 100 c.c.

Several other tissues of the pig have been found to exhibit lipolytic activity towards ethyl butyrate, notably the liver, the submaxillary gland, and the kidney. A comparison of the lipolytic activity of 10 per cent extracts of these tissues has been made in the following manner :—Tubes were prepared containing 4 c.c. of water, 0·1 c.c. toluene, and 0·26 c.c. ethyl butyrate. These were then heated for five minutes at 40°, when 1 c.c. of the extract to be tested was added. The enzyme was allowed to act for forty minutes, at the end of which time the solution was titrated with N/20 KOH. The following were the results obtained :—

	c.c. N/20 KOH required.	Per cent of hydrolysis.
Pancreas	1·4	3·52
Kidney	0·7	1·76
Liver	4·1	10·29
Submaxillary gland	0·5	1·26

Taking the extract of the pancreas as unity, the lipolytic activity of the other tissues of the pig stand in the following ratio :—

Pancreas	1·0
Liver	2·93
Kidney	0·50
Submaxillary gland	0·36

The liver of the pig showed such remarkable lipolytic activity that it occurred to us to compare it with the liver of certain other animals in this respect. Livers of the pig, beef, sheep, chicken, and duck were obtained in fresh condition in the market. 10 per cent aqueous extracts of these were prepared, and their activity toward ethyl butyrate tested in the manner already described.

Duration of experiments, fifteen minutes; temperature, 40°; antiseptic, toluene.

	c.c. N/20 KOH required.	Per cent of hydrolysis.
Pig liver	3·45	8·66
Sheep ,,	1·90	4·77
Duck ,,	1·075	2·70
Beef ,,	0·875	2·20
Chicken ,,	0·775	1·95

Another interesting occurrence of lipase has been observed in the stomach of the pig. It has long been known that fats are hydrolysed to some extent in the stomach (Marcet, *Proc. Roy. Soc.*, 1858, ix., 306; Ogata, *Du Bois Arch.*, 1881, 515; Cash, *Arch. f. Anat. u. Physiol*, 1880, S. 323). The exact cause of this, however, seems not to have been determined with certainty. By some it is believed to be brought about by bacteria in the early stages of gastric digestion (Shäfer, "Text-book of Physiology," 1898, vol. i., p. 443). In order to test this point, 25 grms.

* From the *American Chemical Journal*, xxiv., No. 6.

† At 30° C. (summer temperature), 0·26 c.c. ethyl butyrate weighs 0·2300 grm. This quantity, if completely hydrolysed, would require 39·7 c.c. N/20 KOH. These numbers are employed in the following in calculating the amount of hydrolysis.

of the mucous membrane of the pig's stomach were ground with coarse sand, and water added. The extract was strained through linen cloth, and made up to 100 c.c. A small quantity of toluene was added as the antiseptic. This extract was found to possess lipolytic activity in neutral solutions. It was found to be rendered permanently inactive, however, by free hydrochloric acid in about the quantity normally present in gastric juice. These facts are brought out in the following experiments:—

In the first series of experiments three solutions were employed, labelled A, B, and C, respectively. Solution A contained 5 c.c. of 0·6 per cent hydrochloric acid, and 5 c.c. of the active extract of the pig's stomach. The hydrochloric acid was therefore acting in a concentration of 0·3 per cent.

Solution B contained 5 c.c. of the active extract of the pig's stomach and 5 c.c. of water. Solution C contained 5 c.c. of hydrochloric acid of 0·6 per cent, and 5 c.c. of water.

Experiments (First Series).

Time, thirty minutes; temperature, 40°.

(1). 1 c.c. solution A; 4 c.c. water; 0·1 c.c. toluene; 0·26 c.c. ethyl butyrate.
Increase in acidity = 0·05 c.c. N/20 KOH = 0·13 per cent hydrolysis.

(2). A duplicate experiment of above (No. 1), gave the same result. This slight hydrolysis was due to the hydrochloric acid present; see Exp. 4.

(3). 1 c.c. of solution B; 4 c.c. water; 0·1 c.c. toluene; 0·26 c.c. ethyl butyrate.
Increase in acidity = 0·25 c.c. N/20 KOH = 0·64 per cent hydrolysis.

(4). 1 c.c. solution C; 4 c.c. water; 0·1 c.c. toluene; 0·26 c.c. ethyl butyrate.
Increase in acidity = 0·05 c.c. N/20 KOH; decomposition, 0·13 per cent.

Experiments (Second Series).

Time, thirty minutes; temperature, 40° C.

(1). 2 c.c. extract of pig's stomach (boiled); 2 c.c. water; 0·1 c.c. toluene; 0·26 c.c. ethyl butyrate.
Increase in acidity 0·1 c.c. N/20 KOH; decomposition, 0·25 per cent.

(2). 2 c.c. extract pig's stomach (boiled); 2 c.c. 0·6 per cent hydrochloric acid; 0·1 c.c. toluene; 0·26 c.c. ethyl butyrate.
Increase in acidity 0·2 c.c. N/20 KOH; decomposition, 0·5 per cent

(3). 2 c.c. active extract of pig's stomach; 2 c.c. 0·6 per cent hydrochloric acid; 0·1 c.c. toluene; 0·26 c.c. ethyl butyrate.
Increase in acidity 0·1 c.c. N/20 KOH; decomposition, 0·25 per cent.

(4). 2 c.c. active extract of pig's stomach; 2 c.c. water; 0·1 c.c. toluene; 0·26 c.c. ethyl butyrate.
Increase of acidity 0·8 c.c. N/20 KOH; decomposition, 2 per cent.

These experiments certainly show that while a lipolytic enzyme is present in extracts of the mucosa of the stomach, it cannot effect the hydrolysis of fats in the presence of 0·3 per cent hydrochloric acid, and hence any hydrolysis of fats brought about by it in the stomach would probably be confined to the first stages of gastric digestion. The following experiments show further that this enzyme is rendered permanently inactive by hydrochloric acid of this strength, proving therefore that on passing from the stomach into the intestine, the enzyme does not again become active.

Experiments (Third Series).

(1). 2 c.c. active extract of pig's stomach; 2 c.c. 0·6 per cent hydrochloric acid; 0·1 c.c. toluene.
This mixture was heated ten minutes at 40°, when 0·2 c.c. of litmus solution was added, and the contents of the tube just neutralised with N/20 KOH. 0·26 c.c. ethyl butyrate was then added, and the tube again placed in the bath at 40°. The solution remained neutral permanently.

(2). Repetition of the above gave the same result.

(3). 2 c.c. active extract pig's stomach; 2 c.c. water; 0·1 c.c. toluene.
This mixture was heated for ten minutes at 40°, when 0·2 c.c. of litmus solution, 6·8 c.c. water,* and 0·26 c.c. of ethyl butyrate were added. The tube was then again placed in the bath at 40°. The solution became red in five minutes. After heating for twenty-five minutes, it required 0·7 c.c. N/20 KOH; decomposition, 1·76 per cent. When returned to the bath, after neutralisation, it became red again almost immediately. These experiments were repeated with extracts made from the stomach of a second animal with like results.

Still another occurrence of lipase, of doubtless great physiological interest, has been found in the small intestine of the pig. A short section of the intestine, including the duodenum and upper part of the jejunum, was thoroughly cleansed in running water. At the time the animal was killed a small quantity of fluid was found in the small intestines. After cleansing, the mucosa was scraped off, and macerated with coarse white sand, and extracted with water. A 10 per cent extract was thus prepared. This extract was quite similar in appearance to the pancreatic extracts. Tubes were prepared containing 4 c.c. of water, 0·1 c.c. toluene, and 0·26 c.c. ethyl butyrate. They were then heated in the bath at 40° for five minutes, at the end of which time 1 c.c. of the active or boiled extract was added, after which the tubes were heated for fifteen or thirty minutes. The following results were obtained:—

	Time in minutes.	C.c. N/20 KOH required.	Per cent of hydrolysis.
1	15	0·9	2·26
2	30	1·65	4·14
*3	15	1·00	2·51
4	30	1·30	3·26

* In Experiments 3 and 4, 0·1 grm. thymol was used as the antiseptic.

The boiled extract showed no activity whatever.

According to these results, the mucous lining of the small intestine possesses a lipolytic activity equal to three-fourths that of the fresh pancreas for equal amounts of tissue. The probable physiological significance of this fact will be briefly discussed in a subsequent part of this paper.

Effect of Filtration.

In our earlier work with the enzyme, the attempt was made to obtain it in the form of a clear solution, free from all suspended matter of any kind. By repeated filtration we succeeded in obtaining clear solutions, showing only a slight opalescence. Unfortunately, such solutions were always found to be exceedingly weak in lipolytic power. On the other hand, it was found that if the pancreas was thoroughly macerated with sand, and the macerated mass thoroughly mixed with water, and simply strained through linen or cotton cloth, an extract of great lipolytic power was obtained. The effect of filtration was invariably to diminish the activity of the solutions. This was proved experimentally for aqueous and glycerin extracts of both the pancreas and liver. The same was also found to hold for the pancreatin of Parke, Davis, and Co. A 2 per cent solution of this preparation is yellowish in colour, and is turbid. In this shape it possesses weak but measurable lipolytic power. On filtering a great many times a clear yellow solution is obtained, which possesses only a trace

* This quantity of water was added in order to make the concentration the same as in Experiment 1.

of its original lipolytic activity. To show the effect of filtration on the liver extract, the following experiments are cited:—Before filtering, 1 c.c. of a 10 per cent liver extract was found to hydrolyse 6·28 per cent of ethyl butyrate in fifteen minutes at 40°. After filtering repeatedly through the same filter-paper, it hydrolysed only 2·76 per cent of ethyl butyrate under the same conditions, showing a falling off in activity of over one-half as the result of filtration.* The removal of lipase, along with the suspended matter in the solution, was observed in still another connection. When an active pancreatic extract acts on ethyl butyrate at 40°, the butyric acid produced soon coagulates the proteids in the extract. On filtering, it was found that the clear filtrate possessed little or no lipolytic power, whereas the proteid coagulum was found to be exceedingly active. In view therefore of the injurious effect of prolonged filtration, it was deemed advisable to employ extracts which had been prepared in the manner above described, and which had simply been strained through linen or cotton cloth. Care was taken, however, to macerate thoroughly.

(To be continued).

SOME PRINCIPLES AND METHODS OF ROCK ANALYSIS.†

By W. F. HILLEBRAND.

Part I.—Introduction.

I. *Importance of Complete and Thorough Analyses.*

The composition of the ultimate ingredients of the earth's crust—the different mineral species which are there found and of many of which its rocks are made up—was the favourite theme of the great workers in chemistry of the earlier half of this century, and for the painstaking care and accuracy of Berzelius, Wöhler, and others the mineralogists and geologists of to-day have need to be thankful. Considering the limited facilities at their disposal in the way of laboratory equipment and quality of reagents, the general excellence of their work is little short of marvellous. As an outgrowth of and closely associated with the analysis of minerals came that of the more or less complex mixtures of them—the rocks—to aid whose study by the petrographer and geologist a host of chemists have for many decades annually turned out hundreds of analyses of all grades of quality and completeness. With the growth and extraordinary development of the so-called organic chemistry inorganic chemistry gradually fell into a sort of disfavour. In many, even the best, European laboratories, the course in mineral analysis, while maintained as a part of the curriculum of study, became but a subordinate prelude to the ever-expanding study of the carbon compounds, whose rapid multiplication, offering an easy and convenient field for original research and possible profit, proved a more tempting opening to young chemists than the often-worked-over and apparently exhausted inorganic pasture. For one student devoting his time to higher research on inorganic lines were perhaps fifty engaged in erecting the present enormous structure of carbon chemistry. The instruction afforded the student in mineral analysis was confined to the ordinary separations of the commoner ingredients occurring in appreciable quantities, with little regard to supposed traces, and with still less attempt to find out if the tabulated list really comprised all that the mineral or rock contained.

With the introduction of improved methods of examination by the petrographer, especially as applied to thin rock sections, and the use of heavy solutions, whereby, on the one hand, the qualitative mineral composition of a rock could be preliminarily ascertained with considerable certainty, and on the other, chemical examination of the more or less perfectly separated ingredients was rendered possible, a great help and incentive was afforded to the few chemists engaged in rock analysis. The microscope often obviated in part the necessity for tedious and time-wasting qualitative tests, and the heavy solutions, by permitting the concentration and separation of certain components, facilitated the detection of elements whose existence had long been overlooked.

Meanwhile in the progress of chemistry new methods and reagents for qualitative detection and quantitative separation and estimation were gradually being discovered and devised. The supposed adequacy of some well-established methods was shown to be unwarranted; some had to be discarded altogether; others were still utilisable after modification. In the light thus shed it became possible to explain many hitherto incomprehensible variations in the composition of some rock species or types, as shown in earlier analyses, and in not a few cases it appeared that the failure to report the presence of one or more elements had obscured relations and differences which more thorough examination showed to exist (see Tables I. and II.). Consequently there arose a feeling of distrust of much of the older work in the minds of those chemists and petrographers best fitted to judge of its probable qualities. This, and the incompleteness of nearly all the earlier work (and much of that of to-day unfortunately), as shown by the largely increased list of those elements now known to enter into the normal composition of rocks, is rendering the old material less and less available to meet the increasing demands of the petrographer.

And yet these demands on his part are, with few exceptions, by no means so exacting as they should be. Often the analysis is intrusted to the hands of a student without other experience than that gained by the analysis of two or three artificial salts and as many comparatively simple natural minerals, and with a laboratory instructor as adviser whose experience in rock analysis may be little superior to his own. In other words, one of the most difficult tasks in practical analysis is expected to be solved by a tyro, and his results are complacently accepted and published broadcast without question. Even to those thoroughly familiar with the subject rock analysis is a complex and often trying problem. Although long practice may have enabled one to do certain parts of it almost mechanically, one is still from time to time confronted with perplexing questions which require trained judgment to properly meet and answer, and there is still room for important work in some of the supposedly simplest quantitative determinations. If the results are to have any decided value for purposes of scientific interpretation and comparison, they should be the product of one competent to find his way through the intricacies of an analysis in which from fifteen to twenty-five different components are to be separated and estimated with close approach to accuracy, and this a beginner cannot hope to do in the majority of cases. The conscientious chemist should have a live interest in this matter. He should work with a twofold purpose in view—that of lightening the labours of those who come after him by enabling them to use his work with less supplementary examination, and of thereby enhancing his own reputation by meriting encomiums on work that has stood the test of time.

The petrographer, again, should seek to have his analyses made as complete as possible, and not, as is so often the case, be content with determinations of silica, alumina, the oxides of iron, lime, magnesia, the alkalis, and water. The latter, it is true, are entirely justifiable at times, and may serve the immediate purpose for which they were intended, but their incompleteness may, on the other hand, not only conceal points fruitful

* The same thing has been found to hold true in the case of other enzymes. See Vines, *Ann. of Bot.*, 1891, 409; Wortmann, *Bot. Zeit.*, 1890, 37 *et seq.*; Brown and Morris, *Journ. Chem. Soc. Trans.*, 1893, 604.

† *Bulletin of the United States Geological Survey*, No. 176.

of suggestion to the attentive mind, but, what is of still greater importance, they may be actually misleading. Enough instances of totally inaccurate conclusions to be drawn from them have fallen under my own observation to fully justify this plea in favour of greater completeness in rock and mineral analyses made for purely scientific purposes.

The importance of the points indicated in the foregoing paragraph is shown by the difference between the analyses given in Table I. The specimens were taken and analysed at widely separated times and by different persons, it is true, but they were unquestionably from the same rock mass, in which, however much the relative proportions of the different mineral constituents might vary within certain limits, there can be no reason to doubt the general distribution of all the elements shown by the second analysis.

TABLE I.

	Earlier analysis.	Later analysis (*a*).
SiO_2	54·42	53·70
TiO_2	—	1·92
Al_2O_3	13·37	11·16
Cr_2O_3	—	0·04
Fe_2O_3	0·61 (*b*)	3·10
FeO	3·52 (*b*)	1·21
MnO	—	0·04
CaO	4·38	3·46
SrO	—	0·19
BaO	—	0·62
MgO	6·37	6·44
K_2O	10·73	11·16
Na_2O	1·60	1·67
Li_2O	Trace	Trace
H_2O below 110° C.	—	0·80
H_2O above 110° C.	2·76 (*c*)	2·61
CO_2	1·82	—
P_2O_5	—	1·75
SO_3	—	0·06
F	—	0·44
Cl	—	0·03
	99·58	100·40
Less O for F ..	—	0·19
		100·21

(*a*). A still more recent analysis of another of the series of rocks of which this is an example has shown that this "later analysis" is itself probably incomplete and incorrect in part—incomplete because of the probable presence of 0·2 per cent or more of ZrO_2, incorrect because of the error in Al_2O_3 resulting from having counted the ZrO_2 as Al_2O_3, and from the fact that titanium is not fully precipitable in presence of zirconium by Gooch's method (the one employed). This latter error involves both the TiO_2 and the Al_2O_3. (See *prox.*, "Gooch's Method").

(*b*). From the fact that repeated determinations of the iron oxides in this and related rocks from the same region show always a great preponderance of ferric oxide, it is not improbable that the figures given for the two oxides in the first analysis were accidentally transposed.

(*c*). In the published analysis it does not appear whether this is total water or, as seems probable, only that remaining above 100° C.

Another instance of similar kind is given (Table II.). Here, again, certain differences are explainable by natural variations in the proportions of the constituent minerals, but it can hardly be doubted that TiO_2, BaO, SrO, P_2O_5, and SO_3 were present in both specimens in approximately the same amounts. In the earlier analysis determinations of some supposed unimportant constituents were purposely omitted, or made only qualitatively, with results that cannot be otherwise than fatal to a full comprehension of the mineralogical nature of the rock.

TABLE II.

	Earlier analysis.	Later analysis.
SiO_2	44·31	44·65
TiO_2	Not estimated	0·95
Al_2O_3	17·20	13·87
Fe_2O_3	4·64	6·06
FeO	3·73	2·94
MnO	0·10	0·17
CaO	10·40	9·57
SrO	—	0·37 (*a*)
BaO	—	0·76
MgO	6·57	5·15
K_2O	3·64	4·49
Na_2O	4·45	5·67
Li_2O	—	Trace
H_2O below 110° C.	0·77	0·95
H_2O above 110° C.	—	2·10
H_2O by ignition ..	3·30	—
CO_2	—	0·11
P_2O_5	—	1·50
Cl	—	Trace
SO_3	—	0·61
	99·11	99·92

(*a*). Not entirely free from CaO.

Prof. F. W. Clarke has shown that the combined percentages of titanic and phosphoric oxides in rocks of the earth's crust, averaged from hundreds of analyses, is 0·8 per cent. When the determination of these is neglected, the error falls upon the alumina. If the latter is then used as a basis for calculating the felspars, it is easy to see that a very large average error in the latter may result, amounting to several per cent of the rock.

In order to more strongly emphasise the importance of completeness in analysis, a few facts brought out by the hundreds of rock analyses made in this laboratory may be cited. It has been demonstrated most conclusively that barium and strontium are almost never-failing constituents of the igneous rocks of the United States and of many of their derivatives. These amounts are usually below 0·1 per cent for each of the oxides of those metals, but higher amounts are by no means uncommon. Furthermore, the weight of barium is almost without exception in excess of that of strontium. But a still more important point is that the igneous rocks of the Rocky Mountain region, so far as examined, show far higher average percentages of both metals than the rocks from the eastern and the more western portions of the United States. The following examples serve to illustrate certain types of Rocky Mountain igneous rocks:—Of seven rocks forming a Colorado series, six held from 0·13 to 0·18 per cent of BaO, while in the seventh the percentage was 0·43. The SrO ranged from 0·07 to 0·13 per cent for six, and was 0·28 for that one highest in BaO. Of thirteen geologically related rocks from Montana, embracing basic as well as acid and intermediate types, the range of BaO was from 0·19 to 0·37 per cent, with an average of 0·30 per cent. Three others of the same series contained 0·10 per cent or less, while the seventeenth carried 0·76 per cent BaO. The SrO ranged from 0·37 per cent in the last instance to an average of 0·06 for the other sixteen. Certain peculiar rocks from Wyoming carry from 0·62 to 1·25 per cent BaO, and from 0·02 to 0·33 per cent SrO. Surely this concentration of certain chemical elements in certain geographic zones has a significance which future geologists will be able to interpret if those of to-day are not.

Again, vanadium is an element which few chemists have ever thought of looking for in igneous rocks, though it has long been known to occur in magnetites and other iron ores. Hayes, in 1875, reported its occurrence in a great variety of rocks and ores. Quoting from Thorpe's "Dictionary of Chemistry":—"It is said to be diffused

with titanium through all primitive granite rocks (Dieulafait), and has been found by Deville in bauxite, rutile, and many other minerals, and by Bechi and others in the ashes of plants and in argillaceous limestones, schists, and sands." It is further reported to comprise, as the pentoxide, up to 0·1 per cent of many French and Australian clays, 0·02—0·03 per cent of some basalts, 0·24 per cent of a coal of unknown origin, and 0·45 per cent of one from Peru. Still later examinations in this laboratory of about 100 rocks, chiefly igneous, covering the whole territory of the United States, show not only its general qualitative and quantitative distribution, but that it predominates in the less siliceous igneous rocks, and is absent, or nearly so, in those high in silica. In some of the more basic rocks, it occurs in sufficient amount to seriously affect the figures for the oxides of iron unless separately estimated and allowed for (see *prox.*, "Vanadium")—a matter of considerable importance, since the petrographer lays great stress on accuracy in their determinations.

This same investigation has also thrown some light on the distribution of molybdenum, which seems to be confined to the more siliceous rocks, and to occur in quantities far below those commonly found for vanadium.

Finally, had it not been the writer's practice of late years to look for sulphur in rocks, even when no sulphides were visible to the eye, its almost invariable presence in the form of sulphide, and consequent connection with the long mystifying lack of agreement between results for ferrous iron obtained by the Mitscherlich and the hydrofluoric acid methods, might not have been suspected. (See *prox.*, "Ferrous Iron").

While strongly upholding the necessity for more thorough work, necessarily somewhat at the expense of quantity, it is far from the writer's intention to demand that an amount of time altogether disproportionate to the immediate objects to be sought should be expended on every analysis. But it is maintained that, in general, the constituents which are likely to be present in sufficient amount to admit of determination in the weight of sample usually taken for analysis—say, 1 grm. for SiO_2, Al_2O_3, &c., to 2 grms. for certain other constituents—should be sought for, qualitatively at least, in the ordinary course of quantitative work, and their presence or absence noted among the results. If present in little more than traces, that knowledge alone may suffice, for it is often more important to know whether or not an element is present than to be able to say that it is there in amount of exactly 0·02 or 0·06 per cent. In the tabulation of analyses a special note should be made in case of intentional or accidental neglect to look for substances which it is known are likely to be present. Failure to do this may subject the analyst to unfavourable criticism, when at some future time his work is reviewed and the omissions are discovered by new analyses.

Finally, whenever possible, a thorough microscopical examination of the rock in thin section should precede the chemical analysis. This may be of the greatest aid to the chemist in indicating the presence of unusual constituents, or of more than customary amounts of certain constituents, whereby, possibly, necessary modifications in the analytical procedure may be employed without waste of time or labour.

(*Note.*—The foregoing tables and accompanying remarks, including several sentences preceding the tables, have been largely taken from the writer's papers entitled "A Plea for Greater Completeness in Chemical Rock Analysis," published in the *Journal of the American Chemical Society*, 1894, vol. xvi., pp. 90—93; also in the Chemical News, 1894, vol lxix., p. 163. See also "Distribution and Quantitative Occurrence of Vanadium and Molybdenum in Rocks of the United States," in the *American Journal of Science*, 1898, 4th Series, vol. vi., p. 209; and Chemical News, 1898, vol. lxxviii., p. 216).

II. *Object and Scope of the Present Treatise.*

The literature relating to analysis of silicates is extensive but scattered, and in no single article is there to be found a satisfactory exposition of the methods to be followed or the precautions to be observed, especially in the search for some of the rarer constituents or those which, without being rare, have been of late years recognised as occurring persistently in small amounts. It is not intended to make this article a treatise on mineral analysis, but it is believed that the experience gained by the chemists of this Survey during the twenty years since the establishment of its first chemical laboratory in Denver may be useful to most chemists interested in mineral and especially rock analysis.

The original publication of these data in *Bulletin* No. 148 was primarily intended to show the principles and methods according to which the major part of the very many hundreds of analyses therein brought together had been executed, and thus to furnish a partial measure of the trustworthiness of those analyses, rather than to serve as a practical manual of rock analysis. But the use which has been made by mineral chemists of that Bulletin has seemed to render it advisable to amplify somewhat in detail and to add, besides a few new methods, a number of alternative ones which are known or believed to be good, in order that those who may wish to use this treatise as a practical guide shall have a choice from which to select in case the rather expensive apparatus or complicated arrangements sometimes preferred are not available. Where silicate analyses are very frequently made, however, it is a saving of time and of money in the end to set up permanent arrangements for convenience in estimating water, carbon dioxide, ferrous iron, making reductions in hydrogen, &c.

Stress will be laid on those points meriting particular attention, and now and then a brief discussion or criticism of methods elsewhere in vogue may be entered into.

In the earlier years of the existence of the Washington laboratory opportunity was afforded for the testing of novel methods and the devising of new ones, with most excellent results, as shown especially by the methods for separation of titanium, of lithium, and of boron, due to Prof. F. A. Gooch, to whose inventive skill chemists owe likewise the perforated filtering crucible and the tubulated platinum crucible arrangement for the estimation of water. Of late years the press of routine work has been such as to more fully fill up the time of the much-reduced chemical force, and as a consequence it has been found impossible to subject to critical trial several separation methods of recent origin, some of which seem to be full of promise, or to follow out certain lines of investigation which have been suggested by the observations made in this laboratory. This, then, must be offered in explanation if, in the following discussion, it may seem to some that any of the methods followed are too conservative. In general, the discussion will be confined strictly to such separations as may be required in the analysis of an igneous, metamorphic, or sedimentary silicate rock of complex mineralogical composition, in which the majority—and possibly all—of the ingredients in the list given below may occur in weighable or readily discoverable quantities:—

SiO_2, TiO_2, ZrO_2, Al_2O_3, Fe_2O_3, Cr_2O_3, V_2O_3, FeO, MnO, NiO, CoO, MgO, CaO, SrO, BaO, ZnO, CuO, K_2O, Na_2O, Li_2O, H_2O, P_2O_5, S (usually as pyrite, not infrequently as pyrrhotite, occasionally as lazurite), SO_3, C (as graphite or coaly matter), CO_2, Fl, Cl, N.

The special problems often arising in the analysis of rocks of extra-terrestrial origin—the more or less stony meteorites—will not be considered. An analysis of that kind should never be entrusted to the novice, but only to the chemist who has a knowledge of the composition and properties of the peculiar mineral constituents of those bodies and a judgment fit to cope with the oftentimes difficult problems presented by them.

Thorium, cerium, and other rare earths are seldom

encountered in quantities sufficient to warrant the expenditure of the time necessary for their isolation. A search for them qualitatively even is at present rarely justifiable, unless there is microscopic or other evidence of the presence of minerals likely to contain them. Tantalum, columbium, boron, and glucinum have never been certainly met with in the writer's experience, and yet they must be present in certain rocks, and doubtless traces have been overlooked at times. There is no reason to suppose that other elements may not be found by careful search, possibly all in the known category, and, indeed, Sandberger's researches have shown to what an extent this is true of a large number of those elements contributing to the filling of metalliferous veins. But those in the above list may usually be estimated with ease in weights of from ½ to 2 grms.

If the point be raised that many of the published analyses emanating from the Survey laboratories, even the earlier ones of the writer, are not in accord with the advocacy of completeness contained in the foregoing remarks, it may be remarked that these ideas have been to a considerable degree evolved during a personal experience of twenty years in this line of work, and that frequently the exigencies were such as to compel restriction in the examination. Where the latter has been the case, subsequent developments have in some cases shown it to be bad policy in every respect. It is better, both for the geologist and the chemist, to turn out a limited amount of thorough work than a great deal of what may prove to be of more than doubtful utility in the end.

III. *Statement of Analyses.*

Until recently it has been the practice in this laboratory to tabulate the constituents of a rock somewhat in the order of their determination, beginning with SiO_2 as the chief constituent, and grouping together all chemically related oxides, as shown, for instance, in Tables I. and II.

From a strictly scientific point of view, a chemical classification founded on a separation into basic and acidic atoms or radicals would be more satisfactory, but until we learn to find out what silicic radicals are present, and in what relative amounts, also how much free silica there may be, it is useless to think of employing the arrangement so valuable in stating water analyses.

Of late petrographers have begun to demand, with considerable reason, an arrangement "which shall bring the essential chemical features—both the percentage figures and the molecular ratios—prominently and compactly before the eye, so that the general chemical character and the relations of the various constituents may be seen at a glance" (H. S. Washington, "The Statement of Rock Analyses," *Amer. Journ. Sci.*, 1900, Series 4, vol. x., p. 61).

In accordance with this demand it is now our practice to follow pretty closely the arrangement proposed by Pirsson, and very recently strongly advocated by Washington (*loc. cit.*), namely:—

SiO_2, Al_2O_3, Fe_2O_3, FeO, MgO, CaO, Na_2O, K_2O, H_2O (above 105—110° C.), H_2O (below 105—110° C.), CO_2, TiO_2, ZrO_2, P_2O_5, SO_3, Cl, Fl, S(FeS_2), Cr_2O_3, V_2O_3, NiO, CoO, CuO, MnO, SrO, BaO, Li_2O, C, Nh_3.

By this arrangement the nine constituents which in the great majority of cases determine the character of the rock are placed at the head of the list, thus greatly facilitating the comparison of different analyses similarly arranged, especially when, as Washington recommends, the molecular ratios are calculated for these leading constituents, and placed immediately after the corresponding oxides. The order of the remaining members is determined some what by the following considerations:—CO_2 is placed next after H_2O, since these two are generally a measure of the alteration the rock may have undergone. TiO_2 and ZrO_2 naturally follow CO_2 on chemical grounds, and SO_3 and Cl, being common constituents of the sodalite group, are conveniently placed together.

Fig. 1.—Platinum-tipped Crucible Tongs.
The parts A B, also of heavy platinum, are hollow, to serve as sockets for the cheaper metal of the handles.

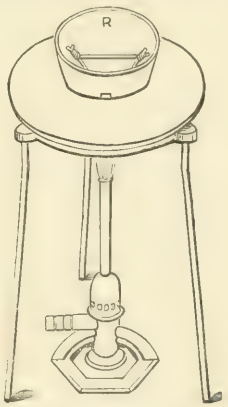

Fig. 2.—Radiator for Rapid and Safe Evaporation.
R is of sheet iron, also nickel (Jannasch). Various sizes. A convenient height is 7 c.m., width at top 7 c.m., and at bottom 5 c.m.

IV. *Time Needed for Making an Analysis.*

The question has often been put, "How long does it take to complete an analysis of this kind?" This will depend, of course, on the mineral complexity of the sample and on the personal factor of the individual worker. If there is a competent assistant to do the grinding, and specific-gravity determinations are not required, it is quite possible after long experience for a quick worker to learn to so economise every moment of time in a working day of seven hours, with an abundance of platinum utensils and continuous use of air and water-baths through the night, as to finish every three days, after the completion of the first analysis, barring accidents and delays, one of a series of rocks of generally similar character, each containing from eighteen to twenty quantitatively determinable constituents, excluding, for instance, fluorine, carbon

as such, nitrogen, metals of the hydrogen sulphide group, and cobalt. On one occasion a series of fourteen rocks, of comparatively simple composition, was completed in one month, with the help of an assistant who made the phosphorus and ferrous iron determinations. But such an output of work is more than exceptional, and implies an unusual freedom from those occasional setbacks to which every chemist is exposed.

It should here be remarked that the Survey laboratory is most exceptionally well equipped with all kinds of platinum vessels and utensils, so that it is rare indeed for delay to arise through lack of dishes of even the largest sizes.

V. *Two Useful Aids in Chemical Manipulation.*

In connection with the foregoing remarks it is in place to mention two aids to the chemist which are in constant use in this laboratory, and have come to be well-nigh indispensable. Neither is novel in principle, and both are in use elsewhere, but they are not so commonly known as they deserve to be, hence this allusion to them.

Fig. 1 represents a form of platinum-tipped crucible tongs devised by Dr. A. A. Blair many years ago. With them a crucible can be securely grasped and brought into any desired position while still hot. To the contents, if in fusion over the blast flame, can be imparted the rotatory motion so often desirable. Above all, the cover need not be in the slightest degree displaced, as when using the common form of platinum-tipped tongs.

Fig. 2 represents a very useful adjunct to the work-table and especially to the draught cupboard, wherein the liquid contents of crucibles can be speedily evaporated at almost any desired temperature, and the dehydration of many solids effected much more safely than on an iron plate or sand-bath. I do not recall who orginated this form of air-bath, but it has been in use here for over fifteen years, and is identical in principle with the later Nickel-becher of Jannasch. Nickel undoubtedly has a certain advantage in not rusting as does iron, but the form depicted in R of Fig. 2 can easily be made anywhere of sheet iron rivetted at the joint, the bottom (not shown in the figure), being securely held by a flange at the extremity of the truncated cone. A crucible placed on the platinum triangle becomes uniformly heated by hot air, and large quantities of liquid, even sulphuric acid, can be thus volatilised in a short time without ebullition or spattering.

(To be continued).

PROCEEDINGS OF SOCIETIES.

ROYAL INSTITUTION ADDRESS TO THE KING.

At the General Monthly Meeting of the Royal Institution held on Monday last, the 4th inst., the following Address to the King was read and approved, and authorised to be signed by His Grace The Duke of Northumberland, K.G., the President, on behalf of the Members:—

To the King's Most Excellent Majesty.

The humble Address of the Members of the Royal Institution of Great Britain.

Most Gracious Sovereign,

We, your Majesty's most loyal and dutiful subjects, the Members of the Royal Institution of Great Britain, established for the promotion of Science, Literature, and the Arts, respectfully crave leave to approach your Sacred Person with expressions of our heartfelt sorrow at the loss sustained by your Majesty, the Royal Family, the Empire, and the World at large, in the death of your Majesty's revered Mother, our late most gracious and beloved Sovereign and Patron of this Institution: and also to testify our unfeigned congratulations upon your Majesty's Accession to the Throne, as well as our sincere attachment to your Royal Person.

That your Majesty may long live in Prosperity and Happiness over a free and affectionate people is the sincere wish and earnest prayer of

Your Majesty's Loyal and Dutiful Subjects,
The Members of the Royal Institution of Great Britain.

The President, in moving a Vote of Condolence on the Death of Her late Majesty, remarked that Her Majesty had been for the whole of Her reign the Patron of this Institution. She had shown her keen appreciation of the value of scientific study and research by the honours she had conferred from time to time on those who followed them. There was one signal act of kindness which should be recorded in connection wth this Institution, namely that she gave to Professor Faraday rooms in Hampton Court Palace, and that when he found himself unable to meet the expense of necessary repairs she took it upon herself. Her Husband and Sons had been frequent attendants at our Lectures, but perhaps the highest debt of gratitude which scientific men owed to our late Sovereign was that she had by her wisdom and skill secured them through a prolonged reign the utmost freedom and tolerance of thought and action, combined with complete order and stability of government, a condition of things most favourable to the pursuit of Science. He was sure that the Members of the Royal Institution shared to the fullest extent the regard which the whole of her people, from the lowest to the highest, had evinced to her memory.

NOTICES OF BOOKS.

Inorganic Chemistry, Non-metallic and Metallic Elements. By Raphael Meldola, F.C.S. Revised to date by J. Castell Evans, F.I.C. Fifth Edition. London: Thomas Murray.

Professor Meldola's Chemistry made its first appearance more than twenty years ago, and it speaks well for the care with which it was originally prepared, that it has been steadily in demand up to the present date, though unrevised till now.

The author's original aim was not to provide the student with a means of cramming, so as to simply get through an examination, but to compress as much thorough, sound chemistry as possible into a small space, making a book that not only would bear, but required to be closely studied.

Owing to the recent rapid advance made in all branches of chemical science, the book naturally fell a little behind the times; the necessary revision has, however, now been taken in hand, and the book has been brought up to date while retaining its characteristic excellence.

The greatest change will be found in the sections devoted to the metallic elements; these have been rearranged in accordance with Mendeleeff's law, and are quite up to the standard of the earlier editions.

Report of the Senior Analyst, Cape of Good Hope, for the Year 1899. Cape Town: W. A. Richards and Sons. 1900.

Although in some respects there has been a falling off in the number of articles analysed, there has been on the whole a considerable increase owing to the work under the Food, Drugs, and Seeds Adulteration Act having been more regularly maintained than in former years. The total number of samples analysed during the year 1899 was 1903, compared with 1650 and 979 in the two previous years. There have been most samples of milk analysed, viz., 481, closely followed by sea-water, 397; then come soils, 161, and water, 142.

With regard to the analysis of sea-water, it is stated that "these analyses have been continued on behalf of the Colonial Marine Biologist. No special remarks need here be made concerning them." It would be interesting to know why such a large number (397) were undertaken, whereas there were only 142 analyses made of ordinary or so-called potable waters. In connection with these latter we may recall the well-known fact that South Africa is a fever-stricken country; this is not to be wondered at when we look over a few of the analyses of waters of which details are given. As an example of the extent to which animal pollution can go we cite the analyses of a well-water at Retreat Police Station:—

Total solids	66·92	grms. per gallon
Chlorine	18·81	„ „
N as Nitrates	0·052	„ „
N as Ammonia	1·202	parts per million
Oxygen absorbed from permanganate in four hours	129·362	„ „
Colour	Dark brownish red	
Appearance	Clear	

This is, of course, an extreme case, but there are numerous other analyses given in which the oxygen absorbed is 11·1, 9·6, 8·1, 7·6, 8·8, &c., parts per million. We are not surprised that such waters as these are condemned as being unfit for human consumption.

The Chemists' Pocket Manual; A Practical Hand-book containing Tables, Formulas, Calculations, Physical and Analytical Methods, for the use of Chemists' Assayers, Metallurgists, Manufacturers, and Students. By G. Richard K. Meade, B.S., Instructor in Chemistry in Layfayette College, Easton, Pa. Easton, Pa.: The Chemical Publishing Company. 1900.

It is a pity that this useful and up to date little manual has not been translated into English, for valuable though it undoubtedly is to American workers it is not likely in its present form to come into great use here. The words sulfur, sulfuric, oxid, hydroxid, and liter look strange, while the ton of 2000 pounds, and the gallon of 231 cubic inches are liable to cause confusion. At the same time there will be found a mass of useful and original data condensed into a small compass; the several examples of graphic methods for saving calculations are very good; examples are given of a table on squared paper for instantly finding the equivalent weights of magnesium pyrophosphate and phosphorus pentoxide, conversion of $Mn_2P_2O_7$ into Mn, $Mg_2P_2O_7$ into MgO, &c. The main object in the book appears to be to "save time." There is a good index, and it is well printed on thin but strong paper, with a flap and band to close it for the pocket.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Note.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, del'Académie des Sciences. Vol. cxxxii., No. 2, January 14, 1901.

Researches on the Formation of Organic Compounds containing Sulphur.—M. Berthelot.—During previous researches, the author examined thermo-chemically carbon disulphide, thiophene, taurine, and the isomers of the sulphocyanic compounds, and he now examines certain fundamental bodies, such as the alcohols and simple ethers; this preliminary examination being devoted to the alcohols containing sulphur, otherwise called mercaptans. The heats of formation, of molecular combustion at constant pressure, and formation from the elements, were found in the case of ethylic mercaptan, C_2H_6S; ethyl sulphide, $C_4H_{10}S$; amylic mercaptan, $C_5H_{12}S$; amyl sulphide, $C_{10}H_{22}S$; and allyl sulphide, $C_6H_{10}S$.

New Researches on the Isomerism of Sulphocyanic Ethers.—M. Berthelot.—It is known that two isomeric series of sulphocyanic ethers exist, under the names of normal sulphocyanides and isosulphocyanides; the latter being the more stable. The author proves that this difference of stability is explained by the thermochemical relations, the transformation from normal sulphocyanides into isosulphocyanides being accompanied by evolution of heat (+10·5 cal. for the methylic ethers, and +9·0 cal. for the ethylic ethers). In each case the substance was burnt in the calorimetric bomb; an estimation each time being made of the sulphur transformed into sulphuric acid during the combustion.

Gaseous Products Evolved when certain Igneous Rocks are Heated.—Armand Gautier.—The author's researches on the origin of atmospheric hydrogen and on the constitution of deep-sea water, led him to the examination of rocks, which, at the moment when they were fixed in their actual position, supported an enormous pressure due to superposed layers. He has already noticed that the mineral acids towards 100°, and pure water itself towards 300°, cause the evolution of a considerable proportion of gas rich in hydrogen from powdered granite. This same evolution occurs from all the igneous rocks which were examined. The quantity and the composition of these gases vary from each specimen, and even from different pieces of the same rock. The gases from various rocks were analysed, and the results are given in this paper.

Action of Hydrogen on Bismuth Protosulphide.—H. Pélabon.—The protosulphide of bismuth, BiS, obtained by melting together bismuth and sulphur in proper proportions, is reduced by means of hydrogen if it is heated in a current of this gas. Inversely, melted bismuth decomposes sulphuretted hydrogen gas. If these reactions take place in a space in which every point is at the same temperature, the two reactions lead to a chemical equilibrium. The author examines the two cases:—(1) When the temperature of the experiment is between the fusion-points of bismuth and of its sulphide; (2) when the temperature is above the fusion-point of the sulphide. It is found that the proportion of sulphuretted hydrogen increases very regularly, starting from zero, in the same way as the proportion of bismuth sulphide, and the relation between the mass of sulphuretted hydrogen and the total mass (ρ), tends towards the number 0·893 when the relation between the weight of undecomposed sulphide to the weight of the mixture formed by this body and the bismuth liberated (R) tends towards 1.

Chlorobromides of Thallium of the Type $ThX_3.3ThX$.—V. Thomas.—As a result of the author's researches, he concludes that if the thallium chlorobromides, $Th_4Cl_4Br_2$ and $Th_4Cl_2Br_4$, exist—which is, apparently, doubtful—they are not stable, and decompose during crystallisation, giving $Th_4Cl_3Br_3$. This latter chlorobromide has a very regular form, and is produced when the solution from which it is crystallised is dilute. When, on the contrary, the solution is concentrated and sufficiently rich in thallium compounds, the chlorobromides which are formed are different, and appear to be of the general type ThX_3ThX.

A New Method of Preparation of the Hydrates of Sodium Peroxide and their Properties.—Georges F. Jaubert.—If sodium peroxide is exposed to the action of damp air, free from carbon dioxide, water is absorbed by the peroxide with no evolution of gas. From this it is apparent that hydrates of the peroxide are formed. These probably are $Na_2O_2+2H_2O$ and $Na_2O_2+8H_2O$, besides intermediate hydrates yet unknown. The hydrate $Na_2O_2+8H_2O$ is very stable in the cold, but when heated

to between 30° and 40° it undergoes partial decomposition, and between 80° and 100° the decomposition is total.

Determination of Latent Heats of Vaporisation of certain Organic Compounds.—W. Louguinine.—The author determines the quantities of heat evolved in the calorimeter during condensation of the vapour of the following substances, and from the numbers obtained calculates the latent heat of vaporisation:—Aniline, 104·17; methylethylacetoxime, 115·73; anisol, 80·30; and butyronitrile, 115·25.

MISCELLANEOUS.

Royal Institution.—A General Monthly Meeting of the Members of the Royal Institution was held on the 4th inst., Sir James Crichton-Browne, Treasurer and Vice-President, in the Chair. Mr. J. Boldero, Mr. J. Y. Buchanan, Mr. A. Lyttleton, Mr. J. Macfadyen, Mr. A. W. Reed, Major J. M. Rogers, Mr. D. Weston, and Dr. T. T. Whipham, were elected Members. The special thanks of the Members were returned to Sir Frederick Abel, Bart., K.C.B., for his donation of £50, and to Professor Dewar for his donation of £50, to the Fund for the Promotion of Experimental Research at Low Temperatures. The following Resolution, passed by the Managers, was read:—"Resolved, That the Managers of the Royal Institution desire to record their sense of the loss sustained by the Institution in the decease of Mr. Basil Woodd Smith, F.R.A.S., F.S.A. He became a Member of the Royal Institution in 1853, and was elected a Visitor in 1876, and a Manager in 1889. He has always taken a warm interest in the welfare of the Institution, and for many years as Manager and Vice-President he rendered valuable assistance in the transaction of the business affairs and concerns of the Institution. The Managers further desire to offer to the Family the expression of the most sincere sympathy with them in their bereavement."

Note on the Action of Sulphuretted Hydrogen on Peroxide of Lead.—L. Vanino and O. Hauser.—When we pass SH_2 over peroxide of lead, either dry or moist, the mass becomes incandescent, and the sulphuretted hydrogen burns with the livid blue flame of lead; peroxide of bismuth gives rise to the same occurrence. Hilger, Silge, and van Scherpenberg have already mentioned this phenomenon, but they only observed it with the dried reagents. This reaction may be utilised for communicating fire to explosive mixtures. Thus, gun-cotton completely saturated with water, can be ignited by means of sulphuretted hydrogen and peroxide of lead. Picrate powder, the metallic aluminium, zinc, and bismuth powders can also be ignited by this means; to ensure the reaction taking place it is necessary for the binoxide of lead to be collected together in a mass, and not spread over a surface.—*Berichte*, vol. xxxiii., p. 625.

MEETINGS FOR THE WEEK.

Monday, 11th.—Society of Arts, 8. (Cantor Lectures). "The Bearings of Geometry on the Chemistry of Fermentation," by W. J. Pope.

—— Royal Institution, 3. "The Origin of Vertebrate Animals," by Arthur Willey, M.A., D.Sc.

Tuesday, 12th.—Royal Institution, 3. "Practical Mechanics" (Experimentally treated), by Prof. J. A. Ewing, M.A., F.R.S., M.Inst.C.E.

—— Society of Arts, 8. "Recent Advances in Pottery Decoration," by William Burton.

Wednesday, 13th.—Society of Arts, 8. "Arsenic in Beer and Food," by William Thomson, F.I.C.

Thursday, 14th.—Society of Arts, 4.30 (at the Imperial Institute, South Kensington). "The Greek Retreat from India," by Col. Sir T. Hungerford Holdich, R.E., K.C.I.E., C.B.

—— Royal Institution, 3. "Society in France before the Revolution," by the Rev. Henry Grey Graham.

Friday, 15th.—Royal Institution, 9. "Electric Waves," by The Rt. Rev. Monsignor Gerald Molloy, D.D., D.Sc.

Saturday, 16th.—Royal Institution, 3. "Vocal Music, its Growth and Decay," by F. Corder, F.R.A.M.

New Term Commenced January 7th.

BIRKBECK INSTITUTION,

Bream's Buildings, Chancery Lane, E.C.

PRINCIPAL: G. ARMITAGE-SMITH, M.A.

DAY AND EVENING CLASSES.

UNIVERSITY OF LONDON.—Complete Day Courses for all the Examinations in Science, and Complete Evening Courses for all the Examinations for the Science, Arts, and Law Degrees.

SCIENCE CLASSES in every Branch, with Practical Work. Well equipped Laboratories for CHEMISTRY, PHYSICS, and METALLURGY.

CONJOINT BOARD: Lectures and Practical Work in Chemistry, Physics, Biology, and Practical Pharmacy.

Prospectus free. Calendar 6d. *(by post* 8d.*) on application to Secretary.*

IMPORTANT TO EXPORTERS.

The Firm of E. HEUER, Chemical Manufactory, in Aussig, Austria, begs to call the attention of Exporters to the Exporting Products of the Factory.

ALCOHOL DERIVATIVES in general, and in particular Ethers of all kinds, such as Sulphuric, Acetic, Rum, Formic, Nitrous, Œnanthic, Butter, Fruit, Grain, and Saccharine Ethers in every specific gravity, all degrees of concentration, and grades of purity.

ABSOLUTE ALCOHOL—98, 99, 99 2/3, and 99 5/7 per cent.

SUPERIOR RUM ESSENCES in all concentrations and contents of spirits.

FIRST CLASS FRUIT ESSENCES, Amylic Alcohols, Amylic Acetates, and Amylic Oxides.

PHARMACEUTICAL CHLOROFORM and Special Brand E.H. CHLOROFORM for Narcosis.

Special Brand E.H. SULPHURIC ETHER for Narcosis.

Correspondence desired.

THE CHEMICAL NEWS.

Vol. LXXXIII., No. 2151.

ON THE PROTEID REACTION OF ADAMKIEWICZ, WITH CONTRIBUTIONS TO THE CHEMISTRY OF GLYOXYLIC ACID.*

By F. GOWLAND HOPKINS, M.A., M.B., University Lecturer in Chemical Physiology, and SYDNEY W. COLE, B.A., Trinity College.

In 1874 Adamkiewicz (*Pflüger's Archiv.*, 1874, vol. ix., p. 156), described the now familiar reaction which results in the production of a violet colour when strong sulphuric acid is added to the solution of a proteid in glacial acetic acid. Adamkiewicz did not apparently look upon the employment of the acetic acid as introducing anything beyond a certain modification of the action of sulphuric acid. His original communication opens with a description of the colour phenomena seen when egg-white is dissolved in strong sulphuric acid; and he begins the description of this reaction, since associated with his name, by speaking of "a special influence which the presence of glacial acetic acid has upon the colour of the sulphuric acid proteid solution." The view has since been generally held that the coloured product of the reaction arises entirely from the proteid molecule itself, as the result of an interaction between precursors liberated under the influence of the strong acids employed.

V. Udranszky (*Zeitsch. f. Physiol. Chem*, 1888, vol. xii., p. 395), believed that the colour change which occurs is, as a matter of fact, to be classed as a furfurol reaction. It is therefore to be compared with the result of such a procedure as that of Molisch's test, in which β-naphthol and sulphuric acid are added to a proteid solution. While in the latter the added naphthol is held to react with furfurol from the proteid; in the Adamkiewicz reaction both the furfurol and a substance capable of reacting with it are supposed to be liberated from the proteid molecule. Such we believe is the prevalent view. Of late years, the Adamkiewicz reaction has been much employed as giving evidence for the presence of carbohydrate groups in certain proteid derivatives, and of its absence from others. More than one writer (*Cf.* Halliburton, "Schäfer's Text Book of Physiology," vol. i., p. 47), however, has referred to an element of uncertainty in the reaction, and it is easy to gather from the literature that this has been commonly observed (*Cf.* Salkowski, *Zeitsch. f. Physiol. Chem.*, vol. xii., pp. 220, 222).

In what follows it will be shown that the mechanism of the reaction has been wholly misunderstood. Proof will be given that the use of acetic acid introduces an extraneous and perfectly specific factor into the reaction, involving the addition of a substance quite necessary to the formation of the coloured product. This substance, moreover, is not acetic acid itself, but an impurity, which, though very generally present, is admixed in varying quantity, and is occasionally absent.

I. *The Reaction due to an Impurity in Acetic Acid.*

We were led to pursue the following investigation by observing that, with a specimen of acetic acid in use in this laboratory last year, it was impossible under any circumstances to obtain the Adamkiewicz reaction.

No matter what form of proteid might be employed, when its solution in this acetic acid was mixed with sulphuric acid, a yellow or brown, slightly fluorescent mixture was all that could be obtained. No modification in the order of the procedure, or in the proportion of the two acids employed, resulted in the production of any trace of red or violet colour.

We afterwards obtained a number of specimens of acetic acid from various makers, and were surprised to find that no small proportion of these gave equally negative results; while, of the remainder, some yielded a much more intense reaction than others, although employed under precisely similar conditions.

Either, therefore, the negative result with particular specimens was due to the presence of some impurity capable of interfering with the production of colour, or the reaction itself must be due to a substance commonly, though not universally, present as an impurity in acetic acid.

We soon obtained evidence that the latter alternative must be accepted. For we found that whenever a specimen of glacial acetic acid yielding a positive result is partially crystallised by freezing, the power to yield the reaction is diminished in the crystals and increased in the mother liquor. It is possible indeed, by repeated recrystallisation, to obtain glacial acid wholly incapable of giving the reaction.

Much more readily, however, is the reactive substance to be concentrated by distillation. Any specimen of glacial acetic acid, if distilled, will yield the whole of any chromogenic substance it may contain in the first runnings. After concentration to about half-bulk—more or less according to the proportion of reactive substance originally present—the residue will yield no trace of red or violet colour when mixed with proteid and sulphuric acid; while, on the other hand, the distillate twice or thrice fractionated yields the reaction with greatly increased intensity.*

It is easy to understand therefore why different specimens of acetic acid obtained in the market yield the reaction with different degrees of intensity, as this will depend upon the stage at which they were collected during distillation in bulk. It is also clear why the reaction has been looked upon by different observers as an uncertain one.

The accepted view, that the colour phenomenon is due to the interaction of two chromogenic groups, both derived from the proteid molecule under the action of the mixed sulphuric and acetic acids, is certainly erroneous. One factor necessary to the reaction is supplied by a substance admixed with the acetic acid. That it is in no sense a furfurol reaction is indicated by the fact that the addition of furfurol confers no power of yielding the colour with proteid upon a specimen of acetic acid previously without it; and, on the other hand, when furfurol is added to acetic acid containing the chromogenic substance in abundance, there is equally a complete absence of the reaction upon mixing with strong sulphuric acid.

II. *Nature of the Substance responsible for the Reaction.*

Our earlier attempts actually to isolate the active substance from acetic acid by fractional distillation were unsuccessful; and, having regard to the fact that, in a reagent so familar as acetic acid, no admixture could well have been hitherto overlooked unless the substances were present in very small amount, we determined to seek first for indirect evidence, such as might give at least some indication as to the kind of substance we had to deal with.

To this end we set out to add to acetic acid, previously deprived by distillation of its chromogenic admixture, various compounds of typical constitution, in the hope that we might find among these some that would yield at least an analogous reaction.

Wholly negative results were obtained with various homologous fatty acids; with formic, acetic, and propionic

* From the Physiological Laboratories, Cambridge. A Paper read before the Royal Society, February 7, 1901.

* This applies to glacial acid; with dilute acid of lower boiling-point, concentration of the product by distillation is less easy.

aldehydes; with acetone, and with various ethereal acetates and other esters.

But, during this preliminary stage of our investigation, the interesting observation was made that formic acid prepared from pure glycerin and pure oxalic acid, and used instead of acetic acid under the ordinary conditions necessary for the reaction, may yield the colour in a perfectly typical manner; the spectroscopic absorption of the product obtained being identical with that seen when acetic acid is used. But from the formic no less than from acetic acid, the chromogenic substance may be distilled off, appearing always in the earlier portions of the distillates, and leaving the remainder of the formic acid to yield wholly negative results.

This result—the explanation of which becomes clear in the sequel—appeared to limit somewhat the ground we had to traverse in our search.

A further and still more definite limitation came to light when we found that the reactive substance in acetic acid is not an impurity of wholly extraneous origin, but is a derivative of acetic acid itself. When a quantity of acetic acid wholly free from the reactive substance has stood for a few weeks, a reaction may always be obtained once more from the earliest portions of a distillate; and, after standing for a month or two, even the bulk may yield a colour of moderate intensity. (*Cf. infra*).

When, again, a pure acetate, and especially calcium acetate, is distilled with excess of sulphuric acid, the first runnings always give a marked Adamkiewicz reaction, though later portions give none. This is true even when the acetate has been made by neutralising acid which was itself wholly incapable of giving a reaction.

Lastly, among the products of the dry distillation of most acetates small quantities of a substance are found which react with proteid in a typical manner. In the case of calcium acetate the reaction obtainable is a marked one—though, as stated above, the active substance is certainly not acetone—while with an aqueous extract of the products of the dry decomposition of mercuric (not mercurous) acetate the reaction with proteid is intense.

With such indications as these facts afforded, we now fortunately elected to experiment with various two-carbon compounds of typical structure, such as might conceivably arise from acetic acid, by oxidation or otherwise.

The first positive evidence came to light when we set out to prepare glycollic aldehyde by Fenton's method (*Journ. Chem. Soc.*, 1895, vol. lxvii., p. 778). As a mere preliminary observation, we oxidised tartaric acid in solution, by means of peroxide of hydrogen in the presence of a little ferrous sulphate, without taking especial care to keep the mixture at 0°, and without attempting to separate the dioxymaleic acid formed. A little of the oxidised solution was heated direct on the water-bath till all evolution of CO_2 had ceased, and then cooled. A trace of Witte's peptone was added to the solution, which was free from excess of peroxide, and then strong sulphuric acid. An intense colour reaction was obtained exactly similar to that seen in a normal Adamkiewicz reaction when carried out with acetic acid rich in the chromogenic substance. The solution gave also in the spectroscope an exactly similar absorption band.

We found subsequently, however, that glycollic aldehyde, isolated, either in the syrupy or crystalline condition,* and whether in aqueous or acetic acid solution, gave no colour reaction under like conditions, but yielded only a charred product when the sulphuric acid was added. Moreover, acetic acid, however rich in the chromogenic substance, never reduces (after neutralising) alkaline copper solutions. A reduction of ammoniacal silver solutions may be obtained, but never any effect upon Fehling's solution.

We came to the conclusion therefore that the substance sought must be an oxidation product of glycollic aldehyde; and we now found that the latter needs only to be treated by Fenton's oxidation method carried out at the temperature of the water-bath to give a product, which, when free from excess of peroxide, yields in acetic or aqueous solution the proteid reaction abundantly.

At this time we made another observation of the greatest assistance to our inquiry, finding that the chromogenic substance is produced in abundance when oxalic acid is reduced in aqueous solution by means of zinc and sulphuric acid, or, more conveniently, by sodium amalgam.

The reduction need last for a few minutes only, and a little of the solution, without further treatment, will then be found to give an intense colour with proteid and sulphuric acid, the product showing spectroscopic appearances identical with those of the ordinary Adamkiewicz reaction.

There was now no doubt that a colour reaction, not to be distinguished from that of Adamkiewicz, is yielded by a substance which is at once an oxidation product of glycollic aldehyde, and a reduction product of oxalic acid. It was difficult to see how this substance could be other than glycollic acid, glyoxylic acid, or glyoxal.

Pure glycollic acid was obtained from Merck. It gave no trace of a colour reaction with proteid solution and sulphuric acid. The product of its oxidation by Fenton's method reacted, however, in a perfectly typical manner, and Fenton and Jones have found that this product is glyoxylic acid.

The latter was therefore prepared from alcohol by the method of Debus. The calcium glyoxylate first obtained was re-crystallised thrice. A minute crystal of the salt dissolved in water, together with a little proteid, gave, upon the addition of strong sulphuric acid, a vivid colour reaction not to be distinguished, spectroscopically or otherwise, from the reaction of Adamkiewicz.

Glyoxal, prepared subsequently from the products of the same Debus oxidation, gave no trace of such a reaction.* When glyoxylic acid is added to glacial acetic acid previously deprived of its chromogenic power by distillation, further distillation now yields a distillate which reacts typically, and the glyoxylic acid comes over characteristically, like the original chromogenic substance in the earlier fractions.

III. *Glyoxylic Acid from Acetic Acid.*

It now became necessary to ascertain whether glyoxylic acid is, as a matter of fact, present in such specimens of acetic acid as yield the Adamkiewicz reaction.

In seeking for evidence as to this, it was necessary to remember that exceedingly little glyoxylic acid is necessary to the reaction. With an aqueous solution of such strength as will give no more than an opalescence with phenylhydrazine, the colour reaction with proteid is well marked.

It was found, however, that oxidation with hydrogen peroxide confers abundant chromogenic power upon acetic acid previously giving no proteid reaction: and it was our first endeavour to ascertain whether, as a result of this, glyoxylic acid is produced in quantity sufficient for its easier identification.

The presence of small quantities of ferrous iron accelerates the oxidation, and is, perhaps, essential to it.† The process occurs most rapidly at boiling temperature, and proceeds most satisfactorily when the acetic acid is repeatedly distilled with the peroxide. The limit of the oxidation is in any case soon reached. Using twenty

* Fenton and Jackson, *Journ. Chem. Soc.*, 1899, vol. lxxv., p. 575. We were indebted to Mr. Hy. Jackson for a supply of the crystalline aldehyde.

* Many specimens of commercial glyoxal give the reaction, but only, as we have found, when they contain glyoxylic acid; preparations of glycollic acid may contain traces of the latter.

† We have found that some specimens of peroxide bring about the oxidation without the addition of iron; others undoubtedly act much less readily, unless a ferrous salt is added. While we have been unable to detect the presence of iron in the former, so small a quantity appears to affect the reaction that it is possible a trace of the metal present as an impurity may account for the difference.

volumes strength, the peroxide is found to be rapidly destroyed till a volume has been added about equal to that of the acetic acid taken; after this the reaction becomes very slow.

We proceeded as follows:—A litre of glacial acetic acid was mixed with an equal bulk of twenty-volume peroxide and some ammonio-ferrous sulphate added (half a grm. per litre, or less). The mixture was slowly distilled nearly to dryness, and the distillate returned and again distilled. The second or third distillate usually showed freedom from peroxide when tested with chromic acid; if not, distillation was repeated.

One-tenth of the final distillate was set aside, and the remainder neutralised with potash. The still acid portion being then mixed with the rest, the whole was distilled as low as possible, avoiding, however, any separation of potassium acetate in the retort. The distillate always gave an abundant proteid reaction, and if any trace of free peroxide had been left at the previous stage, it always disappeared during the distillation of the partially-neutralised mixture as just described. A small trace of free peroxide will interfere with the proteid reaction. On adding phenyl hydrazine hydrochloride (without acetate) to the distillate thus obtained, a light yellow precipitate begins to separate almost at once, and after standing it becomes considerable in amount, and is crystalline. But although, as we were able to show, the hydrazone of glyoxylic acid is present in this precipitate, it is mixed with a considerable proportion of a compound much less soluble in acetic ether and in hot water. If the original precipitate be re-crystallised from a minimal quantity of acetic ether, the substance which separates first consists of perfectly colourless glistening plates, which after re-crystallising from acetic ether may assume the form of rosetted prismatic needles. These melt sharply at 184°.

The nature of this substance became clear after the publication of certain recent observations. Gerhard Ollendorff has shown that formic aldehyde is formed when glycollic acid is oxidised with peroxide of hydrogen, and Fenton (*Journ. Chem. Soc.*, 1900, vol. lxxvii., p. 1296), calls attention to the fact that glyoxylic acid must in this case be the intermediate product. The product we obtained from acetic acid was undoubtedly the compound of formaldehyde described by Wellington and Tollens (*Deutsch. Chem. Ges. Berichte*, 1885, vol. xviii., p. 3330).

A portion repeatedly re-crystallised from acetic ether and showing a constant melting point (184°) was analysed.

0·147 grm. gave 27·4 c.c. moist N at 12° and 758 m.m. N = 22·07 per cent.

Another preparation, re-crystallised from a mixture of alcohol and toluol, melted at 182—183°; of this—

0·211 grm. gave 39·3 c.c. moist N at 14° and 758 m.m. N = 21·87 per cent.

I.	II.	Calculated for $C_{18}H_{16}N_4$.
22·07	21·87	22·22

This hydrazone can be obtained pure in the above manner with great ease if not more than 4 to 5 grms. of phenylhydrazine hydrochloride have been added to the final distillate obtained after oxidising, as above, 1 litre of acetic acid, nearly neutralising the mixture, and distilling. We prepared the compound from formaldehyde, and found it to agree with our product in every particular.

Formaldehyde certainly does not yield the proteid reaction, and its formation when acetic acid is treated as described seems to be in itself evidence for the formation of glyoxylic acid during the process, as it is difficult to see how it could arise during the oxidation of acetic acid if not from a preliminary formation of glyoxylic acid with subsequent loss of carbon dioxide.

But its formation adds greatly to the difficulty of obtaining pure the hydrazone of glyoxylic acid itself, especially as the precipitate produced by phenylhydrazine undoubtedly contains, in addition to the compound of Wellington and Tollens, smaller amounts of the derivatives described by J. W. Walker (*Journ. Chem. Soc.*, 1896, vol. lxix., p. 1280).

After the nature of this by-product was recognised we modified our procedure by neglecting the earlier portions of the final distillate which contains, of course, the greater part of the formaldehyde. Phenylhydrazine hydrochloride added to the latter half, or two-thirds, of such a distillate yields a precipitate which forms more slowly than that obtained when the whole is dealt with. After twenty-four hours it is usually crystalline and of a yellow colour, growing darker with further standing.

We found it easier to obtain a product with a constant melting point by re-crystallising from hot water rather than from an organic solvent, prolonged heating with the water being at any stage avoided. This treatment involves considerable loss, however, and we obtained only about 4 decigrms. of the hydrazone after oxidising 3 litres of acetic acid. This, however, had all the characters of glyoxylic hydrazone, and melted sharply at 137°.

0·204 grm. gave 30·4 c.c. moist N at 16° and 750 m.m. N = 17·14 per cent. Calculated for $C_8H_8O_2N_2$ = 17·07.

When acetic acid has been oxidised as described and the mixture partially neutralised and distilled, the distillate, when treated with excess of chalk, will yield, after standing and filtering, the reaction for glyoxylic acid described by Perkin and Duppa. If after treatment with chalk a slight excess of calcium hydrate be added, and the mixture concentrated *in vacuo* to about one-third its original bulk, this reaction with aniline oxalate is obtained in a highly characteristic manner.

The methods we have hitherto employed do not yield the glyoxylic acid in solutions of sufficient strength to permit of its calcium salt being separated from the associated acetate and isolated in substance. The ease with which the salt dissociates and the volatility of the acid with water vapour make concentration of small avail.

The evidence for the formation of glyoxylic acid during oxidation appears, however, to be conclusive, and it is interesting to note that, judging from the gradual development of the reaction with proteid, this oxidation goes on slowly when acetic acid is exposed to air, and especially under the influence of light. Ferrous iron undoubtedly accelerates this, and if acetic acid giving no proteid reaction be somewhat diluted, and a little ferrous salt added, exposure to direct sunlight will confer a reactive power in the course of a few hours.

We have not been able to separate the hydrazone in quantity sufficient for its identification from average specimens of untreated acetic acid; but it appears equally difficult to do so when small quantities of glyoxylic acid, sufficient to confer an average chromogenic power, have been added to a specimen previously giving no reaction.

On one occasion we obtained a quantity of glacial acid giving the reaction with special intensity. This acid had crystallised in bulk, and we were supplied with drainings from the crystals. Seven litres were fractionally distilled until the chromogenic substance was concentrated into about 1 litre. This was nearly neutralised and again distilled. Phenylhydrazine acetate added to the distillate gave a considerable quantity of crystalline precipitate, yellow at first, darkening on standing. This was obtained before we had identified glyoxylic acid as the substance sought, and most of the hydrazone was lost in preliminary solubility tests. A small quantity was reserved, however, and this, re-crystallised thrice from hot water, melted sharply at 137°.

The observations we have hitherto made give no quantitative indications of any value. In this paper we have been mainly concerned with the endeavour to prove the nature of the active substance in the proteid reaction. We propose to study the oxidation of acetic acid further, and to define if possible the conditions necessary for a maximal yield of glyoxylic acid.

(To be continued).

THE DETECTION AND ESTIMATION OF MINUTE QUANTITIES OF MANGANESE.

By HUGH MARSHALL, D.Sc.

THE most delicate test for manganese in solution consists in converting it into permanganate, recognisable by the colour it imparts to the solution. At present this is generally effected in the way first proposed by Walter Crum—oxidation by means of lead peroxide in presence of nitric acid. The excess of peroxide must be allowed to settle before the colour can be observed, and the presence of the former interferes with the delicacy of the reaction when minute traces of manganese are concerned. It is evident that the test would be greatly improved by the use of an oxidising agent which was itself colourless and soluble.

When a manganese salt is heated with a solution of persulphate the manganese is precipitated as peroxide, precipitation being complete under suitable conditions; by digestion of the mixture for some time a pink solution is sometimes obtained, a small quantity of permanganate apparently being formed, but the production of the pink colour cannot be effected with certainty. Recently, I discovered that the presence of a trace of a silver salt has a remarkable effect on persulphate solutions, greatly accelerating their oxidising action, and apparently, in some cases, bringing about oxidations which would not otherwise occur. Thus, ammonium persulphate solution, to which a small quantity of silver nitrate has been added, undergoes decomposition in the manner indicated by the equation—

$$4(NH_4)_2S_2O_8+3H_2O=7NH_4HSO_4+H_2SO_4+HNO_3.$$

Such actions seem to depend on the formation and decomposition of silver peroxide, which is probably produced by action of water on silver persulphate—

$$Ag_2S_2O_8+2H_2O=2H_2SO_4+Ag_2O_2.$$

This method of oxidation appeared as if it might be suitable for the conversion of manganous salt into permanganate, and experiments confirmed this view. Minute quantities of manganese could be quite easily detected by gently warming the solution with persulphate, in presence of sulphuric or nitric acid, and with addition of a drop of dilute silver nitrate solution. With small quantities there is no separation of manganese peroxide; the solution remains quite clear, but rapidly assumes the characteristic pink colour when a suitable temperature has been reached.

In order to determine the delicacy of the reaction a standard solution was prepared by dissolving 0·029 grm. of potassium permanganate in a litre of water. Some of this was kept for comparison, and the remainder was reduced by the addition of a drop or two of sulphurous acid; the latter then contained one hundredth of a milligrm. of manganese, as manganous salt, per c.c. 1 c.c. of the solution was run into a test-tube containing a pinch of re-crystallised potassium persulphate; a drop of sulphuric acid and a drop of dilute silver nitrate solution were then added, and the mixture was warmed. An unmistakable pink colour was produced. It was found that a distinct colouration could still be obtained when only two drops of the solution (about 0·1 c.c., containing one thousandth of a milligrm. of manganese) were employed, the total quantity of liquid being about half a c.c. This seems to be approximately the limit to which the test is applicable.

In carrying out the test only a minute quantity of silver salt should be employed, otherwise there may be separation of finely divided silver peroxide; it is not advisable to boil the liquid, but rather to allow it to stand for a little at a moderate temperature; while the liquid should be acid, it should be only moderately so, as the reaction does not take place in presence of very concentrated sulphuric or nitric acid; only a small quantity of persulphate is necessary, and either the potassium or the ammonium salt may be employed. Potassium persulphate is much more easily purified than the ammonium salt, and keeps better; it is generally preferable as a reagent except when its sparing solubility, or the presence of potassium, constitutes a drawback.

By means of the above reaction it is very easy to show the presence of traces of manganese in such substances as white marble, dissolving about a grm. in dilute nitric acid, and applying the test directly to the resulting solution. A sample of deep-sea deposit gave the reaction quite distinctly when a few milligrms. were warmed with a small quantity of sulphurous acid, and tested directly; as there was a good deal of chloride in the sample it was necessary to add silver nitrate until no further precipitation took place, and the presence of the white silver chloride did not interfere with the reaction. The same sample gave no distinct manganese reaction when tested with a sodium carbonate bead in the usual manner.

The reaction could apparently be employed colorimetrically for quantitative purposes. This was tested roughly as follows:—5 c.c. of the standard solution (containing 0·05 m.grm of Mn as $MnSO_4$), were oxidised in the usual way; 5 c.c. of the original permanganate solution (containing 0·05 m.grm. of Mn as $KMnO_4$), were acidified and diluted to the same volume. When placed in similar tubes the two solutions showed no appreciable difference as regards depth of colour. On standing for some time the original permanganate solution became decidedly paler than the other, owing to gradual reduction, so that if the reaction were to be employed for quantitative purposes it would be preferable to submit the standard comparison solution to an oxidation process similar to that carried out on the sample being tested; the standard solution could, of course, be prepared from potassium permanganate, and reduced with sulphurous acid, which would ensure that no deposition of manganese peroxide would take place on keeping the solution.

In a communication recently published in the *Proceedings of the Royal Society of Edinburgh*, describing the decomposition of ammonium persulphate solution in presence of silver salts, I have erroneously stated that chromic salts are not oxidised to chromic acid by ammonium persulphate in absence of silver. Oxidation does take place with persulphate alone, but is accelerated by the addition of a silver salt.

NEW PROCESS FOR THE ESTIMATION OF META-CRESOL IN A MIXTURE OF CRESOLS.

By F. RASCHIG.

FOR some years past the picric acid used under the names of melinite, lyddite, &c., in the preparation of explosive materials, has been replaced by a product named cresylite. This substance is obtained by the action of nitric acid on cresol, a cheap by-product of the manufacture of carbolic acid. Cresol consists of a mixture of three isomers, ortho-, meta-, and para-cresol, and the nitrated product which is derived from it consists entirely of trinitro-*m*-cresol, the ortho- and para cresol being transformed entirely into oxalic acid at the boiling-point, and in the presence of an excess of nitric acid.

Commercial cresol contains on an average 40 per cent of ortho-cresol, 35 per cent of meta-cresol, and 25 per cent of para-cresol, and in round numbers gives 60 per cent of trinitro-meta-cresol. The operation entails a considerable loss of nitric acid through the oxidation of the ortho- and para-cresols. By fractional distillation, frequently repeated, the ortho-cresol boiling at 188° can be completely separated from the mixture of cresols, and a mixture is obtained consisting in round numbers of 60 per cent of meta-cresol, and 40 per cent of para-cresol. The boiling-point of these two products is about the same,

viz., 200° and 199·5°, so that they cannot be separated by fractional distillation. However, this mixture of the two cresols has considerable advantages over the mixture of the three cresols, so that it is more in demand, and fetches higher prices; for instance, it gives about 100 per cent of trinitro-meta-cresol, and at the same time requires less nitric acid.

From this it is apparent that the mixture of cresols will be the more valuable from the point of view of the manufacture of explosive materials, as it contains a larger proportion of meta-cresol. For this reason I have devised a method for the estimation of meta-cresol in a mixture of cresols. This method is rapid, easy to perform, does not require the use of complicated apparatus, and does not entail much expense. It is based on the already mentioned property, that the mixture of cresols treated at boiling-point with an excess of nitric acid, furnishes exclusively trinitro-meta-cresol, which, being almost insoluble in water, is easily isolated, dried, and weighed.

The following is the method of procedure finally adopted:—Exactly 10 grms. of cresol were taken, and mixed in an Erlenmeyer flask with 15 c.c. of ordinary sulphuric acid at 66° B. This was left for about an hour in a steam oven. The contents of the flask were then poured into a wide necked flask of 1000 c.c. capacity, and cooled under the tap while shaking.

By this operation the sulph-acid, which is fluid when warm, is deposited in the form of a thick syrup on the sides of the flask. 90 c.c. of ordinary nitric acid at 40° B. are then poured into the Erlenmeyer flask which was used for the sulphonation, and which still contains a little of the sulph-acid. In this manner the whole of the sulph-acid is brought into solution, and the whole of the liquid is poured into the litre flask at once. This latter is immediately shaken vigorously until the whole of the sulph-acid is dissolved, an operation which only requires about twenty seconds. The flask is then placed in the fume closet, and after about a minute a violent reaction commences; the contents of the flask begin to boil violently, accompanied by an abundant disengagement of red fumes; the solution, which has till now been clear, becomes suddenly cloudy, oily drops of trinitro-cresol separate out, and collect at the bottom of the flask; at the end of five minutes the reaction appears to have finished. The flask is, however, left for another five minutes, as the reaction is not really over sooner.

The contents are then poured into a dish containing 40 c.c. of water, and the flask is rinsed with another 40 c.c. of water. On contact with the water the oil froths up, gives off nitrous fumes, and becomes solid, forming a crystalline mass of trinitro-meta-cresol. This is allowed to cool for about two hours, when it is powdered coarsely, and collected on a filter-paper with the help of a filter-pump. The filtration is effected very rapidly; it is washed with 100 c.c. of water, dried on the filter at 95—100°, and weighed, placing a filter-paper of the same size on the other pan of the balance as tare.

With a little practice an estimation can be made in five hours, and ten or twenty analyses can easily be done concurrently.

Chemically pure meta-cresol treated in this manner gives exactly 17·4 grms. of trinitro-cresol, and it has been proved by a large number of experiments that the most variable mixtures of meta-cresol and para-cresol, and of meta-cresol and ortho-cresol, always give 1·74 per cent of trinitro-cresol per 1 per cent of meta-cresol. And again, by mixing 9 grms. of meta-cresol with 1 grm. of phenol, we obtain exactly $9 \times 1{\cdot}74 = 15{\cdot}6$ of the nitrated product.

It is probable that the picric acid derived from the phenol remains in solution under the existing conditions; but in the presence of more than 10 per cent of phenol the picric acid is precipitated with the trinitro-cresol, from which it follows that the process cannot be applied to mixtures very rich in phenol. Such mixtures, however, are not often met with commercially, and further, the presence of phenol can easily be ascertained by the boiling-point, as well as by the fact that the nitrated product, dried at 95—100°, becomes deliquescent, or turns into a soft paste, instead of remaining a solid mass.

Xylenols also, which are to be found more frequently in cresol, behave in the same manner; the nitrated product becomes liquid when warmed, and is not solidified when cooled. On the other hand, a cresol which is almost entirely volatile between 190° and 200°, that is to say, almost entirely free from phenols and xylenols, always gives, under the conditions described, a bright yellow crystalline mass, the weight of which divided by 1·74 represents the amount of meta-cresol present.

In conclusion, I should like to call attention to this point: the quantity of nitric acid used is much more than that necessary to produce complete oxidation. With cresols of average composition, containing 35 to 60 per cent of meta-cresol, 70 c.c. of nitric acid give good results. But in such a case the reaction frequently occurs so quickly that there is hardly time to properly mix the sulph-acid and the nitric acid, and to put the flask on one side; sometimes even there is such a violent reaction that the flask is blown to pieces.

I must therefore insist on the use of 90 c.c. of nitric acid, and I strongly advise the use of a flask of at least 1 litre capacity, and with a large neck. It is also indispensable to pour the whole of the nitric acid into the sulph-acid at once, for fear that a reaction should take place before the whole of the acid is in the flask.—*Zeit. für Angewandte Chemie*, 1900, p. 759.

THE SPECTRA OF RADIUM AND POLONIUM.

By G. BERNDT.

So far experiments on the spectrum of radium by Demarçay and Runge have appeared. By means of radio-active barium chloride of activity 70,000, Demarçay has discovered in the spectrum as far as $\lambda = 3500$ (Angström's units), sixteen new lines, three of which, however, he will not with certainty ascribe to radium. Runge, with his measurements which extend to $\lambda = 2400$, has only confirmed three of the strongest lines, $\lambda = 4826{\cdot}14$, $\lambda = 4682{\cdot}346$, and $\lambda = 3814{\cdot}591$. This negative result probably arose from the use of a salt of insufficient activity. Acting upon the suggestion of Prof. Dorn, I therefore undertook a new experiment on the radium spectrum in the ultra-violet, towards which the great quartz-spectrograph of the Institute afforded immense help.

I used active barium chloride of activity 240 from the Central Society of Chemical Products, Paris, and active barium bromide of De Haën, Hanover. According to the publication of Runge, the salt was fused in a platinum spiral heated to redness by electricity, by which means only a very small quantity is required.

I used about 0·03 grm. A platinum wire served as cathode. The spark was led through two Leyden jars, which were charged from a large induction apparatus. The spiral was heated by four isolated accumulators. Thus, when the spark passes, the space between the electrodes fills with vapours of the salt, and by regulating the stream from the accumulators one can at will obtain the desired quantity of gas.

If the time of exposure is not too extended the spectrum obtained will contain, besides the lines of the experimental salt, only indications of the strongest platinum lines, and only extremely few atmospheric lines.

In the spectra of the active chloride and bromide of barium, I obtained from radium lines only $\lambda = 3814{\cdot}591$ with intensity 2, in which intensities are reckoned from 6 to 1, 6 indicating the greatest intensity.

However, when I used active barium chloride of activity 1000, from the Central Society of Chemical Products, I obtained:—$\lambda = 4682{\cdot}346$, intensity 1; $\lambda = 3814{\cdot}591$, in-

tensity 4; and a new line, λ=2708·6, intensity 1. As far as λ=2100 I have found no more radium lines.

No measurements with regard to the spectrum of polonium have so far appeared. Demarçay's experiments have resulted in the discovery of no new lines. Sir W. Crookes only mentions that polonium shows bright lines in the ultra-violet.

For the photographic production I used active basic bismuth nitrate of activity 300. The spectrum obtained was at once compared with that of ordinary bismuth nitrate, bismuth, antimony, lead, copper, platinum, cadmium, and calcium chloride, and the measurements also with those of the best known spectra, and I think the following fifteen lines may be said to belong to polonium:—

Intensity.	λ.	Intensity.	λ.
1	4596·3	6	3349·2
2	4007·1	4	3191·2
4	3821·9	4	3168·2
3	3467·1	3	3162 9
2	3462·0	1	3152·2
4	3442·0	1	2977·0
6	3361·5	3	2661·9
		4	2327·3

The greatest error in the wave-lengths might be about 1·5 (Angström's units) in the visible part of the spectrum, and about 0·4 in the ultra-violet.

As far as λ=2100 I have found no more lines.

In the photographic production I was assisted by my friend Herr Henning; I wish to express my thanks to him, and above all to Prof. Dorn for his kind help.—*Physikalische Zeitschrift*, 2 Jahrgang, No. 12.

Physical Institute of Halle University.

CONCERNING LIPASE, THE FAT-SPLITTING ENZYME, AND THE REVERSIBILITY OF ITS ACTION.*

By J. H. KASTLE and A. S. LOEVENHART.

(Continued from p. 66).

Stability of Lipase.

THERE seems to be a general impression among those who have worked with this enzyme that in order to obtain active pancreatic extracts they should be prepared within a few hours after the death of the animal (Oppenheimer, "Die Fermente," 1900, 228; Shäfer, "Text-book of Physiol.," 1897, vol. i., p. 339). It is true that, as compared with many enzymes, lipase is very unstable. That it does not disappear from the gland, however, as soon as is commonly supposed, is shown by the following experiments:—Several pancreases were placed in cold storage, without antiseptic, on July 19, 1900. One c.c. of a 10 per cent aqueous extract of a fresh pancreas on July 19, in 4 c.c. of water with 0·26 c.c. of ethyl butyrate and 0·1 c.c. toluene in fifteen minutes at 40°, required 2·45 c.c. of N/20 KOH for neutralisation. It therefore hydrolysed 6·15 per cent of ethyl butyrate. On July 26 one of the pancreases was removed from the cold storage and a 10 per cent aqueous extract was prepared. It had an initial acidity of a 0·2 c.c. KOH, and 1 c.c. of it hydrolysed 2·51 per cent of ethyl butyrate under the same conditions as the first. In seven days, therefore, at a temperature of 4°, there was a falling off in lipolytic activity of about 60 per cent. Still another pancreas in which putrefactive changes had begun, was observed to possess feeble lipolytic power. Still another preparation of the pig's pancreas throws light on the stability of lipase. The attempt was made to get rid of fat in the pancreatic extract by dissecting the gland as free from fat as possible, then grinding to a stiff paste with dry sand, and drying the resulting mass by exposing it in thin layers on filter-paper for several hours at ordinary temperature in the air. The dried mass was then extracted with ligroin and dried again in the air, and finally a small quantity of thymol was ground into the siliceous mass to act as a preservative. An aqueous extract of the sand thus prepared was found to possess lipolytic activity, although it was much less active than the fresh aqueous extract of the pancreas. This preparation was made on July 12th. It was kept in the dark room in a glass-stoppered bottle. On August 17, an aqueous extract of the siliceous mass was again made, and this was found to be nearly, if not quite, as active as it was originally. With proper precautions, the extracts of the pancreas and liver can also be preserved for some time without materially losing their activity. That such is the case may be seen from the following:—

A 10 per cent aqueous extract of the pancreas was prepared on July 20th. The extract was placed in the refrigerator (temperature, 1°), and kept there for several days; its activity being tested at intervals on ethyl butyrate in the following manner:—1 c.c. of the enzyme with 4 c.c. of water, 0·1 c.c. toluene, and 0·26 c.c. ethyl butyrate were heated together in a test-tube for fifteen minutes at 40°, at the end of which time titration was made with N/20 KOH.

The following results were obtained:—

	N/20 KOH required.	Per cent of hydrolysis.
	c.c.	
Initial activity of extract	1·63	4·09
Activity of extract after forty-eight hours	1 77	4·44
Activity of extract after seventy-two hours	1·65	4·14

During seventy-two hours the initial acidity of the extract had increased from 0·1 c.c. to 0·25 c.c. N/20 KOH. This was allowed for in the above calculations. Similar results have been obtained with the aqueous extracts of the liver of the pig. A 10 per cent aqueous extract was prepared on July 24th and kept on ice for several days in a glass-stoppered bottle. Its activity towards ethyl butyrate was tested at intervals, the experiments being carried out in test-tubes, using 1 c.c. of the enzyme solution, 4 c.c. water, 0·1 c.c. toluene, and 0·26 c.c. ethyl butyrate. Temperature, 40°; duration of experiments, fifteen minutes.

	N/20 KOH required.	Per cent of hydrolysis.
	C.c.	
Initial activity of extract	1·7	4·26
Activity of extract after six hours..	2·5	6·27
Activity of extract after forty-eight hours	2·4	6·03

The increase in the activity of these extracts on standing is interesting. The above are by no means the only cases in which such an increase in activity has been observed. The best explanation of this increase in activity on standing would seem to be that during the interval a certain amount of zymogen had been transformed to enzyme. It has also been observed that glycerin extracts of the pancreas are more stable than aqueous extracts of the same activity. Some idea of the stability of the glycerin pancreatic extracts may be gathered from the following observation:—A glycerin extract was made on June 15th, 1900, and made use of in the investigation until June 23rd. Some of it was then preserved in sealed tubes in the dark room at summer temperature until August 18th, when it was still found to possess considerable lipolytic activity.

The Effect of Temperature on the Activity of Lipase.

It is well known that the activity of lipase is dependent on the temperature. According to Hanriot (*Comptes Rendus*, 1897, cxxiv., 235), the optimum temperature of the enzyme is 55°. At 60° he observed it to become con-

* From the *American Chemical Journal*, xxiv., No. 6.

siderably slower in its action, and at 72° it was found to lose its activity altogether. Towards ethyl butyrate the activity of pancreatic lipase has been found to increase more or less regularly from 0° to 40° C. Above this temperature there is a gradual falling off in activity with rise of temperature. On exposure to a temperature somewhere between 65° and 70° for five minutes, a 10 per cent pancreatic extract loses its activity altogether. The activity of hepatic lipase varies much more with the temperature between 0° and 40° C. than that of the pancreatic enzyme, as may be seen from the following experiments:—Tubes containing 4 c.c. of water, 0·1 c.c. of toluene, and 1 c.c. of a 10 per cent extract of the liver or pancreas, were kept in baths at 40°, 30°, 20°, 10°, 0°, and −10° C. respectively, for five minutes in order to let them acquire the temperature of the bath. At the end of this time, 0·26 c.c. of ethyl butyrate was added to each tube, after which the tubes were allowed to remain in their respective baths thirty minutes, when they were placed in ice-water and titrated with N/20 KOH. The following results were obtained:—

With the Pancreatic Extract.

Temperature.	N/20 KOH required.	Per cent of hydrolysis.
	C.c.	
40°	1·125	2·82
30	1·26	3·16
20	1·00	2·51
10	0·75	1·88
0	0·50	1·25

With the Hepatic Extract.

Temperature.	N/20 KOH required.	Per cent of hydrolysis.
	C.c.	
40°	4·5	11·29
30	2·375	5·96
20	2·10	5·27
10	1·55	3·89
0	0·9	2·26
−10	0·28	0·70

Similar results have been obtained by Hanriot (*Comptes Rendus*, 1897, cxxiv., 778) for serum and pancreatic lipase. He found the latter, for example, to exhibit the same activity between 15° C. and 42° C., whereas the serum lipase hydrolysed twice as much monobutyrin at 42° C. as at 15° C. In this connection it is well to bear in mind that Schmiedeberg (*Arch. f. Exp. Path. u. Pharm.*, 1881, xiv., 379) seems to have made a distinction between the enzyme of the liver which splits hippuric acid, fats, &c., and which he calls histozyme, and ordinary pancreatic lipase. On the other hand, Nencki (*Arch. f. Exp. Path. u. Pharm.*, 1886, xx., 367) has shown that the pancreas can also split hippuric acid.

On the Relative Stability of Different Ethereal Salts towards Lipase.

It is well known that other ethereal salts besides the fats are hydrolysed in the intestine. Baas (*Zeit. Physiol. Chem.*, 1890, xiv., 416), for example, found that, in the dog, salol was hydrolysed in one case to the extent of 69 per cent and in another to 43·95 per cent. Methyl salicylate to 24·75 per cent and ethyl salicylate to 21·20 per cent. Heritsch (*Centrbl. Med. Wis.*, 1875, 449) has also found that lipase could hydrolyse ethereal salts; for example, ethyl acetate. It occurred to us, therefore, that it might be interesting to measure the hydrolysis of a few of the commoner ethereal salts. Unfortunately, at this particular time, only a limited number of these were on hand of sufficient purity for the purposes of the investigation. Ethyl formate, ethyl acetate, ethyl propionate, and ethyl butyrate were therefore selected for the experiments. Tubes were prepared containing 4 c.c. of water, 0·1 c.c. toluene, and 1 c.c. 10 per cent pancreas extract. These were heated in the bath at 40° C. for five minutes. The ethereal salt to be tested was then added in the proportion of twice the molecular weight of the salt in m.grms. The tubes were then heated for fifteen minutes, when they were placed in ice-water and titrated with N/20 KOH. The following results were obtained:—

	Quantity of ethereal salt used.	N/20 KOH required.	Per cent of hydrolysis.
	Grm.	C.c.	
Ethyl formate	0·148	0·65	1·60
„ acetate	0·176	0·37	0·93
„ propionate ..	0·204	0·42	1·05
„ butyrate	0·232	1·26	3·13

A second series of experiments, exactly like the above, was tried, a more active pancreatic extract being used. The following results were obtained:—

	N/20 KOH required.	Per cent of hydroiysis
	C.c.	
Ethyl formate	0·7	1·75
„ acetate	0·7	1·75
„ propionate	1·15	2·87
„ butyrate	1·75	4·37

Both series exhibit the same order of stability, and both show that the higher the molecular weight of the acid, the more readily is its ethyl ester hydrolysed by lipase. Ethyl formate is very easily hydrolysed by pure water. This would probably account for the high values obtained with this compound.

In this connection it occurred to us that it might prove interesting, and perhaps valuable for future work upon this subject, to compare quantitatively the hydrolysing power of certain acids with that of lipase upon ethyl acetate and ethyl butyrate. Hence, normal solutions of hydrochloric, acetic, and butyric acids were made use of in very much the same way as the enzyme in the experiments described in the above. Tubes were prepared containing 4 c.c. of water and 0·176 grm. of ethyl acetate. These were then heated in the bath at 40° C. for five minutes. One c.c. of the normal acid was then run in and the tube heated for the desired length of time, at the end of which it was titrated with N/20 KOH. The following are the results obtained:—

Acid	Time.	N/20 KOH reduired.	Per cent of hydrolysis.
	Minutes.	C.c.	
Water	15	0·05	0·13
	60	0·00	0·00
Hydrochloric ..	15	2·45	6·14
	30	4·45	11·15
Acetic	15	0·05	0·13
	60	0·4	1·0
Butyric	15	None	None
	60	„	„

Second Series with N-Hydrochloric Acid.

Time.	N/20 KOH required.	Per cent of hydrolysis.
Minutes.	C.c.	
15	2·45	6·14
30	4·45	11·15
45	6·10	15·29
60	8·15	20·43
90	10·75	26·95
120	14·05	35·21

Similar experiments on the hydrolysis of ethyl butyrate by acids gave the following results:—

Conditions of Experiment.—Temperature, 40° C.; quantity of ethyl butyrate used in each experiment=0·232 grm.

Acid.	Time. Minutes.	N/20 KOH required. C.c.	Per cent of hydrolysis.
Hydrochloric ..	30	0·05	0·12
	60	0·8	2·00
	90	1·3	3·25
	120	1·5	3·75
Acetic..	30	None	None
	60	0·1	0·25
	90	0·1	0·25
	120	0·3	0·75

Several interesting conclusions may be drawn from these results, the chief of which is the remarkable difference displayed by lipase and hydrochloric acid in effecting the hydrolysis of ethyl acetate and butyrate. Both pancreatic and hepatic lipase hydrolyse ethyl butyrate considerably more rapidly than the acetate, and this notwithstanding the fact that the latter is entirely in solution under the condition of the experiment, whereas the former is not. On the other hand, normal hydrochloric acid hydrolyses the acetate about ten times as rapidly as the butyrate. As regards the cause of this remarkable difference between these two processes we are at present in the dark; it certainly offers an interesting field for further investigation.

(To be continued).

SOME PRINCIPLES AND METHODS OF ROCK ANALYSIS.*

By W. F. HILLEBRAND.

(Continued from p. 70).

VI. *Limits of Allowable Error in Summation of Analytical Results.*

As is well known, a complete silicate rock analysis which foots up less than 100 per cent is generally less satisfactory than one which shows a summation somewhat in excess of 100. This is due to several causes. Nearly all reagents, however carefully purified, still contain, or extract from the vessels used, traces of impurities, which are eventually weighed in part with the constituents of the rock. The dust entering an analysis from first to last is very considerable, washings of precipitates may be incomplete, and if large filters are used for small precipitates the former may easily be insufficiently washed.

Given the purest obtainable reagents, an ample supply of platinum, facilities for working, and a reasonably clean laboratory, there is no excuse for failure on the part of a competent chemist to reach a summation within the limits 99·75 and 100·50. Failure to attain 100 per cent in several of a series of analyses of similar nature should be the strongest evidence that something has been overlooked. Excess above 100·5 per cent should be good ground for repeating portions of the analysis in order to ascertain where the error lies, for it is not proper to assume that the excess is distributed over all determined constituents. It is quite as likely, in fact more than likely, to affect a single determination, and one which may be of importance in a critical study of the rock from the petrographic side.

VII. *Quality of Reagents.*

It is due to say that all analyses performed in the Survey laboratories have been made with the purest reagents obtainable, either by purchase in the open market, or by special preparation on the part of manufacturers, or in the laboratory. The best acids made in this country are of a high grade, and need no re-distillation except for special experiments. Ammonia has always been redistilled at short intervals; and no sodium carbonate which exceeds 2½ milligrms. of total impurity (see *prox.*, "Sodium Carbonate"), in 20 grms. (0·012 per cent) is used for the main portions, in which silica, alumina, &c., are to be estimated. For other portions, as phosphoric acid, fluorine, sulphur, a poorer grade is entirely allowable, provided it is free from the element to be determined, and from any other which might interfere with its estimation.

Hydrofluoric acid was always freshly distilled with potassium permanganate until the introduction of ceresine bottles afforded an article sufficiently pure for all but the most exacting work. Care must be exercised even yet, however, that no particles of paraffin or ceresine are floating on the acid, and that the latter is free from traces of chlorine whenever it is to be used for attacking silicates with a view to estimating chlorine (see *prox.*, "Chlorine").

Potassium bisulphate has usually been prepared in the laboratory from sulphuric acid and potassium sulphate, since it is not always to be bought of satisfactory quality. Even then the normal sulphate had first to be examined, for it has been found to contain, on different occasions, notable amounts of lead, calcium, and silica.

The phosphorus salt used for precipitating magnesium has been found to contain iron and silica, and calcium is almost always a constituent of ammonium oxalate. The latter has therefore to be purified or specially prepared, as also oxalic acid, ammonium chloride (in which latter manganese has been observed), and occasionally other reagents. Some hydrogen peroxide contains fluorine, which renders it unfit for use as a chemical reagent.

A "C. P." label is no guarantee whatever of the purity of a reagent; hence no chemicals should be taken on trust because of bearing such a label. Every new purchase should be examined, if it is one in which purity is a desideratum. In general all so-called "C. P." chemicals should at least stand the tests laid down by Krauch ("Die Prüfung der Chemischen Reagentien," 3rd Edition, Berlin, Julius Springer, 1896.

Of late years the appearance upon the market of so-called guaranteed reagents promised to meet a long-felt want. But experience has shown that with the pioneer in this line at least the guarantee amounts to nothing, the reagents being sometimes worse than the "C. P." articles emanating from sources which make no claim to special purity for their goods, and redress being unobtainable. The "guaranteed reagent" needs checking as much as any other.

VIII. *Preliminary Qualitative Analysis.*

A complete qualitative analysis of a rock, preceding the quantitative examination, is in most cases a sheer waste of time. A few constituents may now and then be specially looked for, but in general time is saved by assuming the presence of most of them and proceeding on that assumption in the quantitative analysis.

PART II.—METHODS.

I. *Introductory Remarks.*

The order hereinafter followed in describing the various chemical separations has little relation to the affinities of the constituents of the rock, but those are grouped together which can be conveniently determined in the same portion of rock powder. Thus, in the main portion are usually determined SiO_2, TiO_2, MnO, NiO, CaO, SrO, MgO, total iron, and the combined weight of all the following:—Al_2O_3, TiO_2, P_2O_5, ZrO_2, all iron as Fe_2O_3, and nearly if not quite all vanadium, as V_2O_5, also perhaps rare earths if present. In a separate portion is estimated FeO, and also the total iron, as well as BaO, if these last are desired as checks. The alkalis need a portion for themselves. In another, ZrO_2, BaO, and total sulphur are very conveniently determined. For V_2O_3 and Cr_2O_3 still another and usually much larger portion is to be used. Determinations of CO_2, C, H_2O, Fl, Cl, are all best made in separate portions of substance, though various combinations are possible, as CO_2 and H_2O, C and H_2O, or H_2O, Fl, and Cl. In fact, by a judicious selection and combination of methods a very satisfactory analysis can sometimes be

* *Bulletin of the United States Geological Survey*, No 176.

made on 4 grms. of material without omission of anything of importance, though the time consumed will be greater than if ample material is available.

As an illustration of the advantage to be gained by a little judgment in the combination of methods, the case of sulphur, barium, and zirconium may serve. Many chemists never look for the second and third of these, but by following the procedure given later on very little more labour is expended in confirming their presence or absence than that of sulphur alone.

With only occasional exceptions, nearly all the constituents mentioned (see II., *ante*), can be estimated if present in portions of powder not exceeding 1 grm. each in weight.

This is a convenient weight to take for the main portion in which silica, alumina, &c., the alkaline earths, and magnesia are to be sought; but it should, in general, be a maximum, because if larger the precipitate of alumina, &c., is apt to be unwieldy. Its weight can not often be much reduced with safety if satisfactory determinations of manganese, nickel, and strontium are to be expected. For the alkali portion one-half grm. is a very convenient weight. In general, it may be made a rule not to use more than 2 grms. for any portion which has to be fused with an alkali carbonate, as for sulphur, fluorine, and chlorine. For carbon dioxide the weight may rise to 5 grms., or even more, if the amount of this constituent is very small, without expenditure of any more time than is required by 1 grm., and with correspondingly greater approach to correctness in the result. For vanadium also a larger weight than 2 grms. is usually demanded.

II. *Specific Gravity.*
By Suspension in Water.

Ordinary Method.—This determination, when required, is best made upon one or several fragments weighing up to 20 grms. They are held together by a fine platinum wire ready for suspension from the balance, and thus held are placed in a small beaker to soak over-night in distilled water under the exhausted receiver of an air-pump, side by side with a similar beaker of water. Boiling is, of course, a much less effective means of removing air than the air-pump, and the boiling water may exert an undesirable solvent and abrading effect. In the morning the wire is attached to the balance arm, the rock fragments remaining immersed in the water; a thermometer is placed in the companion beaker of water, now likewise in the balance case, and the weight is at once taken. Both vessels of water having precisely the same temperature, it is quite unnecessary to wait for the water to assume that of the balance should it not already possess it. The fragments are now lifted out, without touching the vessel, and carefully transferred to a tared crucible or dish; the wire is removed, and at once re weighed, with the precaution that it dips just as far into the water now as when weighted. Hereby a special weighing of the wire out of water is avoided. The sample may now be dried on the water-bath, and then at 110° C. for some hours to certainly expel all absorbed water, and weighed after prolonged cooling in the desiccator. It is better to ascertain the weight of the dry rock after soaking in water than before, in order to avoid the error due to possible breaking off of a few grains between the two weighings. Should the density of the rock in air-dry condition be required, it may be left exposed to the air for a long period after drying and before weighing;* but the difference will only in exceptional cases affect the second decimal by more than a single unit. For instance, an undried rock of 2·775 specific gravity, containing in the uncrushed state the high percentage of 0·3 hygroscopic moisture, will have a density of 2·79 when dry; a rock of 2·982 specific gravity, undried, will have a density of 3·00 after removal of 0·3 per cent of moisture. The difference becomes greater as the density of the rock increases.

This method of ascertaining the specific gravity of rocks is certainly more convenient than, and for compact rocks is believed to be decidedly preferable to, that of the pycnometer, in which the fragments must be reduced to small size with consequent formation of more or less powder, which is subject to slight loss in the various manipulations. To exclude this powder and employ only small fragments would introduce a possible source of error, since it is likely to consist largely of the most easily abraded minerals, and consequently not to have the average composition of the mass. By following the instructions given above, loss of material is absolutely avoided, a decided saving in time is effected, and considerable weights can be easily employed with consequent lower probable error in the results. To vesicular rocks, however, notably certain lavas, the above procedure is, of course, inapplicable, unless the datum is desired for certain considerations in which the relative density of large rock masses as they occur in nature is sought, as for the comparison of building stones or the calculation of large known or assumed areas of particular rocks.

Penfield's Method for Mineral Fragments.—Penfield (*Am. Journ. Sci.*, 1895, Series 3, vol. l., p. 448), recommends the following modification of the suspension method as more convenient than that by the pycnometer in many cases for small fragments of minerals.

After boiling in water, the substance is transferred with water to a small glass tube about 8 m.m. by 35 m.m., provided with a fine platinum wire for suspension, This is weighed full of water in another vessel of water, and again after the removal of the mineral, the weight of which is found after drying.

This method is, of course, more applicable to homogeneous minerals than to rock fragments, and will therefore be applied in rock analysis chiefly to the determination of the specific gravity of the mineral grains separated by heavy solutions or acids.

(To be continued).

* In view of the uncertainty as to what constitutes hygroscopic water (see *post*), this course is perhaps more to be commended than the former, and seems imperative for certain zeolitic rocks. In such cases it is best to weigh the fragments before putting to soak, and afterwards to collect on a Gooch crucible the grains which may have fallen off in the water. Should no crucible of this kind be available, a paper-filter may unhesitatingly be used and incinerated with the powder, owing to the small amount of which the error due to loss of even all its water during ignition is quite negligible.

PROCEEDINGS OF SOCIETIES.

PHYSICAL SOCIETY.

Annual General Meeting, February 8th, 1901.

Mr. G. GRIFFITH, Vice-President, in the Chair.

THE report of the Council was read and adopted.

Professor Willard Gibbs and Dr. Rudolph Kœnig were elected to the two vacant Honorary Fellowships of the Society.

The following Officers and Council were elected for the ensuing year:—

President—Prof. S. P. Thompson.

Vice-Presidents (Members who have filled the office of President)—T. H. Blakesley, C. V. Boys, Prof. J. D. Everett, and J. Walker.

Secretaries—H. M. Elder and W. Watson.

Foreign Secretary—Dr. R. T. Glazebrook.

Treasurer—Prof. H. L. Callendar.

Librarian—W. Watson.

Other Members of the Council—Prof. Armstrong, W. R. Cooper, G. Griffith, E. H. Griffiths, Dr. R. A. Lehfeldt, S. Lupton, Prof. Perry, Dr. Porter, W. A. Price, and R. Threlfall.

Prof. S. P. THOMPSON then took the chair and delivered an Address.

In opening, the President gave in detail the various

ways in which the aim of the Physical Society to promote the progress and study of physics has been accomplished during the twenty-six years of the Society's existence.

Referring to the election of two Honorary Fellows, Prof. Thompson said they had added to their roll two men distinguished in very different walks of physics. Prof. Willard Gibbs is a United States mathematical physicist whose work in thermodynamics, elastic solid theory of light, and other specialised subjects, is of the highest order, and is valued for its beauty and profundity. Dr. Rudolph Kœnig, of Paris, is known as a maker of acoustical instruments—of perfect standard tuning-forks in particular. He has, however, found time to extend the borders of acoustics, and to him we owe the manometric flames, the wave-syren, and other instruments of research. He has also published work on the facts about the combinations of pure tones.

The President appealed to all teachers of physics in the country to make use of the Society and give it their active support. It was mainly in the interest of teachers and students that the Society undertook the publication of *Science Abstracts*. By means of the *Abstracts* teachers have at hand the latest information on the subject, and can thus continually supplement their text-book knowledge. Every teacher from time to time devises new or improved modes of presenting his subject. At the Physical Society, the Fellows always welcome contributions of this kind, even although there may be little of actual novelty in the principles so illustrated. The routine work and administrative duties of teachers, although hampering their usefulness to science and diminishing their fruitfulness, prevents their attention, without intermission, to one subject, and produces a direction of thought over various domains of physics which is to be welcomed rather than deplored. It has been the custom for Fellows of the Physical Society to bring models to illustrate physical principles. This practice of using models is regarded by our Continental brethren as a peculiarly English matter, and one that shows a sort of mental constitution they do not quite understand. Models have become a part of our mental furniture. It never occurs to us that there is anything unusual in the habit. Faraday has used them in connection with the electrostatic field surrounding charged bodies. Lord Kelvin has made models to convey his ideas of elasticity, of the elastic solid theory of matter, and of the constitution of matter itself. Maxwell's models of heterogeneous dielectrics and the mutual induction between two circuits are well known. These models are useful for teaching purposes, and for enabling one to grasp that which in its nature is abstract, by contemplating the representation of it or its analogue in the concrete. The French physicist cannot understand a complicated phenomenon until he has reduced it to a mathematical equation. The British physicist must construct a model which will produce mechanically the analogous operation. Both methods are right, but—judging by their fruitfulness—the method of Faraday has advantages over that of Poisson.

Referring to the new Teaching University of London, the President said that now was the time for Fellows to offer suggestions for the teaching of physics.

An Ordinary Meeting of the Society was then held.

A paper on "*A Mica Echelon Grating*," by Prof. R. W. Wood, was read by Mr. Watson.

This grating occupies a position midway between an ordinary grating and an echelon with thick plates. A number of sheets of mica were examined with the interferometer, and one selected over a considerable portion of which the fringes were straight and unbroken. This portion was marked off and cut up into rectangles. The mica was about 0·05 m.m. thick, and the retardation of one of the rectangles was found to be fifty wave-lengths for sodium light. Nine of these rectangles were used to form the grating, and they were put in position under a microscope and cemented together at the edges with sealing wax. The grating space was 0·5 m.m. The battery was mounted on a square of cardboard over a rectangular opening of the same size, a clear space, 0·5 m.m. wide, being left to serve as the first grating line of zero retardation; the number of lines was therefore ten. The resolution of the sodium lines was beyond the power of the instrument, but the yellow mercury lines were easily separated. The distance between the lines was one-third of the distance between the spectra. For the sake of comparison, a grating of the same spacing and number of lines was ruled on a piece of smoked glass, and it was found that in the first order the grating was unable to separate the extreme red and blue ends of the spectrum. The Zeeman effect can be shown with an echelon made of four interferometer plates, the light being the green rays from a mercury tube.

The Society then adjourned until February 22nd.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Note.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, del'Académie des Sciences. Vol. cxxxii., No. 3, January 21, 1901.

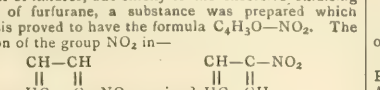
Properties of Sodium Dioxide.—M. de Forcrand.—The author criticises G. F. Jaubert's paper, which appeared in the last numbers of the *Comptes Rendus*. He announces that the heat of formation and solution of Na_2O_2 have already been found, and the properties of this substance described in detail.

Compounds of Ammonia Gas with Aluminium Chloride.—E. Baud.—The author establishes the fact that aluminium chloride forms with ammonia at least four compounds:—(1) $Al_2Cl_6.2NH_3$, which is a very stable substance, capable of being distilled at about 450° without undergoing decomposition; (2) $Al_2Cl_6.10NH_3$, also a very stable substance, which is dissociated under atmospheric pressure at about 380°; (3) $Al_2Cl_6.12NH_3$, a substance which dissociates under atmospheric pressure at about 180°; (4) finally, the compound probably having the formula $Al_2Cl_6 + 18NH_3$, which is very easily dissociable, and which can only be obtained at temperatures approaching the liquefying-point of ammonia gas.

The Isolation of Yttria, Ytterbia, and New Erbia.—G. and E. Urbain.—The authors, in a previous paper, described a new method of fractionating the yttria earths by the crystallisation of their ethyl sulphates. In the most soluble portions were found yttria, new erbia, and ytterbia. These fractions did not contain a trace of the earths of the lanthanum group, and apparently contained no earths of the samarium and gadolinium groups. This latter group was eliminated by this method of fractionation before holmia, dysprosia, and new holmia. Since that time, the authors have prepared large quantities of these mixtures, and have examined methods of separating earths of the same group. The method which has given the best results is still that of the partial decomposition of the nitrates by heat. The crude rare earths were first subjected to ten crystallisations as ethyl sulphate. The final mother-liquor was found to contain yttria, erbia, ytterbia, and a trace of thoria. This mixture was then transformed into nitrate, and after about twenty fusions the authors obtained in the least basic portion a mixture of ytterbia and thoria. The thoria was then separated by Wyrouboff and Verneuil's method. The atomic weight of the remaining ytterbia was found to be 172·6, and the spectrum of this ytterbia was absolutely free from absorption bands. Yttria and erbia were obtained in almost as pure a form.

An Arsenide and a Chloro-arsenide of Tungsten.—Ed. Defaçoz.—It is known that phosphoretted hydrogen reacts on tungsten hexachloride, giving a definite compound. The author finds that hydrogen arsenide reacts on the same hexachloride, and a new compound is formed, having the formula WAs_2. Also liquid hydrogen arsenide acts on the hexachloride, giving in this case a chloro-arsenide, W_2AsCl_2, a substance of a bluish black colour in the form of little crystals similar to those of the hexachloride. This compound is very hygroscopic, and is decomposed slowly when left in contact with air.

Nitrofurfurane.—R. Marquis.—After a series of researches on the preparation of furfuranamine, $C_4H_3O{-}NH_2$, by an indirect method, the author now proceeds to prepare the nitrated derivative. After a number of failures, due chiefly to the excessive oxidising power of furfurane, a substance was prepared which analysis proved to have the formula $C_4H_3O{-}NO_2$. The position of the group NO_2 in—



being as yet undetermined.

Absorption-spectra of the Indophenols.—Paul Lemoult.—The author succeeds in obtaining the mobility of the red band in the series of the indophenols, and in discovering the causes which provoke its displacement. The colouring-matters having a discontinuous absorption-spectrum show a red band, of which the centre is fixed (for a molecular dilution and an invariable thickness) as long as the molecule is only complicated with non-significative substitutions, whilst the middle of this band is very sensibly displaced, when the number of tertiary nitrated groups is modified.

New Organo-metallic Compounds of Mercury.—Auguste Lumière, Louis Lumière, and M. Chevrotier.—Mercury-phenoldisulphonate of sodium, prepared by the decomposition of the sodium salt of phenoldisulphonic acid, is obtained in the form of a white amorphous powder, containing about 40 per cent of mercury and very soluble in water. Solutions of this substance lose their metallic taste and even the saline taste of sodium salts; they are not precipitated by soda, hydrochloric acid, or ammonium sulphide.

Methods of Formation and Preparation of Propylbenzene.—F. Bodroux.—When trimethylene bromide acts on benzene in presence of aluminium chloride, the author obtains, at the same time as symmetric diphenylpropane, a notable quantity of propylbenzene. The presence of this hydrocarbide proves, without doubt, the decomposition of a part of the diphenylpropane by the aluminium chloride. Bromine reacts on this substance at 160°, giving rise to dibromophenylallyle, $C_6H_5{-}CHBr{-}CHBr{-}CH_3$. Bromine itself, in presence of aluminium bromide reacting on propylbenzene, gives pentabromopropylbenzene. This latter substance is accompanied by a very small quantity of hexabromobenzene.

Purification of Air by Soil.—Auguste Gérardin.—The authors experiments establish the following facts:—(1) The earth is permeable to the air, and its permeability is independent of its composition; (2) the resistance of the earth to the passage of air is proportional to the thickness of the filtering layer; (3) the resistance of the earth to the passage of air is proportional to the quantity of water which moistens it.

Bulletin de la Société Chimique de Paris.
Series 3, Vol. xxiii., Nos. 16 and 17.

The Action of Iodides and of Hydriodic Acid on Sulphurous Acid.—J. Volhard.—The author has found that hydriodic acid causes the decomposition of sulphurous acid into sulphuric acid and sulphur, without its elements taking part in the reaction; in fact, the hydriodic acid remains unchanged after the decomposition of the sulphurous acid, so that a minimum amount of the former suffices for the decomposition of an infinite quantity of the latter. The reaction takes place the quicker as the solutions are more concentrated. The author attributes this catalysis to the concurrence of two simultaneous reactions: the sulphurous acid oxidises the hydrogen of the hydriodic acid and sets free sulphur and iodine, another portion of iodine, while decomposing the water, causes the oxidation of the sulphurous acid into sulphuric acid, at the same time regenerating the hydriodic acid, and thus the series of reactions goes on:—

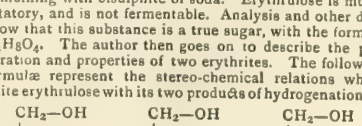
$$SO_2+4HI=2H_2O+4I+S,$$
$$2SO_2+4H_2O+4I=2SO_4H_2+4HI,$$
$$3SO_2+2H_2O+4HI=2SO_4H_2+S+4HI,$$

or, abstracting the elements of water, $3SO_2=2SO_3+S$.

The Reduction of Tungstic Anhydride by Zinc. Preparation of Pure Tungsten.—Marcel Delépine.—Already inserted in full.

On some Phosphoric Ethers.—J. Cavalier and E. Prost.—The authors have prepared some new derivatives of normal propylic, isopropylic, and isobutylic alcohols, viz., their phosphatic ethers, which are analogous to those of the methylic and ethylic alcohols and are prepared in the same manner. For the neutral ethers, PO_4R_3, corresponding quantities of triargentic phosphate and alcoholic iodide are caused to react together by gently heating. Take up with ether and distil, first on the water-bath and then *in vacuo*. The two acid ethers are obtained simultaneously during the reaction of phosphoric anhydride on anhydrous alcohol. On taking up with water, a solution is obtained which contains the three acids, PO_4R_2H, PO_4RH_2, and PO_4H_3. These are easily separated by forming salts of barium neutral to phthalein, and taking advantage of their great difference of solubility in water. The properties of these bodies are then described in full.

The Oxidation of Erythrite by the Bacteria of Sorbose. Production of Two New Sugars, *d*-Erythrulose and *d*-Erythrite.—Gabriel Bertrand.—Erythrulose is obtained in the following manner:—A decoction of brewer's yeast, containing 5 grms. of soluble matter per litre, is treated with 4 per cent of erythrite, then placed in portions 2·5 c.m. in thickness in several large matrasses with wide necks. These are closed with plugs of cotton-wool and sterilised at 110°; they are then infected and kept at a temperature of 28—29° for three weeks, when the transformation of the erythrite is complete. The liquid is then separated and exactly saturated with baryta-water; it is then evaporated to a syrup, which is gradually taken up with half a litre of absolute alcohol to which two volumes of dry ether are then added. A brown precipitate is formed, which is treated again with alcohol and ether, and the solutions, added together and filtered, are evaporated *in vacuo*; in this manner a syrup very rich in erythrulose is obtained. It can be further purified by taking advantage of its property, very rare among sugars, of combining with bisulphite of soda. Erythrulose is multirotatory, and is not fermentable. Analysis and other data show that this substance is a true sugar, with the formula $C_4H_8O_4$. The author then goes on to describe the preparation and properties of two erythrites. The following formulæ represent the stereo-chemical relations which unite erythrulose with its two products of hydrogenation:—



l-Erythrite. *d*-Erythrulose. *d*-Erythrite.

It must be concluded that the sugar obtained by the action of the bacteria of sorbose on erythrite is *d*-erythrulose.

Products of Condensation of Dichlorophthalic Anhydride with Diethylaniline.—E. C. Severin.—By substituting diethylaniline for dimethylaniline a series of bodies entirely comparable with the methylic series is obtained; these are all fully described in a somewhat lengthy paper.

Action of Chloride of Aluminium on Camphoric Anhydride.—G. Blanc.—Already noticed.

The Campholytic and Isolauronolic Acids.—G. Blanc.—An examination of the nature of the isomerism of these two acids.

Diphenylcarbazide: a very Sensitive Reagent for some Metallic Compounds, such as those of Copper, Mercury, Iron (Per-salts), Chromic Acid. — P. Cazeneuve.—Already noticed.

MISCELLANEOUS.

Alkalimetric Method for the Estimation of the Salifiable Alkaloids.—H. M. Gordin.—We prepare N/20 solutions of hydrochloric acid and potash, as well as an iodo-iodised solution (I 10 grms., KI 15 grms., H_2O to 1000 c.c.), and then proceed in the following manner:— 0·20 grm. of morphine, dried at 120°, is placed in a 100 c.c. flask, 30 c.c. of N/20 HCl are added, then the iodo-iodised liquor until the precipitate is no longer formed. The liquid is diluted up to 100 c.c., shaken well to collect the precipitate, and filtered. 50 c.c. are taken and decolourised with 10 per cent hyposulphite of soda; the acidity of the liquor is then titrated with N/20 soda, in the presence of phthalein. We know by difference the number of c.c. of N/20 HCl which corresponds to 0·20 of morphine, and consequently, the proportion of this base which corresponds to 1 c.c. of N/20 HCl. The corresponding quantities of the other alkaloids can be deduced from their molecular weights. 1 c.c. N/20 HCl=0·0137 of anhydrous morphine, 0·0184 of hydrastine, 0·0160 of strychnine, 0·0102 of crystallised caffein, 0·0139 of atropine, and 0·0146 of cocaïne.—*Berichte*, vol. xxxii., p. 287.

MEETINGS FOR THE WEEK.

MONDAY, 18th.—Society of Arts, 8. (Cantor Lectures). "The Bearings of Geometry on the Chemistry of Fermentation," by W. J. Pope.
—— Royal Institution, 3. "The Origin of Vertebrate Animals," by Arthur Willey, M.A., D.Sc.
—— Society of Chemical Industry, 8. Discussion on "Occurrence and the Detection of Arsenic in Manufactured Products."
TUESDAY, 19th.—Royal Institution, 3. "Practical Mechanics" (Experimentally treated), by Prof. J. A. Ewing, M.A., F.R.S., M.Inst.C.E.
—— Society of Arts, 4.30. "The Crisis in China—its Causes and Solution," by By Jos. Walton, M.P.
WEDNESDAY, 20th.—Society of Arts, 8. "Some Features of Railway Travelling—Past and Present," by Frederick McDermott.
—— Royal Institution, 3. "Vocal Music, its Growth and Decay," by F. Corder, F.R.A.M.
—— Microscopical, 7.30. Exhibition of Bacteria and Blood Parasites, by Mr. C. Beck.
THURSDAY, 21st.—Chemical, 8. "Isomeric Hydrindamine Mandelates and Phenylchloracethydrindamides" and "Isomeric Benzylhydrindamine Bromocamphorsulphonates and some Salts of *d-l*-Hydrindamine," by F. Stanley Kipping and H. Hall. "Condensation of Phenols with Esters of the Acetylene Series—IV., Benzo-γ-pyrone and its Homologues," by S. Ruhemann and H. W. Bausor. "Constitution of Bromocamphoric Anhydride and Camphanic Acid," by A. Lapworth and W. H. Lenton. "The Action of Acetylchlor- and Acetylbrom-aminobenzenes on Amines and Phenylhydrazine," by F. D. Chattaway and K. J. P. Orton.
—— Royal Institution, 3. "Society in France before the Revolution," by the Rev. Henry Grey Graham.
FRIDAY, 22nd.—Physical, 5. "How Air subjected to X Rays Loses its Discharging Property, and How it Discharges Electricity," by Prof. Emilio Villari. "On the Propagation of Cusped Waves and their Relation to the Primary and Secondary Focal Lines" and "On Cyanine Prisms, and a New Method of Exhibiting Anomalous Dispersion," by Prof. R. W. Wood.
—— Royal Institution, 9. "Metals as Fuel," by Sir W. Roberts-Austen, K.C.B., D.C.L., F.R.S.
SATURDAY, 23rd.—Royal Institution, 3. "Sound and Vibrations," by the Rt. Hon. Lord Rayleigh, F.R.S., &c.

ERRATUM.—The publisher of the new "Inorganic Chemistry," reviewed on p. 70, col. 2, is "Thomas Murby," and not, as there given, "Thomas Murray."

RAINHAM, ESSEX.

To Manufacturing Chemists, Engineers, and others.

MESSRS. FULLER, HORSEY, SONS, and CASSELL are instructed to SELL by AUCTION, in Lots, at the Faraday Chemical Works, on TUESDAY, FEBRUARY 26, 1901, at 11 o'clock precisely,—

CHEMICAL PLANT and MACHINERY,

including Galloway Boiler, three Lancashire and Cornish Boilers, Vertical Engine, 18 cast- and wrought-iron Stills and Extractors, three Vertical Engines and Gearing, 13 cast-iron Pans, 36 cast- and wrought-iron Tanks, Ammonia Boiler, five Scrubbers, Superheater, 12 Woolf Jars, 17 Vats and Backs, part lead lined, four wood Mixers with Gearing, Mortar Mill, nine "special" Steam Pumps, Roots Blower, two Centrifugals, Disintegrator, two Crabs, three Weighing Machines, Vices, Shafting, Johnson Filter Press, 100 tons Piping Castings and Ironwork, Laboratory Utensils, Office Furniture, and other effects.

May be Viewed day preceding, and Catalogues had on the premises; and of Messrs. FULLER, HORSEY, SONS, and CASSELL, 11, Billiter Square, E.C.

The Laboratory, Corporation St., Lancaster.

SPECIALITIES:—

COMBUSTIONS—C, H, and N (DUMAS).

FURFURAL DETERMINATIONS and the ANALYSIS AND DETERMINATIONS OF RADICALS IN CARBON COMPOUNDS, and other routine work necessary in Chemical Research.

Research work undertaken in Organic and Agricultural Chemistry, and other preliminary investigations for Chemical Experts, Scientific Investigators, College Professors, Manufacturers, &c. Work involving the use of large Experimental Digester and Vacuum Pans undertaken.

References, List of Charges, and other information on application.

IMPORTANT TO EXPORTERS.

The Firm of E. HEUER, Chemical Manufactory, in Aussig, Austria, begs to call the attention of Exporters to the Exporting Products of the Factory.

ALCOHOL DERIVATIVES in general, and in particular Ethers of all kinds, such as Sulphuric, Acetic, Rum, Formic, Nitrous, Œnanthic Butter, Fruit, Grain, and Saccharine Ethers in every specific gravity, all degrees of concentration, and grades of purity.

ABSOLUTE ALCOHOL—98, 99, 99 2/3, and 99 5/7 per cent.

SUPERIOR RUM ESSENCES in all concentrations and contents of spirits.

FIRST CLASS FRUIT ESSENCES, Amylic Alcohols, Amylic Acetates, and Amylic Oxides.

PHARMACEUTICAL CHLOROFORM and Special Brand E.H. CHLOROFORM for Narcosis.

Special Brand E.H. SULPHURIC ETHER for Narcosis.

Correspondence desired.

COVERS FOR BINDING.

Cloth, Gilt-lettered Covers for Binding the Half-yearly Volumes of the

ON THE

PROTEID REACTION OF ADAMKIEWICZ, WITH CONTRIBUTIONS TO THE CHEMISTRY OF GLYOXYLIC ACID.*

By F. GOWLAND HOPKINS, M.A., M.B., University Lecturer in Chemical Physiology, and SYDNEY W. COLE, B.A., Trinity College.

(Concluded from page 75).

IV. *Remarks on the Colour Reaction; Spectroscopic Phenomena.*

Adamkiewicz (*loc. cit.*, p. 158), observed that the colour produced in the reaction varies from red to violet, the blue element increasing with increase in the amount of acetic acid employed. When glyoxylic acid in aqueous solution is used, unless the solution be very dilute, the colour partakes more of a blue shade than is usually seen with ordinary specimens of acetic acid. But after concentrating the reactive substance of the latter by fractional distillation (*supra*) or upon large dilution of the glyoxylic acid solution, the colours obtained become identical. The spectroscopic absorption is identical whichever reagent is employed.

When sulphuric acid is added to a solution of proteid in acetic acid wholly free from glyoxylic acid, a considerable amount of charring occurs, and the mixture becomes somewhat fluorescent. When, under similar circumstances, very little glyoxylic acid is present, the reddish colour obtained is still associated with fluorescence. But, when sufficient of the glyoxylic acid is present, whether in acetic or aqueous solution, to combine with the whole of the proteid product concerned in the reaction, there is complete absence of charring and little or no fluorescence. The solution becomes of a pure violet-blue colour.

The coloured product of the Adamkiewicz reaction is usually stated to show an absorption band between *b* and F in the position of the urobilin band; and Krukenberg described another between D and E. Salkowski found the former to be inconstant, and we are convinced that the latter alone is proper to the real product of the colour reaction: the former, when seen, being due to some accessory effect of the strong acids upon proteids. It is never seen in the original form of the reaction unless the acetic acid employed is greatly deficient in reactive power, and it is not observed with glyoxylic acid. The other band is always present, and is identical after the use of a satisfactory specimen of acetic acid and when a solution of glyoxylic acid is used.

The band shrinks rapidly from its more refrangible edge on dilution of the solution, its redward edge shifting but little.

The following readings show the correspondence seen after employing acetic acid as obtained in the market (but with its active substance concentrated by distillation), and that seen after the use of glyoxylic acid in aqueous solution. The strengths were so arranged that, before dilution, the colour of each solution appeared to be of the same intensity. Witte's peptone was the proteid employed to obtain the reaction:—

	Acetic acid.	Aqueous glyoxylic acid.
Strong	λ 480—λ 625	λ 480—λ 630
Diluted with an equal volume of sulphuric acid	λ 495—λ 625	λ 495—λ 625
Diluted with thrice its volume of sulphuric acid	λ 530- λ 610	λ 530—λ 615

V. *Other Sources of the Reactive Substance.*

Of the typical two-carbon compounds—glycol, glycollic aldehyde, glycollic acid, glyoxal, glyoxylic acid, and oxalic acid—none but the aldehyde-acid (glyoxylic acid, HCO.COOH or $CH(OH)_2.COOH$), gives the smallest indications of yielding a colour reaction with proteid on addition of sulphuric acid. It would seem that the reaction is not common to aldehyde-acids, as glycuronic acid, $HCO(CH.OH)_4COOH$, gives wholly negative results. Again, a ketonic acid so closely related to glyoxylic acid as pyruvic acid, $CH_3.CO.COOH$, gives no indication of a reaction.

Glyoxylic acid stands, of course, alone in containing the aldehydic and carboxylic groups in juxtaposition. Our observations are far from being complete enough to enable us to assert that a reaction with proteid of the special type under consideration depends essentially upon this particular structure. But the preliminary observations we have made tend to give some probability to this view. At least it may be said that hitherto we have never obtained a reaction except with products in which either glyoxylic acid has been shown to be present, or in which its presence is extremely probable.

For instance, we have found that mesoxalic acid (prepared from barium alloxanate) in aqueous solution gives with proteid and sulphuric acid a perfectly typical Adamkiewicz reaction; but under the conditions employed we have found that a portion at least of the mesoxalic acid present loses carbon dioxide, so that it is in the highest degree probable that glyoxylic acid is in this case also the substance which reacts.

Pyruvic acid gives, as we have said, no trace of a reaction, but the product of its oxidation by peroxide of hydrogen undoubtedly reacts. *Paralactic acid*, itself inactive, yields also an active product on oxidation by Fenton's method at the temperature of the water-bath. These two cases go together, as Fenton and Jones have shown that lactic acid yields pyruvic acid when oxidised at 0° in the presence of ferrous iron. It seems extremely probable that the oxidation of the pyruvic acid at the higher temperature yields mesoxalic acid, and that the reaction obtained is therefore due in each case to glyoxylic acid.

One abundant source of a reactive substance is found in the oxidation of *glycerin* by Fenton's method, carried out at the temperature of the water-bath. *Glyceric acid* yields the substance under like conditions; and, as Fenton and Jones (*Journ. Chem. Soc.*, 1900, vol. lxxvii., p. 72), have shown that glyceric acid, when the oxidation is carried out in the cold, gives a product which is almost certainly either hydroxy-pyruvic acid or the tautomeric substance dihydroxyacrylic acid, the facts here quite probably fall into line with those just enumerated. The substance which reacts with proteid is only obtained in quantity in these cases when the oxidation is carried out at higher temperatures than those used by Fenton, and if the oxidised products are distilled, it is always found that the distillate gives the reaction.

When *dextrose* solutions are boiled with peroxide in the presence of ferrous salts a substance is formed, volatile with steam, which yields the proteid reaction abundantly. Preliminary observations that we have made leave little doubt that this is glyoxylic acid itself.

If it should prove that the reaction is, as a matter of fact, peculiar to glyoxylic acid, it certainly forms a very delicate test for that substance.

* From the Physiological Laboratories, Cambridge. A Paper read before the Royal Society, February 7, 1901.

VI. *Glyoxylic Acid Solutions a Practical Test for Proteids.*

By replacing the acetic acid of the Adamkiewicz reaction by weak aqueous solutions of glyoxylic acid a very beautiful and reliable test for proteids is obtained. The colour reaction is brilliant, and the test is, of course, subject to none of the uncertainty inseparable from the use of acetic acid.*

In preparing such a test solution, there is usually no need to separate the glyoxylic acid from associated products. Excellent test solutions may be made by oxidising upon the water-bath, in the presence of small quantities of ferrous iron, either weak solutions of tartaric acid or mixtures of glycerin and water, great care being taken to ensure that no trace of free peroxide remains at the close of the operation. But we strongly recommend the use of reduced oxalic acid for the purpose, as a solution can be prepared with great ease, and almost without regard to conditions. In a moderately strong solution of oxalic acid a few lumps of sodium amalgam are placed, the amount taken of the latter being less than sufficient to neutralise the acid. When the evolution of hydrogen has ceased, the solution is poured off from the mercury and filtered. It will be found, even after large dilution, to yield an intense reaction with proteids if used instead of acetic acid under the familiar conditions of the Adamkiewicz test. The proteid, or the proteid solution to be tested, should be first added to the reagent, and then strong sulphuric acid poured down the side of the test-tube. The reaction may be first observed at the junction of the fluids, and the latter subsequently mixed. At least one-third volume of sulphuric acid should be used, but the quantity may be almost indefinitely increased. There is no tendency to charring.

Summary.

The proteid reaction described by Adamkiewicz is not a furfurol reaction, but depends upon the presence of small quantities of an impurity in the acetic acid employed. Some specimens of acetic acid yield no reaction, and all may be deprived of chromogenic power by distillation.

The substance essential to the reaction is glyoxylic acid.

Small quantities of glyoxylic acid are produced during the oxidation of acetic acid by hydrogen-peroxide in the presence of ferrous iron. Under the conditions used in this research, part of the glyoxylic acid thus formed is split up, yielding formaldehyde.

Glyoxylic acid is slowly formed when acetic acid stands in the air, and more rapidly in the presence of ferrous iron and under the influence of direct sunlight. Most specimens of acetic acid contain small amounts of glyoxylic acid as an admixture.

A dilute aqueous solution of glyoxylic acid, which may be readily prepared by the reduction of oxalic acid with sodium amalgam, forms an admirable test for proteids when used instead of acetic acid under the ordinary conditions of the Adamkiewicz test.

In carrying out this investigation we have been led to employ extensively the method of oxidation described by H. J. H. Fenton, and as a result we have in some degree trenched upon the systematic study of the oxidation of organic acids which he has in hand. It is with his consent that such of our observations are published.

The expenses of the research were met by a grant awarded to one of us by the Government Grant Committee of the Royal Society.

* It is certainly rare to find a specimen of acetic acid which yields no reaction, though many contain too little glyoxylic acid to give a satisfactory colour. It seems to be possible, however, that there have been cases of a proteid derivative being found to yield no Adamkiewicz reaction, in which the negative result was really due to the acetic acid employed. We have, for instance, prepared and carefully purified the primary albumoses from Witte's peptone by the method of E. P. Pick (*Zeitsch. f. Physiol. Chem.*, 1899, vol. xxviii., p. 219). Unlike this observer, we have found these products to yield a marked Adamkiewicz reaction; and with all reserve, we venture to suggest that the acetic acid employed by Pick at this stage of his observations may have chanced to be free from chromogenic power.

CONCERNING LIPASE, THE FAT-SPLITTING ENZYME, AND THE REVERSIBILITY OF ITS ACTION.*

By J. H. KASTLE and A. S. LOEVENHART.

(Continued from p. 80).

On the Effect of Antiseptics on Lipase.

For certain parts of the work it was necessary to exercise considerable care in the choice of an antiseptic. It was therefore thought desirable to study the effect of a number of the commoner antiseptics on this enzyme. Such a study seemed all the more desirable inasmuch as but few, if any, systematic studies of the action of antiseptics in general on enzymes have been undertaken. Some observers have studied the effect of one particular substance, and others that produced by another, but few, if any, general comparisons of the action of antiseptics have ever been made. The first series of experiments was made with salicylic acid. Tubes were prepared containing water (quantity indicated in the following table), 0·1 c.c. of toluene, 1 c.c. of 20 per cent pancreas extract, together with a certain amount of salicylic acid, varying in the amount from 0·1 to 1 c.c. of a 0·5 per cent solution. The tubes were heated for five minutes at 40° C., when 0·26 c.c. of ethyl butyrate was added. The tubes were then allowed to remain in the bath at 40° for fifteen minutes, when they were removed and titrated with N/20 KOH.

Quantity of water used.	Quantity of a 0·5 per cent solution salicylic acid used.	N/20 KOH required.	Per cent of hydrolysis.
C.c.	C.c.	C.c.	
4·0	None	2·25	5·65
3·9	0·1	2·12	5·32
3·5	0·5	1·4	3·51
3·0	1·00	0·2	0·50

This series exhibits a regular decrease in the activity of the enzyme in the presence of increasing amounts of salicylic acid.†

In the second series of experiments the following substances were employed in solution in the proportion of 1 to 1000:—Silver nitrate, mercuric chloride, hydrocyanic acid, salicylic acid, thymol, and sodium fluoride. Tubes were prepared containing 4 c.c. of water or of the solution of the antiseptic to be tested and 1 c.c. of the enzyme (15 per cent pancreatic extract). The tubes were then heated for five minutes at 40°, at the end of which time 0·26 c.c. of ethyl butyrate was added to each tube. The tubes were then allowed to remain in the bath at 40° for fifteen minutes, at the end of which time they were titrated with N/20 KOH. The following are the results:—

Substance used.	N/20 KOH required.	Per cent of hydrolysis.
	C.c.	
Water	1·8	4·52
Hydrocyanic acid ..	1·7	4 27
Thymol	1 6	4·02
Mercuric chloride ..	0·3	0·75
Silver nitrate	0·15	0·38
Salicylic acid	None	None
Sodium fluoride	None	None

In the third series of experiments, the following substances were tried:—Potassium cyanide, ammonium oxalate, and toluene. These substances were used in a solution containing 1:1000. Tubes were prepared containing 4 c.c. of water, or of the solution of the antiseptic to be tested, and 1 c.c. of pancreatic extract. These were heated at 40° for five minutes, when 0·26 c.c. of ethyl butyrate was added to each tube. They were allowed to

* From the *American Chemical Journal*, xxiv., No. 6.

† An investigation of the power of salicylic acid to prevent the fermentation of wine-must by Neubauer gave similar results. See *Journ. Prakt. Chem.*, [2], xi., 1.

remain in the bath at 40° C. for fifteen minutes and then they were titrated with N/20 KOH. The following are the results :—

Substance used.	N/20 KOH required.	Per cent of hydrolysis.
	C.c.	
Water	1·4	3·51
Ammonium oxalate	1·25	3·14
Toluene	1·15	2·89
Potassium cyanide	0·3	0·75

The effect of antiseptics 1 : 1000 was next tried on a 10 per cent hepatic extract, which had been made up originally without an antiseptic. Ethyl acetate was employed in this series of experiments. Tubes were prepared containing 3 c.c. of water, 1 c.c. of enzyme, and 1 c.c. of the antiseptic. These tubes were then heated at 40° for fifteen minutes, after which 0·19 c.c. ethyl acetate was added. The tubes were then allowed to remain in the bath at 40° for thirty minutes, when they were titrated with N/20 KOH. The following are the results :—

Substance used.	N/20 KOH required.	Per cent of hydrolysis.
	C.c.	
Water	2·65	6·62
Toluene	2·90	7·25
Chloroform	2·50	6·25
Hydrocyanic acid	2·30	5·75
Mercuric chloride	2·00	5·00
Thymol	1·85	4·63
Silver nitrate	1·60	4·00
Salicylic acid	1·50	3·75
Osmic acid	1·45	3·63
Sodium fluoride	0·10	0·25

After titration the tubes were allowed to stand at ordinary temperature (30° C.) for an hour and a half, when they were titrated a second time, with the following results :—

Substance used.	N/20 KOH required.	Per cent of hydrolysis.
	C.c.	
Water	3·02	7·55
Toluene	3·90	9·75
Chloroform	3·65	8·82
Hydrocyanic acid	3·40	8·50
Mercuric chloride	2·70	6·75
Thymol	3·00	7·50
Silver nitrate	2·20	5·50
Salicylic acid	3·05	7·60
Osmic acid	2·45	6·12
Sodium fluoride	0·20	0·50

Finally, the attempt was made to determine the effect of a number of antiseptics on liver and pancreatic extracts of about the same activity towards ethyl butyrate. Therefore a 10 per cent liver extract was compared with a 20 per cent pancreatic extract under the following conditions :—Tubes were prepared containing 3 c.c. of water, 1 c.c. of the antiseptic (1 : 1000), and 1 c.c. of the enzyme. These were heated at 40° C. for five minutes to give the antiseptic a chance to act. Then 0·26 c.c. ethyl butyrate was added, and the tubes allowed to remain in the bath at 40° C. for fifteen minutes, when they were removed and titrated with N/20 KOH. The results are given in Tables A and B.

It is believed that in the last two series of experiments a mistake was made in not allowing the antiseptic to remain in contact with the enzyme for a greater length of time in order that the effect of the weaker of them might have been more pronounced.

It will be observed that certain of the antiseptics tested exert the same effect on both the pancreatic and liver extracts; for example, chloroform is almost without effect, and thymol, hydrocyanic acid, and sodium fluoride each reduces the activity of the two extracts to the same extent. On the other hand, some of the substances used behave differently towards the two enzymes. For example, while strychnine sulphate and phenol both reduced the activity of the pancreatic extract about 30 per cent, they were without effect on the activity of the liver extract. On the other hand, osmic and salicylic acids seem to exert a more detrimental effect on the hepatic than on the pancreatic lipase. While perhaps not conclusive, these results are suggestive at least, for, if after repeated trials, it were to turn out that several substances exerted a different effect upon liver and pancreatic lipase, it would probably indicate that the two enzymes are in reality different substances. Upon pancreatic lipase especially, nearly all kinds of substances seem to exert a harmful effect. Towards a number of them, on the other hand, the lipase of the liver is more stable. Generally speaking, the more germicidal and antiseptic the substance, the greater its power to inhibit and destroy the activity of lipase. Substances like silver nitrate, mercuric chloride, salicylic acid, and osmic acid exert a more pronounced detrimental effect than the weaker antiseptic substances —such as toluene, chloroform, thymol, &c. One point of especial interest in this connection is the remarkably destructive action of sodium fluoride on lipase. In all of our tests, this substance has been found to exert the most destructive influence upon lipase of any substance yet

tried, unless it is hydrofluoric acid itself. The effect of acids in general has also been found to be very injurious.*

(To be continued).

LONDON WATER SUPPLY.

REPORT ON THE COMPOSITION AND QUALITY OF DAILY SAMPLES OF THE WATER SUPPLIED TO LONDON FOR THE MONTH ENDING JANUARY 31ST, 1901.

By SIR WILLIAM CROOKES, F.R.S.,
and
PROFESSOR DEWAR, F.R.S.

To CHARLES PERRIN, Esq., M.Inst.C.E.,
Water Examiner, Metropolis Water Act, 1871.

London, February 11th, 1901.

SIR,—We submit herewith, at the request of the Directors, the results of our analyses of the 216 samples of water collected by us during the past month, at the several places and on the several days indicated, from the mains of the London Water Companies taking their supply from the Thames and Lea.

In Table I. we have recorded the analyses in detail of samples, one taken daily, from Jan. 1st to Jan. 31st inclusive. The purity of the water, in respect to organic matter, has been determined by the Oxygen and Combustion processes; and the results of our analyses by these methods are stated in Columns XIV. to XVIII.

We have recorded in Table II. the tint of the several samples of water, as determined by the colour-meter described in previous reports.

In Table III. we have recorded the oxygen required to oxidise the organic matter in all the samples submitted to analysis.

Of the 216 samples examined by us during the month, all were found to be clear, bright, and well filtered.

The rainfall at Oxford during January has been exceptionally small, only 1·04 inches having been registered; the average fall for the past thirty-five years is 2·08 inches; we therefore have to record a deficit of 1·04 inches, or 50·0 per cent on the thirty-five years' average.

Our bacteriological examinations of 550 samples have given the results recorded in the following table; we have also examined 40 other samples, from special standpipes, &c., making a total of 590 samples in all:—

	Microbes per c.c.
New River, unfiltered (mean of 27 samples) ..	671
New River, filtered (mean of 137 samples) ..	28
Thames, unfiltered (mean of 27 samples) ..	4069
Thames-derived water, from the clear-water wells of eight Thames-derived supplies (mean of 293 samples)	49
Ditto ditto .. .. highest	363
Ditto ditto .. .. lowest	0
River Lea, unfiltered (mean of 27 samples) ..	450
River Lea, from the East London Company's clear-water wells (mean of 39 samples) ..	16

Of the 469 samples of the filtered water supplied to London, examined bacteriologically during the past month, fifty-nine samples, or 12·5 per cent of the whole number of samples examined, contained more than 100 microbes per c.c.; the mean of the excess samples being 150. The microbic purity of the general supply was not so good as during the month of December; this was no doubt due to the heavy snow-fall and foggy weather experienced during the second week in January. For the last fortnight the water has been in its normal good condition for the time of year.

We are, Sir,
Your obedient Servants,
WILLIAM CROOKES.
JAMES DEWAR.

* Quite recently, in fact since this article was written, Kastle and Hardin have been engaged in studying the toxic action of different acids on lipase. It is their intention to present the results obtained in the form of a separate communication. It may not be out of place to state in this connection, however, that it has been found in general that the toxic effect of acids upon lipase is proportional to their strength.

SOME PRINCIPLES AND METHODS OF ROCK ANALYSIS.*

By W. F. HILLEBRAND.

(Continued from p. 81).

II. *Specific Gravity* (continued).

Pycnometer Method.

IF the pycnometer has to be used, as is generally the case when the density of any one of the mineral ingredients of a rock is desired after separation by one of the approved methods, it being then in a more or less finely divided state, the most accurate procedure is that adopted in this laboratory by Mr. L. G. Eakins a number of years ago. The pycnometer used is one with a capillary stopper, provided with a millimetre scale etched in the glass, the divisions being numbered both ways from the centre and calibrated by mercury so that the value of each one in weight of water is known. The capacity of the flask filled with water to the zero division is then calculated for every half degree of temperature from 0° C. to 30° C., by making a series of careful weighings, in which, the capacity of the stem being known, it is quite immaterial at what level the water stands provided it is within the limits of the scale. The exact temperature is obtained by an accurate thermometer placed in a companion vessel of similar shape to the pycnometer, and containing a like amount of water, both being left in the balance case till its temperature has been nearly or quite assumed, as shown by a second thermometer. The weighing must of course be made before the thread of water has sunk beneath the lowest division, which it will do after a time, even though at first filling the bore to the top of the stopper; and the corrected weight full of water to the zero mark is found by adding or subtracting the needed amount, as shown by the height of the thread on the scale.

For each pycnometer in use, and these are of different sizes, is prepared a table showing its weight, the value of each scale division in grms. of water, and the capacity of the flask at different temperatures, as indicated above. The preparation of such a series of flasks is time saved in the end, for the weighing of the flask full of water each time a density determination is made is rendered superfluous. All that is necessary is to look up in the table the weight corresponding to the temperature.

The density of the previously weighed substance in this case is now determined in much the same way, after the unstoppered pycnometer containing it and nearly filled with water has stood with its companion vessel of water under the air-pump the necessary length of time. The water needed to fill the flask is taken from its companion.

All who have used the pycnometer method for fine substances know the difficulty experienced in preventing a portion from being held at the surface, despite all attempts at making it sink. Hence it often happens that a very small portion runs out around the sides of the stopper on inserting it. If the flask rests in a small tared dish the grains thus forced out may be washed down into it and weighed after evaporation in order to get the correct weight of that in the flask; or, after weighing, the contents of the flask may be emptied into a tared dish, and the water slowly evaporated off in order to get the weight

* *Bulletin of the United States Geological Survey*, No. 176.

of the mineral. Usually this way is less to be recommended than the other.

Heavy Solutions not Suitable for Rocks.

Because of their roughness, porosity, and complex mineral composition, the density of rock fragments can not be accurately determined by that of heavy solutions in which they may remain suspended.

III. *Preparation of Sample for Analysis.*

Quantity of Rock to be Crushed.

In the great majority of cases a few chips from a hand specimen will well represent the average of the mass, but with rocks in which a porphyritic structure is strongly developed the case is different. Here a large sample should be provided, gauged according to the size of the crystals, and the whole of this should be crushed and quartered down for the final sample. Unless this is done, it is manifest that the analysis may represent anything but the true average composition of the rock.

Crushing.

Mechanical appliances for reducing samples to fine powder are much in use in technical laboratories, where they answer their purpose more or less satisfactorily, and something similar is needed in those scientific laboratories where rock analysis is of daily occurrence, and many samples must be reduced to fine powder in a short space of time. For accurate analyses the use of steel crushers and mortars is out of the question, because of the danger of contamination by particles of metal, and the impossibility of cleansing the roughened surfaces after they have been in use a short time. Extraction by the aid of a magnet of steel particles thus introduced into the powder is quite inadmissible, since the rocks themselves, almost without exception, contain magnetic minerals. The method of rough crushing on a small scale found to be most satisfactory in practice is to place each fragment as received on a hard steel plate about 4½ c.m. thick and 10 c.m. square, on which is likewise placed a steel ring 2 c.m. high, and of about 6 c.m. inner diameter, to prevent undue flying of fragments when broken by a hardened hammer. In this way a considerable sample can soon be sufficiently reduced for transfer to the agate grinding mortar with a minimum of metallic contamination.

For breaking large pieces or rock to small sizes a thick iron plate with specially hardened surface and a similarly hardened pounder, such as street pavers use, will probably render the best service, but the hardening must be done with extreme care.

Grinding.

Of the various grinding arrangements on the market purporting to fulfil their purpose few, if any, observed have met the conditions required by the work in hand. Either the mechanical arrangement is complicated or cumbersome, requiring more power or space than is usually at disposal, or causing too much noise, or thorough cleansing is difficult and troublesome, or there is likelihood of contamination from oil or grease or lack of facility for the removal of all powder from the mortar. These last defects are especially prominent in those forms in which the mortar is fixed in its setting.

All rock samples have therefore been reduced to powder by hand, involving a great expenditure of time and labour. Ordinarily an extremely fine state of division is unnecessary, except in the case of those portions in which alkalis and ferrous iron are to be estimated, or where soluble constituents are to be removed by acids, &c., and in such cases the final grinding can be done at the balance table on a small portion slightly in excess of the quantity to be weighed off.

The process of sifting through fine cloth, the German "Beuteln," is not one always to be commended, because of the time required, and, more especially, because of the certainty of contamination by cloth fibre, which in the ferrous-iron portion might affect the result. Still less should metal sieves be used.

Weight of Ground Sample.

The sample when ground should weigh not less than 10 grms., and preferably 20 in case it should be necessary to repeat or advisable to employ unusually large portions for certain determinations, notably carbonic acid. Rock analysis has in this respect an advantage over mineral analysis, since material is almost always available in ample quantity, and any desired number of separate portions may be used, whereas with a mineral the analyst is frequently compelled to determine many or all constituents in a single, often very small, portion of the powder. This course often involves delay, and the employment of more complicated methods of separation than are usually necessary in rock analysis.

IV. *Water—Hygroscopic, Zeolitic, Crystal.*

Importance of Employing Air-dry Powder for Analysis.—The time-honoured custom of drying a powdered specimen before bottling and weighing has long seemed to the writer one that has no sound basis in reason. Its object is of course plain, namely, that of securing a uniform hygroscopic condition as a basis for convenient comparison of analytical results, since some rocks contain more hygroscopic moisture than others. Nothing, however, is more certain than that by the time the substance is weighed it has re-absorbed a certain amount of moisture, small, indeed, in most cases, but very appreciable in others; and further, with every opening of the tube moisture-laden air enters and is enclosed with the remainder of the dry powder. It therefore may very well happen that a powder at first dry will, after several openings of the tube, especially at considerable intervals, be nearly as moist as when first inclosed.

It is preferable to weigh the air-dry powder and to make a special determination of moisture. If all the portions necessary for an analysis are weighed out one after another, or even at different times on the same day, the error due to difference of hygroscopicity in dry and moist weather, which for most of the separate portions is an entirely negligible quantity, is eliminated. Only in the main portion, in which silica and the majority of the bases are to be estimated, can it ever be an appreciable factor.

Temperature of Drying.—As to the temperature to be adopted for drying in order to determine so-called hygroscopic moisture, the practice has varied at different times and with different workers, ranging from 100° to 110° C. For the great majority of rock specimens it is quite immaterial which of these temperatures is adopted, since no greater loss is experienced at the higher than at the lower temperature, given a sufficient time for the latter. It is the present practice in this laboratory to employ a toluene bath giving a temperature of about 105° C. Should the results show a very unusually high loss, the powder is reheated at, say, 125°, in order to learn if the loss is progressive with increased temperature. In the affirmative case it may be well to repeat the drying at 100°, for a portion of the loss at 105° was probably due to combined water from a mineral or minerals in the rock; but in that case even the loss at 100° may sometimes very well include combined water, in which case drying over sulphuric acid alone may be desirable, or over dry sand.

Cautionary Hints.—In this latter connection it is proper to point out certain pitfalls in the path of the unwary, which, however, are far more likely to be encountered in the analysis of minerals, where their influence may be of far-reaching consequence.

A mineral which loses a great deal of water over sulphuric acid—2 or 3 per cent, for instance—may need an exposure of several days or even weeks for its complete extraction. If the weighings are made from day to day, the apparent limit may be reached long before all water really removable has been taken up by the acid. Whenever the crucible, after weighing, is replaced in the

desiccator it is no longer in a dry but a more or less moist atmosphere, and its contents, even when covered, sometimes absorb a part of this moisture, and retain it so persistently that the acid is unable to bring the powder beyond its previous state of dryness in the next twenty-four hours. In fact, it may be unable even to reach it unless greater time is allowed. An experiment on 1 grm. of tyrolite, made and published some years ago, seems to illustrate this point in part:—

TABLE III.

Hours exposed.	Loss. Grm.	Hours exposed.	Loss. Grm.
18	0·0231	24	0·0002
26	0·0083	24	0·0003
23	0·0029	48	0·0006
24	0·0012	24	0·0002
23	0·0008		
24	0·0001	283	0·0380
25	0·0003		

placed, and again weighed the next day. It had regained 1½ per cent of its original weight, although the desiccator was tightly closed and the crucible covered, showing apparently a drying power superior to that of the acid.

A specimen of tyrolite was found on one occasion to lose 10·34 per cent at 280° C., and on another occasion 14·33 per cent. In the latter case the drying and heating at progressive temperatures had continued during a period of 528 hours, the weighings being made usually from day to day; whereas in the former the duration of the experiment was much shorter, and the intervals between weighings were but a few hours each.

Procedure in Special Cases.—For experiments of the kind just indicated the powder should be heated in a weighed tube, through which a current of dry air can be passed, and allowed to cool therein, or else the water given off should be collected and directly weighed in suitable absorption tubes, even though the long time often required is an objection to this latter method, since the absorption tube may gain weight, other than that of the

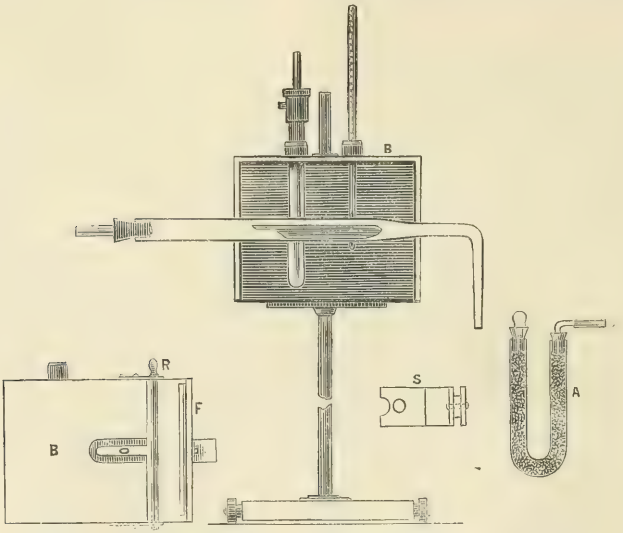

FIG. 3.—CHATARD'S FORM OF DRYING-OVEN FOR WATER DETERMINATIONS.

B, Copper box, 18 c.m. long, 10½ c.m. high, 9 c.m. wide, open in front, its sides and top covered with asbestos board; S, two slides of different sizes to close the openings, O, after the tube is in position; F, asbestos board front, stiffened by an interlaid sheet of copper; R, metal rod to hold front in place; A, calcium chloride absorption tube.

The experiment might reasonably have been considered ended after the one hundred and fifty-eighth hour, when a loss of but 0·1 milligrm. was shown during twenty-four hours; but nevertheless a nearly steady loss of 0·3 milligrm. per day took place for six days more, and might have been longer observed but for the interruption of the experiment.

Again, it is a common practice to determine the water given off by hydrous minerals in an air-bath at temperatures far above 100° C. To insure accuracy this experiment should not be made in crucibles or dishes which must be cooled in a desiccator. One instance will suffice: A grm. of a mineral mixture containing about 17 per cent of water, of which about 3 per cent was driven off at 100° and 8 or 9 per cent at 280°, was, after several hours' heating at the latter temperature, placed in a desiccator over sulphuric acid, and weighed as soon as cold, then re-

water from the mineral, sufficient to introduce an appreciable error.

The recent important research of Friedel (*Bull. Soc. Min.*, 1896, vol. xix., pp. 14, 94; *Comptes Rendus*, 1896, vol. cxxii., p. 1006), well shows what errors are possible in the determination of this easily removable water, since he found that certain zeolites which had been largely dehydrated but not heated to the point of rupture of the molecular net, could then absorb, instead of water, various dry gases in which they might be placed, as carbon dioxide, ammonia, carbon disulphide, and others, even air in large quantities, and certain liquids. In the light of this observation the cause of the great increase of 1½ per cent in weight of the partially dehydrated mineral mentioned above may very possibly be attributed to air from the desiccator instead of moisture, as was at the time supposed. At any rate, as Friedel says, the danger of

accepting a loss in weight as an index of the amount of water lost is clearly shown, and thus that method of determining water is for many cases fully discredited. Just what method to adopt must be largely left to the judgment of the operator, who will often be guided by the mineral composition of the rock as revealed by the unaided eye or the microscope.

Friedel (*loc. cit.*) indicates a means for determining the true weight of water lost by minerals behaving like the zeolites, even without collecting the water lost, namely, by driving out of the dehydrated and weighed mineral, under proper precautions, any air it may have absorbed in the process of drying and cooling, and collecting and measuring this air, and thus finding its weight, which, added to the apparent loss, gives the true contents in water.

Argument in Favour of including Hygroscopic Water in Summation.—The question has been asked: "If the so-called hygroscopic water is not always such, but not infrequently includes combined water, why is not its determination and separate entry in the analysis entirely unnecessary? Why make a distinction, which, after all, may not be a true one?" The question involves the further consideration of the advisability of including in the analysis at all the loss at 100° or 110° C. Many petrographers desire to have all analyses referred to a moisture-free basis, in order that they shall be strictly comparable, and therefore, would omit the "hygroscopic" water from the list of constituents. This would be eminently proper were it always possible to be sure that the loss at 100° truly represents mechanically held water. Since it very often represents more, and the determination as to whether or not it does in each case is not always possible, and would add to the time required for the analysis, it seems necessary to include this water. What errors may arise from its exclusion the following rather extreme case well illustrates: Certain rocks of Wyoming in powder form lost from 1 to 2 per cent of moisture at 110°. That not even an appreciable fraction of this was truly hygroscopic, the fact of the uncrushed rocks losing the same amount fully demonstrates; yet the rule followed by many chemists and petrographers would have involved the removal of all this water as a preliminary to beginning the analysis, and not only would a most important characteristic have passed unnoticed, but the analyst would have reported an incorrect analysis, inviting to false conclusions and possibly serious confusion.

Separate Entry of Hygroscopic and Combined Water.—To revert now to the primary question, it may be said that the estimation of the loss at 100° or 110° C. and its separate entry in the analysis is advisable as not infrequently affording at once to the lithologist an indication of the mineral character of one or more of the rock constituents, thus perhaps confirming the microscopical evidence or suggesting further examination in that line. An unusually high loss at 100° would be regarded as probable evidence of the presence of zeolites or other minerals carrying loosely combined water. It has been objected that the true hygroscopic moisture varies with the degree of comminution of the sample and with the condition of the air at the time of weighing, and that it is therefore improper to incorporate it in the analysis; but this variation is ordinarily not at all great. Perhaps the time may come when it will be the rule to ascertain by additional heating at a higher temperature whether the water lost at 100° is to be regarded as purely hygroscopic. In such case it would be proper to omit it, and a distinct advance would undoubtedly be scored.

Is all True Hygroscopic Water Expelled at 100°?—It has been tacitly assumed in the foregoing that true hygroscopic water can all be expelled at 100°, which perhaps is not to be accepted as universally true. Eminent authority holds that it is impossible, in the cases of certain foliaceous minerals, notably the micas, to thus entirely remove it, but that a part is only driven off at higher temperatures. If this is true a further uncertainty is introduced in its determination, which not only strengthens the argument in favour of entering all water in the tabulation, but also serves to emphasise the difficulties of the situation.

Apparatus for the Direct Determination of Water at Different Temperatures.

A form of drying-oven devised by Dr. T. M. Chatard (*Am. Chem. Journ.*, 1891, vol. xiii., p. 110; *Bull. U. S. Geol. Survey*, No. 78, p. 84) is in use in this laboratory for determining water at different temperatures up to 350° C., and gives entire satisfaction. It is an asbestos-covered copper box, B, shown in different aspects and parts in the accompanying Fig. 3. The box is so constructed that the tube with its contents can be removed without detaching from either the drying or collecting tubes, which is a great advantage if it is desired to afterwards apply the direct heat of a lamp in order to expel the water retained at 300° to 350° C. To facilitate this removal the stand is on rollers, so that after clamping the projecting end of the tube and removing the front of the box, F, and the little side pieces, S, closing the horizontal slits, the oven can be rolled bodily backward, leaving the tube and its attachments in their original position, ready for further heating over a burner or blast. The removable front, F, of the oven is made of two pieces of sheet asbestos board stiffened by an interlaid piece of sheet copper. The inner piece of asbestos board fits snugly into the box, while the outer one, being slightly larger, by its projecting edges hinders the door from falling in and helps to prevent air currents. This door is held in place by the metal rod R. The little slides, S, are made in a somewhat similar manner, and are intended to slip in from the front and close the two openings, O, after the tube is in place, but before closing the front.

For other forms of tubes adapted to similar determinations, see Figs. 6, 10, and 11.

(To be continued).

Institute of Chemistry Examinations.—Pass Lists (January, 1901).—*Intermediate Examination*: J. Evans, King's Coll., London, and Pharmaceutical Society; R. S. Finlow, Univ. Coll. of N. Wales, Bangor; E. Hinks, King's Coll., London; W. A. Handcock, Finsbury Tech. Coll., London; D. Northall-Laurie, King's Coll., London, and under E. Jackson, Esq., F.I.C.; G. Steedman, Glasgow and West of Scot. Tech. Coll. *Final A.I.C. Examination—Branch* "A" (*Mineral Chemistry*): J. H. Austin, Birmingham University; R. M. Clarke, B.Sc. (Glasgow), Glasgow University; J. W. Cotterill, Birmingham University (for Fellowship); F. Cunliffe, Owens Coll., Manchester; W. D. Dick, King's Coll., London; A. Gray, Glasgow and West of Scot. Tech. Coll.; W. Chapman, Pharmaceutical Society and King's Coll., London; J. A. Dewhirst, Yorkshire Coll., Leeds, and Pharmaceutical Society; A. H. Mitchell, B.Sc. (Lond.), Owens Coll., Manchester, and Univ. Coll., London (for Fellowship); E. A. Pinchin, B.Sc.(Lond.), Roy. Coll. of Science, London.

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Ordinary Meeting, February 7th, 1901.

Professor Thorpe, C.B., F.R.S., President, in the Chair.

Messrs. R. M. Caven and J. B. Harrison were formally admitted Fellows of the Society.

The following certificates were read for the first time:—William Carrick Anderson, 2, Florentine Gardens, Hillhead, Glasgow; George Stanfield Blake, Purley Lodge, Purley, near Croydon; Edward Richards Bolton, 7, Leazes Terrace, Newcastle-on-Tyne; William Carter, 7, Victoria Street, Clitheroe; Henry Drysdale Dakin, 9, Beech Grove Terrace, Leeds; John Hanley, 4, Guion Road, Litherland, Liverpool; John Ansted Harrison, 47, London Road, Neath, Glamorganshire; Henry Herbert Higgs, 26, Anglesey Street, Lozells, Birmingham; Albert John Murphy, Preston House, Leeds; Arthur Theodore Neil, 21, South Grove, Highgate, N.; William Robertson, 41, Rosenau Road, Battersea Park, S.W.; Samuel Fenton Stell, 20, Henry Street, Keighley; George Edward Welch, 88, Caledonian Road, Leeds; Adam Storer Wylie, 93, Manchester Street, Oldham.

The Address to the King.

The President read the following Address, which the Council that afternoon had resolved to present to his Majesty the King. He moved that the Fellows of the Society should join with the Council in paying respect to the memory of the illustrious Queen they had so recently lost and in offering their homage to the new Sovereign. This was seconded by the Treasurer and carried unanimously, the Fellows all standing.

To His Most Gracious Majesty King Edward VII.

May it please your Majesty.

We, the President, Council, and Fellows of the Chemical Society, beg leave to approach your Majesty with expressions of deep sympathy in the grievous loss which your Majesty and the Empire have sustained through the death of our revered Sovereign, Queen Victoria, during whose beneficent reign the science of Chemistry, for the promotion of which her Majesty granted the Society a Royal Charter, has made immense progress.

We recall with gratitude the leading part which your illustrious Father, the Prince Consort, took in securing the extension of scientific knowledge in this country, and especially the great assistance he rendered in the foundation, in the year 1845, of the Royal College of Chemistry (since developed into the Royal College of Science), of which College he became the President.

We desire respectfully to congratulate your Majesty on your accession to the Throne, and most heartily to wish your Majesty a long, happy, and prosperous reign.

We venture to express the hope that your reign may be marked by discoveries in the science we represent not less brilliant than those which have characterised the reign of her late Majesty.

Signed on behalf of the Chemical Society,

T. E. Thorpe, President.
W. A. Tilden, Treasurer.
Wyndham R. Dunstan, Alexander Scott, } Honorary Secretaries.
R. Meldola, Foreign Secretary.

The Day and Hour of Meeting.

Mr. F. J. Lloyd asked whether the President could give any information as to the reasons which had led the Council to issue its recent circular requesting the views of the Fellows on a proposal to change the day and hour of the Ordinary Meetings of the Society.

The President, in reply, said that he was glad to take advantage of the opportunity which Mr. Lloyd had afforded him to state the attitude of the Council on the question. The expediency of an alteration in the day and hour of meeting had been mooted on more than one occasion, though no action was taken till the question was formally raised at a recent meeting of Council. The Secretaries were thereupon directed to issue with the "Journal" for this month the circular and card referred to, with the view of eliciting the opinion of the Fellows upon the subject.

With respect to Mr. Lloyd's question as to the reasons for the inquiry, he might remind the Fellows that a great change had come over the social life of London during the fifty or sixty years of the Society's existence. A great number of what used to be called the "resident" Fellows now lived in suburbs which were extending in all directions more and more widely. Moreover, the facilities for reaching town had been so enormously increased that it seemed worth while inquiring whether a re-arrangement of the day and hour of meeting would render it possible for the country Fellows to attend the meetings of the Society in greater numbers than at present. He (the President) thought it would thus be seen that the Council had good *primâ facie* grounds for testing the opinion of the general body of Fellows.

He might add that more than half of the cards issued had been returned, and of these a very large majority were in favour of the suggested alteration. No exact analysis had as yet been made, but the Fellows might be interested to know that those in favour of the change were in the ratio of about four or five to one. Of the "resident" Fellows about two to two and a-half to one were in its favour. He expressed a wish that the remaining cards should be returned as quickly as possible so that the Council might have the opportunity of considering the replies, and of dealing with the matter, if necessary, at the Annual General Meeting.

A ballot for the election of Fellows was held, and the following were subsequently declared duly elected:—

Andrew Charles Aitken, Thomas Stewart Barrie, John Cardew Bedwell, B.Sc., Herbert John Bult, Merrick W. Burrows, M.Sc., Robert Waley Cohen, B.A., Herbert H. Cousins, M.A., Gilbert Howard Daniel, B.Sc., Robert Dodd, Frederick G. Donnan, M.A., Ph.D., John Alfred Emery, Reginald W. Ferguson, Henry Edward Haddon, Arthur Houldershaw, Bernard Farmborough Howard, Edward Hughes, Robert Salmon Hutton, M.Sc., Stephen Archigenes Ionides, Major J. L. T. Jones, I.M.S., Robert Henry Jones, M.Sc., H. T. G. van der Linde, Nicholas Henry Martin, James Menzies, William Meredith, James Moir, M.A., B.Sc., Arthur W. Nunn, Theodore Henry Page, Thomas Slater Price, Ph.D., D.Sc., Lionel Guy Radcliffe, William Cecil Ramsden, Herbert Kilburn Scott, Harry Metcalfe Smith, John Talbot, B.A., B.Sc., Albert Edward Thomas, B.Sc., Major-General J. Waterhouse, William A. Wayland, J. S. Wilson, M.D., C.M.

Of the following papers, those marked * were read:—

*8. "*The Action of Hydrogen Bromide on Carbohydrates.*" By H. J. H. Fenton and Mildred Gostling.

It was previously shown by the authors (*Trans.*, 1898, lxxiii., 554, and 1899, lxxv., 423), that bromomethylfurfuraldehyde results when hydrogen bromide acts upon lævulose, sorbose, inulin, or cane sugar, and it was shown that the formation of this substance is characteristic of ketohexoses or of substances which give rise to them on hydrolysis. The experiments have now been extended, using a higher temperature and chloroform as the solvent. Under these conditions, all forms of *cellulose* give large yields of bromomethylfurfuraldehyde, and the results appear conclusively to prove that cellulose must contain a grouping or nucleus similar to that in lævulose. An account was also given of the behaviour of several other carbohydrates under similar conditions.

*9. "*The Ketonic Constitution of Cellulose.*" By C. F. Cross and E. J. Bevan.

Having received a private communication of the results obtained by Fenton and Gostling, which are described in the preceding note, it has been deemed opportune to state fully the experimental evidence available for the solution of the problem of the constitution of cellulose.

For the view that cellulose is a near analogue of starch, that is, a polyanhydride of dextrose, the evidence is slender, resting mainly (1) on the well established empirical formula $(C_6H_{10}O_5)_n$ and (2) on the somewhat superficial study of the products of ultimate hydrolysis by Braconnot (*Ann.*, 1819, [ii.], xii., 172), and Flechsig (*Zeit. Physiol. Chem.*, 1883, vii., 523).

The later evidence comprises the following items: (*a*) The tetracetate (Cross and Bevan) appears to be an ester of the unresolved cellulose (anhydride) with a formula $C_6H_8O\cdot(OAc)_4$, from which may be deduced as probable the ketonic formula $CO{:}(CHOH)_4{:}CH_2$, for the cellulose unit; (*b*) Will and Lenze have shown (*Ber.*, 1898, xxxi., 68) that the ketoses yield nitric esters with two ester groups less than the corresponding aldoses, two hydroxyl groups being condensed by internal reaction. Cellulose giving a trinitrate (C_6) with yields less than the theoretical (for the simple ester reaction) conforms with this general character of the ketoses and their anhydrides; (*c*) Faber and Tollens (*Ber.*, 1899, xxxii., 2595), in a recent study of the oxycelluloses, have identified in the soluble products of the oxidation tartaric and oxalic acids and a dibasic acid containing five atoms of carbon. *Saccharic acid was not formed.* Further, the oxycelluloses digested with calcium hydroxide yield dioxybutyric and isosaccharic acids. Acids with the normal six carbon chain are again conspicuously absent; (*d*) Brown and Morris (*Trans.*, 1893, lxiii., 604) have established that cane sugar is a first product of chlorophyllic assimilation, and starch is probably only a derived overflow product. Further, that cane-sugar, amongst the soluble carbohydrates, has a maximum nutritive value when tested in relation to chlorophyllic assimilation (*Trans.*, 1890, lxxvii., 484). A similar observation, but more directly with lævulose in relation to cellulose production, was made by A. Brown (*Trans.*, 1886, xlix., 432).

On the above grounds, the authors had previously concluded that cellulose is not a polyaldose (anhydride), but is of ketonic constitution.

Fenton and Gostling, by condensing celluloses to methylfurfural as a main reaction, have opened an entirely new direction of experimental attack, the first result of which is at least to render the polyaldose view of its constitution questionable.

Their results directly suggest that lævulose or other ketose is the raw material for cellulose elaboration, and also offer a simple explanation of the origin of unsaturated compounds such as the furfural derivatives which are constituents of the lignone complex. It also further weakens the evidence upon which all furfural yielding constituents of plants have been assumed to be pentoses or pentosanes.

Discussion.

Dr. Horace Brown, whilst fully admitting that a considerable amount of evidence can now be brought forward in favour of the ketonic constitution of cellulose, expressed a doubt whether the small amounts of the bromo-derivative of methylfurfural obtained by Mr. Fenton from purified starches would justify the conclusion that starch contains the carbonyl group. More evidence is required of the specific nature of the reaction, and also of the absolute freedom of the starch from traces of "starch cellulose." He was unable to add anything to the physiological evidence put forward by Dr. Morris and himself some years ago, and which certainly did appear to lend some countenance to the view that in the plant economy lævulose has some genetic connection with cellulose rather than with starch.

Mr. Fenton said that although he and his colleague were at present concerned chiefly in demonstrating a ketonic grouping or nucleus in cellulose, he considered it not at all improbable that such a grouping exists, as a fraction of the whole, in the complex molecule of starch.

The product of hydrolysis of the portion containing such a grouping may very conceivably have been overlooked in the methods of identification hitherto employed.

*10. "*Note on a Method for Comparing the Affinity Values of Acids.*" By H. J. H. Fenton and H. O. Jones.

In a former communication (*Trans.*, 1901, lxxix., 92), the authors described a simple method for comparing the affinity values of acids based upon the decompositions of the hydrazone of oxalacetic acid. This substance when heated with pure water yields the hydrazone of pyruvic acid and carbon dioxide:—

$$\begin{array}{l} CH_2CO_2H \\ | \\ C{:}N_2HPh \\ | \\ CO_2H \end{array} = \begin{array}{l} CH_3 \\ | \\ C{:}N_2HPh \\ | \\ CO_2H \end{array} + CO_2.$$

From 83 to 90 per cent is decomposed in this manner, the slight differences observed in different specimens depending on their purity. But in presence of acids of sufficient concentration an entirely different change occurs; water is lost and Wislicenus's pyrazolone carboxylic acid is formed without evolution of any carbon dioxide:—

$$\begin{array}{l} CH_2CO\cdot OH \\ | \\ C{:}N\cdot N\overset{H}{\underset{Ph}{}} \\ | \\ CO_2H \end{array} = \begin{array}{l} CH_2\cdot CO \\ | \quad | \\ C:N\cdot NPh \\ | \\ CO_2H \end{array} + H_2O.$$

With acids of insufficient concentration both changes occur simultaneously, the amount of carbon dioxide evolved being less as the concentration of the acid increases. Making exactly parallel experiments with different acids, it was shown that the volumes of carbon dioxide obtained are in the inverse order of the affinity-values of the acids.

In order to explain the nature of this influence, the authors suggest that the undissociated molecule of the hydrazone tends only to lose water, giving the pyrazolone derivative, but that the negative ion, $CO_2H—CN_2HPh—CH_2CO_2$, is unstable and tends to lose carbon dioxide. Upon this hypothesis any circumstance tending to prevent ionisation should favour the production of the pyrazolone derivative, and the presence therefore of a sufficient concentration of hydrogen ions should cause the change to take place in this direction more or less completely.

Other explanations might, of course, be offered, referring, for example, to the dehydrating influence of acids or to the "basic" character of the pyrazolone ring, and it was therefore considered advisable to make further experiments in order to ascertain whether other conditions went in harmony with the ionisation hypothesis.

The investigations had reference to the influence of—(*a*) salts, (*b*) non-electrolytes, (*c*) acids in presence of their own salts, and (*d*) solvents other than water.

In all the experiments the conditions were made exactly parallel, about 0·1 grm. of the hydrazone being heated to 100° with 7·5 c.c. of the liquid to be examined in the manner previously described.

The solutions examined and results obtained are given in the accompanying table.

Bases likewise have practically no influence; thus 0·1001 grm. hydrazone heated with a quantity of soda representing slightly *less* than 1 equivalent gave 8·58 c.c. (corr.) of carbon dioxide.

The conclusions which may be drawn from these experiments are:—

(*a*) The influence of salts, bases, and non-electrolytes is *nil*, the results being practically identical with that given by pure water;

	Weight in grms. in 100 c.c.	Weight of hydrazone.	Corrected volume of carbon dioxide.
			C.c.
1. Pure water	—	0·0998	8·31
2. Sodium sulphate (cryst.).	6	0·1000	8·75
3. Cane-sugar	6	0·1005	8·12
4. Urea..	1	0·1000	8·31
5. Sulphuric acid	0·49	0·1003	2·60
6. Sulphuric acid and sodium sulphate	0·49 / 6	0·1000	7·12
7. Acetic acid	0·6	0·1001	7·07
8. Acetic acid and sodium acetate (cryst.)	0·6 / 3	0·1002	8·31
9. Amyl alcohol	—	0·0989	3·53
10. Toluene	—	0·1078	2·29
11. Nitrobenzene	—	0·1026	2·29

(*b*) The effect of a salt in presence of its own acid is greatly to diminish the influence of the acid; and

(*c*) Solvents having different ionising powers give very different results; the amount of carbon dioxide evolved being greatest in the case of water, less in amyl alcohol, and least in toluene and nitrobenzene.

With regard to the three last-named solvents, it may be remarked that, although they were carefully dried, water is produced in the pyrazolone formation; hence it is not surprising that some action should take place in a solvent such as toluene, which when pure has presumably little or no ionising power.

It is evident therefore that the results are, on the whole, well in harmony with the ionisation hypothesis, which certainly appears to offer the most satisfactory explanation of the phenomena, although other explanations are, of course, possible.

The purification of the hydrazone by re-crystallisation is a troublesome and wasteful process, but the crude substance answers perfectly, since the results required are only relative. It is advisable to employ the same sample, for each set of observations, and the substance should be freshly prepared.

Discussion.

Dr. Travers remarked that the evolution of carbon dioxide from the acid seemed to take place under conditions similar to those which obtained during the electrolysis of the salt of an acid, and to be dependent on the concentration of the negative ion, in one case in the solution generally, and in the other on the surface of the anode. It would be interesting to know how the corresponding diphenylhydrazone would behave under similar conditions.

Mr. Fenton, in reply, said that one example of a disubstituted hydrazine had been investigated, namely, benzylphenylhydrazine, but that the oxalacetic derivative was extremely unstable, and only the pyruvic derivative could be isolated.

(To be continued).

Royal Institution.—On Saturday next, February 23, the Right Hon. Lord Rayleigh, Professor of Natural Philosophy in the Royal Institution, will deliver the first of a course of six lectures at the Royal Institution on "Sound and Vibrations." On Tuesday, February 26, Dr. Allan Macfadyen will begin a course of five lectures on "The Cell as the Unit of Life"; and on Thursday, February 28, Professor Percy Gardner will deliver the first of a course of three lectures on "Greek and Roman Portrait Sculpture."

NOTICES OF BOOKS.

On Sanitary and Other Matters. By George S. Keith, M.D., LL.D., &c. London: Adam and Charles Black. 1900. Pp. 127.

The papers comprising this volume are of a curiously mixed character, and we cannot see that they lead to anything in particular. The author is a firm believer in earth closets as a preventive of the waste of water; there is of course no objection to their use by intelligent persons, but we shudder to think what the result would be if their general use was ordained throughout London.

Another chapter, "The Story of an Eye," is purely a personal narrative, and though it compels our sympathy for the author's sufferings, it is really only of interest to members of the medical profession.

Altogether we cannot help feeling after a perusal of this book that the author is "oppositely polarised" to the greater number of his fellow creatures.

The Microscopy of the More Commonly Occurring Starches. By Hugh Galt, M.B., C.M. (Honours, Glasgow), D.P.H. (Camb.), &c. Illustrated by twenty-two original Micro-photographs. London: Baillière, Tindall, and Cox. 1900. Pp. 108.

The results of an investigation carried out by the author as a research student in the Public Health Laboratory at the University of Glasgow are embodied in this work.

It is pointed out by the author that in spite of the importance from many points of view of an accurate delineation of the starches, very little has been done in this direction, in this country, up to the present time; moreover, a good deal of the information given by the various text-books is not remarkable for accuracy.

A large portion of the work on this subject has naturally to be done by the aid of the microscope, and to render this work intelligible to others either diagrams or photographs must be made; a good deal of stress is here laid on the "personal equation" of the individual, whether teacher or student, who makes the diagrams. This drawback is almost entirely avoided by adopting microphotographic methods; there is, however, still the risk of the photograph not telling the whole truth.

The author then fully describes and illustrates a number of different kinds of starches, and sums up their leading microscopical characters in two tables on pp. 101—102. The book is well arranged and printed, and fully indexed.

The Boyle System of Ventilation. Robert Boyle and Sons, Limited.

This handsome volume may be best described as a treatise on Ventilation combined with a Trade Catalogue.

The particular system applied by the authors consists in removing the pressure of the external air from the top of the shaft by means of an "air-pump" ventilator, combined with certain improved air inlets at the lower parts of the building, thus causing a continuous change of air at low velocity in accordance with the natural laws which govern ventilation.

The higher temperature in an occupied building, particularly in cold weather, combined with the ascensional movement of the heated air arising from the lungs and body, are also utilised as auxiliaries in changing the air even when there is no perceptible movement outside. It is stated that the special construction of the air inlets completely prevents the lodging or accumulation of dust, and they are also easily accessible for cleaning purposes. In the last few pages there is an interesting series of coloured diagrams, illustrating several systems of ventilation, both good and bad. We need hardly add that the Boyle system is shown to be the best.

CORRESPONDENCE.

NUMBERING CRUCIBLES.

To the Editor of the Chemical News.

Sir,—It would be a great convenience if manufacturers would mark porcelain crucibles with consecutive numbers—in sets, say, of five or ten. Where several estimations are in hand simultaneously, crucibles not infrequently get mixed in the exsiccator unless some distinguishing mark has been affixed.

The numbers would preferably be on the side, but if this were objectionable from any manufacturing point of view, it could very well be on the biscuit surface at the bottom along with the trade mark. Failing this, however, numbers can be marked on the bottoms with a 10 per cent solution of platinic chloride containing a little gum acacia, applied, of course, with a quill, allow to dry, and heat up the crucible in a blowpipe flame. The results are very distinct.—I am, &c.,

A. Andrew Kelly.

41, Highfield Road, Dartford,
February 8, 1901.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Note.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. cxxxii., No. 4, January 28, 1901.

Hydrogen from Igneous Rocks. Action of Water-vapour on Ferrous Salts.—Armand Gautier.—In a preceding paper the author showed that igneous rocks, when brought to a red heat, evolve a considerable quantity of gas which, for the most part, did not pre-exist. He now further examines these evolved gases and the processes which cause their presence. In all cases hydrogen is present in the largest proportion, but this gas is always accompanied by a little ammonia. The various rocks, when powdered and acted upon by acidulated water, show the presence of small quantities of ferrous salts. The explanation, apparently, is that when ferrous salts (chloride, sulphide, carbonate, &c.) are heated to 750° or 800° in the presence of water-vapour, the negative radicle is volatile at this temperature, and incapable of yielding up its oxygen, so an oxide of iron is always formed—generally the magnetic oxide—at the same time as the free hydrogen.

Nitrate of Uranium.—Œchsner de Coninck.—An examination of the action of heat on uranium nitrate leads the author to the following conclusions:—(1) Calcination of crystalline uranium nitrate gives a red modification of the sesquioxide of uranium, which is apparently the polymer of the orange modification. (2) This red modification, calcined for about forty hours at a dull red heat in a platinum capsule, is partially transformed into a brown oxide. If heated for the same length of time at a bright red heat in a closed platinum crucible, it is not transformed into the green oxide, but a very small quantity of brown oxide is produced. (3) The orange modification of uranium sesquioxide, which is produced when uranium nitrate is but slightly heated, if kept at a dull red heat for twenty-six hours is partially transformed into the red variety.

Action of Boron Bromide on the Iodides of Phosphorus and on the Halogen Compounds of Arsenic and Antimony.—M. Tarible.—The author's researches on the action of boron bromide on the halogen compounds of phosphorus, arsenic, and antimony, lead to the results which are shown in the following table:—

Body placed in presence of BBr_3.	Products of the reaction.
PCl_3	The compound $PCl_3.2BBr_3$
PCl_5	,, $PCl_5.2BBr_3$
PBr_3	,, $PBr_3.BBr_3$
PBr_5	,, $PBr_5.BBr_3$
P_2I_4	,, $P_2I_4.2BBr_3$
PI_3	,, $P_2I_4.2BBr_3 + I$
$AsCl_3$	Double decomposition.
$AsBr_3$, AsI_3, AsI_5	Solution.
$SbCl_3$	Double decomposition.
$SbCl_5$	,, ,,
$SbBr_3$	Solution.
SbI_3	,,

All these reactions are in complete harmony with the thermo-chemical constants determined by different observers.

Action of Œnanthylic Alcohol on its Sodium Derivative. New Method of Synthesis of Alcohols. Marcel Guerbet.—When œnanthylic alcohol acts on its sodium derivative, the following substances are formed:—Œnanthylic acid, di-œnanthylic alcohol, tri-œnanthylic alcohol, and the corresponding acid. The tri-œnanthylic alcohol is due presumably to the ulterior action of the di-œnanthylic alcohol already formed on the sodium derivative of œnanthylic alcohol still present in the mixture:—$2C_{14}H_{30}O + C_7H_{15}NaO = C_{21}H_{44}O + C_{14}H_{27}NaO_2 + 4H$. These reactions are in every way analogous to those previously observed with inactive amylic alcohol; that reaction, in particular, which gives rise to tricœnanthylic alcohol shows that it is possible to generalise, at least with regard to the alcohols higher than butylic alcohol, and to state that when a primary alcohol is heated with the sodium derivative of another primary alcohol the following reaction takes place:—

$$2C_mH_{2m+2}O + C_nH_{2n+1}NaO = C_{m+n}H_{2(m+n)+2}O + C_mH_{2m-1}NaO_2 + 4H.$$

Direct Hydrogenation in presence of Reduced Nickel. Preparation of Hexahydrobenzene.—Paul Sabatier and J. B. Senderens.—Reduced nickel is a very active agent, causing hydrogenations and molecular decompositions to take place at a comparatively low temperature. The action of the metal is certainly due to the formation of temporary products, such as unstable hydrides. These products provoke a large number of exothermic reactions which only take place usually at high temperatures, and which are unfavourable for the stability of the substance produced. This process permits of the direct hydrogenation of benzene and its homologues at temperatures below 300°. Hexahydrobenzene is thus formed in an almost pure state:—$C_6H_6 + H_6 = C_6H_{12}$.

MEETINGS FOR THE WEEK.

Monday, 25th.—Society of Arts, 8. (Cantor Lectures). "The Bearings of Geometry on the Chemistry of Fermentation," by W. J. Pope.
—— Royal Institution, 3. "Practical Mechanics" (Experimentally treated), by Prof. J. A. Ewing, M.A., F.R.S., M.Inst.C.E.

Tuesday, 26th.—Royal Institution, 3. "The Cell as the Unit of Life," by Allan Macfadyen, M.D., B.Sc.

Wednesday, 27th.—Society of Arts, 8. "The Outlook for the World's Timber Supply," by Dr. W. Schlich, C.I.E.

Thursday, 28th.—Society of Arts, 4.30 (at the Imperial Institute, South Kensington). "Railways and Famine," by Horace Bell, M.Inst.C.E.
—— Royal Institution, 3. "Greek and Roman Portrait Sculpture," by Prof. Percy Gardner, Litt.D.

Friday, March 1st.—Royal Institution, 9. "Enamels," by Henry Hardinge Cunynghame, C.B., M.A.

Saturday, 2nd.—Royal Institution, 3. "Sound and Vibrations," by the Rt. Hon. Lord Rayleigh, F.R.S., &c.

THE ELECTRO-CHEMIST AND METALLURGIST.

THE ONLY JOURNAL IN ENGLAND DEALING WITH THESE BRANCHES OF SCIENCE.

Published Monthly. The Second Number appeared February 15th.

SUBSCRIPTION RATES.

United Kingdom or Abroad:—Six months, 3/9; Twelve months, 7/6.
Price per single copy, 6*d.*; Post free, 7½*d.*

Copies can be obtained direct from the Office, or through Messrs. W. H. SMITH & SONS.

ADVERTISEMENT RATES ON APPLICATION to 20, St. Bride St., E.C.

Editorial Offices: 82, VICTORIA STREET, WESTMINSTER, S.W.

THE
DAVY FARADAY RESEARCH LABORATORY
OF
THE ROYAL INSTITUTION.

Directors:
The Right Hon. LORD RAYLEIGH, M.A., D.C.L., LL.D., F.R.S.
Professor DEWAR, M.A., LL.D., F.R.S.

Superintendent of the Laboratory:
Dr. Alexander Scott, M.A., D.Sc., F.R.S.

This Laboratory was founded by Dr. Ludwig Mond, F.R.S., as a Memorial of Davy and Faraday for the purpose of promoting, by original research, the development and extension of Chemical and Physical Science.

The Laboratory is open free of charge to Workers of either sex, and any nationality, prosecuting individual investigations; and the extensive collection of Physico-Chemical Apparatus presented by the Founder is available for their use, together with such materials, chemicals, electricity, &c., as the Directors may authorise.

Assistants and a trained mechanician are attached to the Laboratory to aid Workers in the prosecution of their researches.

All persons desiring to be admitted as Workers must send evidence of scientific training, qualification, and previous experience in original research, along with a statement of the nature of the investigation they propose to undertake.

Michaelmas Term.—Monday, October 1, to Saturday, December 15.
Lent Term.—Monday, January 7, to Saturday, March 30.
Easter Term.—Monday, April 22, to Saturday, July 27.

Forms of application can be had from the Assistant Secretary, Royal Institution, Albemarle Street, W.

New Term Commenced January 7th.

BIRKBECK INSTITUTION,

Bream's Buildings, Chancery Lane, E.C.

Principal: G. ARMITAGE-SMITH, M.A.

DAY AND EVENING CLASSES.

UNIVERSITY OF LONDON.—Complete Day Courses for all the Examinations in Science, and Complete Evening Courses for all the Examinations for the Science, Arts, and Law Degrees.

SCIENCE CLASSES in every Branch, with Practical Work. Well equipped Laboratories for CHEMISTRY, PHYSICS, and METALLURGY.

CONJOINT BOARD: Lectures and Practical Work in Chemistry, Physics, Biology, and Practical Pharmacy.

Prospectus free. Calendar 6*d.* (*by post* 8*d.*) *on application to Secretary.*

IMPORTANT TO EXPORTERS.

The Firm of E. HEUER, Chemical Manufactory, in Aussig, Austria, begs to call the attention of Exporters to the Exporting Products of the Factory.

ALCOHOL DERIVATIVES in general, and in particular Ethers of all kinds, such as Sulphuric, Acetic, Rum, Formic, Nitrous, Œnanthic, Butter, Fruit, Grain, and Saccharine Ethers in every specific gravity, all degrees of concentration, and grades of purity.

ABSOLUTE ALCOHOL—98, 99, 99 2/3, and 99 5/7 per cent.

SUPERIOR RUM ESSENCES in all concentrations and contents of spirits.

FIRST CLASS FRUIT ESSENCES, Amylic Alcohols, Amylic Acetates, and Amylic Oxides.

PHARMACEUTICAL CHLOROFORM and Special Brand E.H. CHLOROFORM for Narcosis.

Special Brand E.H. SULPHURIC ETHER for Narcosis.

Vol. LXXXIII., No. 2153.

THE BOILING-POINT OF LIQUID HYDROGEN, DETERMINED BY HYDROGEN AND HELIUM GAS THERMOMETERS.*

By JAMES DEWAR, M.A., LL.D.,
Professor of Chemistry at the Royal Institution, and Jacksonian Professor, University of Cambridge.

In a former paper ("On the Boiling-point of Liquid Hydrogen under Reduced Pressure," *Roy. Soc. Proc.*, 1898), it was shown that a platinum-resistance thermometer gave for the boiling-point of hydrogen −238·4° C., or 34·6° absolute. As this value depended on an empirical law correlating temperature and resistance which might break down at such an exceptional temperature, and was in any case deduced by a large extrapolation, it became necessary to have recourse to the gas thermometer.

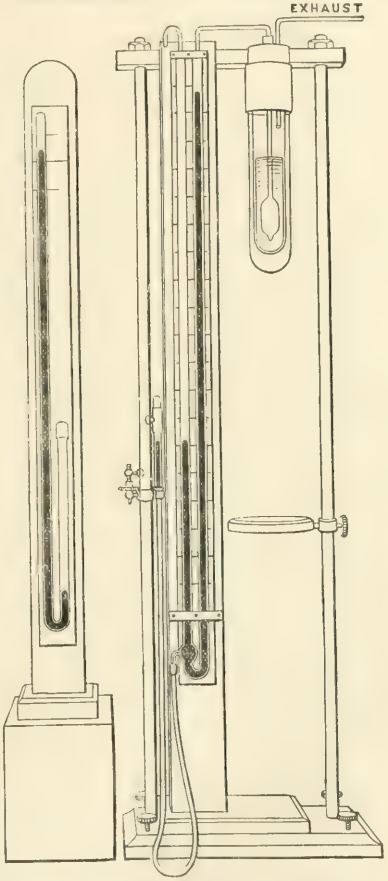
In the present investigation the advantage claimed for the constant pressure gas thermometer over the constant volume thermometer is absent. The effect of high temperature combined with large increase of pressure does not occur in these experiments, where only very low temperatures and a maximum range of pressure of less than one atmosphere were encountered. At the same time, before dispensing with the effect of pressure upon the capacity of the reservoir of the thermometer, it was carefully estimated and found that it could not affect the volume of the reservoir by as much as 1/60,000th part. This being determined a particular advantage results from the use of the constant volume form, because in its case it is unnecessary to know the actual volumes of the reservoir, and of the "outside" space. It is only necessary to know the ratio of these two volumes, and as this ratio appears only in the small terms of the calculation it is not a serious factor in the estimation of such low temperatures.

Two constant volume thermometers (called No. I. and No. II.) were employed, in each of which the volume of the reservoir was about 40 c.c., and the ratio of the outside space to the volume of the reservoir was 1/50 and 1/115 respectively. A figure of the apparatus is given herewith, where A is the thermometric bulb covered with a vacuum vessel to hold the liquid hydrogen, and be exhausted when necessary; B is the manometric arrangement for adjusting the mercury at C to constant volume, and D is the barometer. The readings were made on a fixed scale by means of a telescope with cross-wires and level attached. A similar telescope was permanently fixed on the mark to which the volume had to be adjusted. As the observations had to be made quickly, it was found convenient to use both telescopes on the same massive stand and to read the barometer placed alongside simultaneously.

The formula of reduction used was that given by Chappuis in the "Travaux et Mémoires du Bureau International des Poids et Mesures," tome vi., p. 53, namely,—

$$\left(V_0+\frac{v}{1+at}\right)H_0=\left(\frac{V_0(1+\delta T)+\beta h}{1+at}+\frac{v}{1+at}\right)(H_0+h) \quad . \quad (1),$$

where V_0 is volume of reservoir at 0° C.;
T., temperature of reservoir, measured from 0° C.;
v, volume of "outside" space at the temperature of the room;
t, temperature of the room;
a, coefficient of expansion of the thermometric gas;
β, coefficient of alteration of volume of reservoir, due to change of pressure;
δ, coefficient of expansion of substance of reservoir;
H_0, initial pressure (in these experiments always reduced to 0° C.);
H_0+h, pressure at temperature T., after all corrections have been made.



On putting $\beta=0$ as already explained, equation (1), by algebraic transformation and without any approximation, was altered into the form—

$$T=T_1\frac{273+t+x273}{273+t-x1_1}\,(\text{say})=T_1\theta \quad . \quad . \quad (2),$$

where—

$$T_1=\frac{P-P_0}{aP_0-\delta P} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (3),$$

in which P_0 and P replace H_0 and H_0+h, and

$$x=\frac{v}{V_0(1+at)}.$$

* A Paper read before the Royal Society, February 7, 1901.

The gases used as thermometric substances were hydrogen, oxygen, helium, and carbonic acid. The values of α adopted in equation (3) were taken from Chappuis' memoir, and were 0·00366254 for the first three, and 0·00371634 for carbonic acid. The reciprocals of these coefficients are 273·035 and 269·083. The number "273" which appears in θ is so nearly equal to the reciprocal of the former value for α that it was allowed to remain for the first three gases; but in dealing with carbonic acid it was replaced by 269·083.

In these experiments T_I is always negative, and numerically less than 273, so that the value of θ is always greater than unity; nevertheless it differs from it but slightly, its value being unity when $T_I = -273°$ C., and rising to 1·02 when $T_I = 0°$ C. in the case of thermometer No. 1, where $x = 1/50$. It may be noted that when δ is neglected T_I is the usual value given by Boyle's law; there is a convenience therefore in this form of Chappuis' formula for approximation, because T_I can quickly be calculated, and the correcting factor θ can be applied later if desired.

In the first experiment (No. 1 of subjoined Table I.), thermometer No. 1 was filled with electrolytic hydrogen. The initial pressure (the pressure at 0° C.) was almost three-eighths of an atmosphere, and was taken low in order to obviate any complication from condensation on the walls of the reservoir. Two other possible causes might abnormally reduce the pressure at very low temperatures; these were polymerisation, and the presence as impurity of small quantities of gases liquefying above the boiling-point of hydrogen. The measurement of the density of the gas at its boiling-point showed that there was no polymerisation, and further proof of this was evident in the constancy of the value of the boiling-point when different initial pressures were taken. To guard against the presence of gases with a higher boiling-point than hydrogen, the electrolytic hydrogen was allowed to pass continuously for eighteen hours through the thermometric bulb before it was sealed off. It was further calculated that an impurity of oxygen necessary to reduce the boiling-point of hydrogen by a degree would amount to 3 per cent, a quantity too large to escape detection. This experiment gave the boiling-point of oxygen as $-182·2°$, and that of hydrogen as $-253·0°$.

In the second experiment (No. 2) a new thermometer, No. II., was constructed with a much smaller value of x, and as a further protection against the presence of impurities, palladium hydrogen was employed as the source of the gas. A rod of palladium, weighing about 120 grms., kindly placed at my disposal by Mr. George Matthey, F.R.S., was charged with hydrogen in the manner described in my paper "On the Absorption of Hydrogen by Palladium at High Temperatures and Pressures" (*Proc. Chem. Soc.*, 1897), and subsequently used as the source of supply to fill the thermometer. The initial pressure was slightly less than that in the first experiment; the corresponding results were $-182·67°$ and $-253·37°$.*

The new thermometer was filled afresh (No. 4) with palladium hydrogen at an initial pressure rather less than one atmosphere, and gave for the boiling-point of hydrogen the temperature $-252·8°$. This result is a confirmation of the absence of polymerisation.

The next step was to compare these results with the results of similar experiments made upon another gas whose boiling-point fell within the range of easily determined temperatures; and as a further precaution the gas used in the thermometer was the vapour rising from the liquefied gas whose boiling-point was to be determined. The gas first selected was oxygen (No. 5), and as an additional condition to be noted, the initial pressure was made slightly more than an atmosphere, so that it would be in a Van der Waal's "corresponding" state with the hydrogen in the first two experiments, namely, the initial pressure in each case was about 1/50 of the critical pressure. The critical pressure of oxygen was taken about 51 atmospheres, and that of the hydrogen about 18 atmospheres. There are good reasons for believing that the critical pressure of hydrogen is more likely to be about 11 or 12 atmospheres. In the event of the lower value being eventually found the more correct, the effect as between the oxygen thermometer and the hydrogen thermometer will be to make the boiling-point of hydrogen a little too high. The result obtained from this experiment was to place the boiling-point of oxygen at $-182·29°$, thus corroborating in a satisfactory manner the reliability of the method of determining the boiling-point of hydrogen.

The question still remained: How far is a gas thermometer to be trusted at temperatures in the neighbourhood of the boiling-point of the gas with which it is filled? To answer this question the oxygen thermometer was used to determine the boiling-point of liquid air (No. 7) in which a gold-resistance thermometer was simultaneously immersed. The gold thermometer had been previously tested, and found to give correct indications of temperature down to temperatures not only well below the point in question, but lower than those obtainable by any other metal thermometer. In the result the oxygen thermometer gave $-189·62°$, and the gold thermometer $-189·68°$ as the temperature of that particular sample of air boiling at atmospheric pressure.

For another method of comparison this oxygen thermometer was partially discharged (No. 8) until its initial pressure was nearly the same as that in the first hydrogen thermometers. In this state it gave the boiling-point of oxygen as $-182·95°$, establishing again the reliability of the method. All the boiling-points of the liquid gases were made on samples produced at different times.

As an extreme test of the method, I charged the thermometer No. II. with carbonic acid (No. 11) at an initial pressure again a little less than one atmosphere, and used it to determine the boiling-point of dry CO_2; the result was $-78·22°$, which is the correct value.

Hence it appears that either a simple or a compound gas at an initial pressure somewhat less than one atmosphere may be relied on to determine temperatures down to its own boiling-point, in the constant volume gas thermometer.

(To be continued).

* This thermometer gave 99·7° for the boiling-point of water.

TREATMENT OF THE MIXED ORES OF ZINC AND LEAD.

ELLERHAUSEN'S PROCESS.

By E. VILLEJEAN.

Besides the rich ores of lead and zinc, of which the metallurgy is too well known to require mention here, there exist in nature a large quantity of mixed sulphides formed of an intimate mixture of blende and argentiferous galena, which until a few years ago appeared to be unamenable to treatment, as the separation of the lead from the zinc and silver seemed to be impossible without an enormous loss of one or the other of these metals.

The mechanical separation based on the different densities of blende (4) and galena (7·4) is not possible as a matter of fact, except with minerals in a fairly coarse condition; when we have to do with small crystals it only succeeds partially, and with an enormous loss of silver.

The blende retains a large proportion of lead, and its percentage of metallic zinc is hardly more than 35; on the other hand, the galena always retains at least 10 per cent of zinc, which is a great drawback to its ulterior treatment.

The chemical treatment of these mixed ores for the separation of the zinc by an acid after roasting, is too expensive, and has had to be abandoned.

Finally, the separation in the furnace is extremely

difficult; the zinc reduced at the same time as the lead is carried by its volatility to the mouth of the furnace, where it becomes oxidised, forming hard, infusible, and very refractory deposits, which it is absolutely necessary to remove from time to time; this necessitates frequent stoppages and deterioration of the furnace. When the mineral contains more than 12 per cent of zinc it becomes necessary to subject it to a preliminary roasting, or to add to it oxidised minerals, and even in this case it is very inconvenient, as it gives a matt which must be removed, and a pasty slag which causes a considerable loss of lead and silver. In fact, the operation becomes more expensive, and works irregularly.

It therefore became of great importance to try and find a practical and economical method which could be applied to minerals looked upon as poor in zinc and lead, and of which the treatment by ordinary means would not appear to be remunerative. Of such a class are those containing 20 to 30 per cent of zinc, and 15 to 20 per cent of lead, with 0·1 per cent of silver; even to this day such minerals are looked upon as being of no value; producers of lead refuse to treat them because they are not sufficiently rich in metal, and zinc smelters reject them as they contain too much lead.

This difficult problem has now been solved, thanks to the perseverance of M. Ellerhausen, a well known engineer, who has been working on this subject for at least six years. His process has been exhibited in a works at Angoulême, and the results are so satisfactory that it may well be predicted that his method will retain in France an enormous sum of money that is now paid away to other countries, and that the time is not far distant when France will in her turn become an exporter of zinc and lead.

The new process comprises two operations:—1. The simultaneous extraction of the zinc, lead, and silver by volatilisation. 2. The chemical separation of the argentiferous lead in the metallic state, and the zinc in the form of sulphide.

1. *Volatilisation of the Metals.*

The ore is crushed into fragments about the size of an egg, mixed in the usual manner with the necessary amount of coke, carbonate of lime, and oxide of iron, then melted in a blast-furnace. The slag and the matts are run off as in the older methods, but by reason of the high temperature of the furnace the whole of the lead and zinc and a large part of the silver are volatilised; if this latter metal is not entirely removed in the form of vapour it will be found in the matt with the gold and copper which may be present in the ore under treatment.

The difficulty was to remove these metallic fumes and to condense them without loss; Ellerhausen has overcome this difficulty by drawing the fumes off by means of powerful ventilating fans placed in the mouth of the furnace, and into which he injected cold water under very great pressure; this has the effect of condensing them and putting them completely in suspension in the water, which naturally becomes heated, and is then run off into settling vats, when it is cooled previous to being used over again in the ventilating fans, until it is saturated with sulphate of zinc.

We may here remark that the ventilators used were about 1·50 metres in diameter, fitted with copper vanes so that they would remain unattacked, and that they rotated with a speed of 500 revolutions per minute; their capacity must necessarily be greater than that of the blowing-machinery of the blast-furnace, as their function is not only to remove the metallic fumes against a great pressure of water, but also to draw off the products of combustion in the furnace.

The heavy grey deposit formed in the vats consists principally of a mixture of sulphite of lead, sulphide and sulphite of zinc, oxide of zinc, a little carbonate of lime, and oxides of iron, antimony, and arsenic.

The following is the analysis of the deposit from the works at Angoulême:—

Sulphite of lead	67·24
Sulphide of zinc	16·23
Sulphite of zinc	6·63
Oxide of zinc	2·75
Carbonate of lime	2·34
Peroxide of iron	1·00
Oxide of antimony	0·84
Arsenious acid	0·46
Insoluble matter	2·20
Copper	Traces
Silver	220 grms. per ton.

This deposit is collected and dried in the filter-press, but as it still contains about 35 per cent of moisture it is spread out again and slowly dried by means of the waste heat from the blast-furnace.

2. *Separation of the Metals.*

The above-mentioned deposit is gradually added to a solution of raw soda-lye, kept at boiling-point in large iron boilers; a lively effervescence takes place accompanied by a considerable disengagement of heat. When the addition of a further quantity of the deposit provokes no reaction we know that the whole of the lead is reduced to the metallic state, and will be found at the bottom of the boiler together with the silver that was present in the mineral. The zinc, in the form of sulphide, forms a slag with the excess of the free or carbonated soda and the sulphate of soda formed during the operation.

This slag is utilised for the precipitation of the sulphate of zinc, with which the water injected into the ventilators becomes finally saturated, so that eventually we get the whole of the zinc from the original ore in the state of sulphide, hydrate, or carbonate, which can be separated by means of the filter-press from the sulphate of soda which remains in solution. This latter salt is dried and then treated by the Leblanc process for regeneration into raw caustic lye.

As for the mixture of oxide and sulphide of zinc, it is dried separately, roasted, and reduced by the ordinary methods.

Such is, in short, a summary of this remarkable process, of which we will now consider the theory and the advantages.

We will pass rapidly over the reactions which take place in the blast-furnace; they are analogous to those described in the standard books. They may be summed up by saying that the current of warm air at the level of the tuyères, gives rise to the formation of carbonic acid, which is reduced on contact with the red-hot carbon at a higher level, forming carbonic oxide, which sets free metallic iron.

This spongy iron removes a part of the sulphur from the ore, giving sulphide of iron, which we find in the matt combined with sulphide of lead. The ferric oxide which escapes reduction is found in the slag combined with the silica and gangue; it is the same with the lime, of which it is well to have a rather large proportion present so as to keep the lead, zinc, and silver out of the slag.

On the other hand, the atmosphere in the blast-furnace being oxidising, the sulphides are transformed, part into oxides and part into sulphates, which react one on the other, giving the metal and liberating sulphurous gas according to the well-known equations.

Finally, the metals which are volatilised and drawn off by the ventilators, come in contact with oxygen and sulphurous acid in the upper part of the furnace, and are brought into the state of sulphites, as is proved by the analysis we gave above.

It is surprising that even a small portion of the sulphite of lead is not converted into sulphate by the action of the oxygen of the air from the blowing-engine. Neither have we ever found the presence of oxide of lead or of an oxysulphide in the furnace gases; but a portion of the sulphurous gas is transformed into sulphuric acid, in such a manner that the decantation pans end by depositing

sulphate of zinc—about one part of sulphate for three and a half parts of sulphite.

We have seen above that the separation of the lead and zinc rests on the use of a caustic lye—this is perhaps the most interesting point of the whole process; it must be remarked that the caustic lye used is a raw impure one of which the preparation costs very little; it contains hydrate of sodium, as well as carbonate, sulphide, and sulphate of sodium.

In reacting on the deposit, composed principally of sulphites, it reduces the lead and silver to the metallic state, and the metal produced is practically pure, besides being free from antimony and arsenic, which is again a great advantage.

Although the actual equations are, as a general rule, more complicated than those used to show the final reaction, and although in metallurgy especially it is possible to form numerous hypotheses, the author proposes to establish the theory of this operation in the following manner:—

1. The sulphide of sodium transforms the sulphite of lead into sulphide of lead and gives sulphite of sodium; on contact with the caustic soda and the carbonate of soda, the sulphide of lead gives rise to the formation of sulphate of sodium, to a double sulphide of sodium and lead, and to metallic lead, according to the following equations:—

$$7PbS+4Na_2CO_3=Na_2SO_4+3(Na_2S.PbS)+4CO_2+4Pb.$$
$$7PbS+8NaOH=Na_2SO_4=3(Na_2S.PbS)+4H_2O+4Pb.$$

2. At the same time the excess of alkaline hydrate has set free oxide of lead, which reacts on a part of the sulphide of lead, $PbS+2PbO=Pb_3+SO_2$.

3. Another portion of the sulphide of lead reacts on the sulphate of soda, regenerating sulphide of sodium, $2PbS+Na_2SO_4=Na_2S+2SO_2+2Pb$.

It is conceivable that the alkaline sulphide may re-commence a fresh cycle of decomposition in such a manner that the reduction of the lead will continue as long as the strength of the caustic is sufficient, and although the reaction only required a small proportion of sulphide at the commencement.

The process we have just shortly described is in reality but little complicated, and the following advantages must be admitted:—

The whole of the lead and silver is collected, the zinc is separated in the form of a commercial product easy to dispose of; further, the two first of these metals are produced completely free from arsenic and antimony.

The process is applicable to mixed ores which cannot be treated economically by the ordinary methods; it is capable of great extension, subject to having enough land for the construction of sedimentation pans; and, finally, it requires neither fine crushing or preliminary roasting.—*Journ. de Pharm. et de Chim.*, Series 6, vol. xiii., No. 3.

The Colour of Picric Acid and its Solutions.—W. Marckwald.—Picric acid is of a more or less yellow colour, but when crystallised in concentrated hydrochloric acid it is almost colourless; if this latter acid is removed and the picric acid is washed with water it regains its yellow colour. The mother-liquors, which are faintly tinged with yellow, take a much deeper tint on the addition of water. All these phenomena can be explained by the theory of electrolytic dissociation, if we admit that picric acid by itself is quite or nearly colourless, but that the ion $C_6H_2(NO_2)_3O$ is yellow. The different manners in which picric acid behaves can be shown by the following lecture experiment:—When we add yellow commercial picric acid to ligroin we obtain with this non-dissociating solvent a colourless solution which contains very little picric acid. If we remove this liquid and shake it up with several times its volume of water, the latter becomes of an intense yellow colour. Picric acid, when crystallised from a warm saturated solution of ligroin, is almost white.—*Berichte*, vol. xxxiii., p. 1128.

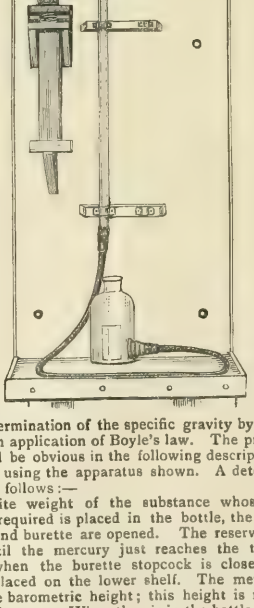
A FORM OF VOLUMOMETER.

By F. W. JONES.

The apparatus shown in the accompanying figure has been found to be a very useful form of volumometer for the determination of the specific gravity of substances which cannot be brought in contact with water. It was designed for the determination of the specific gravity of explosives containing ingredients soluble in water.

The parts are inexpensive and easily procured. They consist of a gas burette with stopcock, connected at one end with a stoppered bottle and at the other end with a reservoir of mercury. The burette shown is a 100 c.c. gas-measuring tube of a Lunge's nitrometer. The bottle is sold as an ozone generator. The bottle must be of small capacity and have two openings in the stopper, one with a stopcock; the stopper must be accurately ground.

The unstoppered opening of the bottle and the burette are connected by stout rubber tubing; the stopper of the bottle being fixed, and the bottle supported by a spring platform. The bottom of the burette is connected with the reservoir of mercury in the usual manner; it is advisable, however, to make the rubber connection with the burette a water joint.



The determination of the specific gravity by a volumometer is an application of Boyle's law. The principle involved will be obvious in the following description of the method of using the apparatus shown. A determination is made as follows:—

A definite weight of the substance whose specific gravity is required is placed in the bottle, the stopcocks of bottle and burette are opened. The reservoir is then raised until the mercury just reaches the top of the burette, when the burette stopcock is closed and the reservoir placed on the lower shelf. The mercury then falls to the barometric height; this height is read off in cubic centimetres. When the air in the bottle has stood long enough to take the temperature of the room, the stopcock of the bottle is closed and that of the burette opened. The mercury immediately falls; the height at which it remains stationary being read off in cubic centimetres; also the rise in the reservoir should be noted.

If V_1 is the gas volume of the bottle and its connections to the burette (P being the barometric pressure), and if v is the volume of gas in the burette at the reduced pressure p, we have the relation according to Boyle's law—

$$V_1 P = (V_1 + v)p;$$

from which—

$$V_1 = \frac{v\,p}{P - p};$$

also—

$$p = d + r;$$

where d = the amount the mercury drops in the burette, and r = the amount the mercury rises in the reservoir. Thus—

$$V_1 = v\,\frac{d + r}{P - d - r}.$$

The burette being of uniform bore, d is ascertained from the observation, when it is known how many cubic centimetres correspond to one inch.

To ascertain the volume occupied by the substance, it is necessary to know the volume of the bottle and its connections to the burette when empty, viz., V; this can be obtained by making a test with the bottle empty. It is advisable, however, to ascertain this figure by making tests with different volumes of mercury. The following figures were obtained with the apparatus shown:—

Bottle containing—	V_1.	V obtained.
	C.c.	C.c.
Empty	109·8	109·8
10 c.c. mercury	100·1	110·1
20 ,, ...	90·2	110·2
30 ,, ...	80·1	110·1
40 ,, ...	70·1	110·1
50 ,, ...	60·2	110·2

If W were the weight of substance taken, then the specific gravity is obviously given by—

$$\text{Specific gravity} = \frac{W}{V - V_1}.$$

The above table shows that, by such an apparatus as figured, specific gravities accurate to the second place of decimals can be obtained.

SOME PRINCIPLES AND METHODS OF ROCK ANALYSIS.*

By W. F. HILLEBRAND.

(Continued from p. 91).

V. *Water—Total or Combined.*

Arguments Against "Loss on Ignition" Method.

In a few cases the simple loss on ignition of a rock will give the total water with accuracy, but in the great majority there are so many possible sources of error that this old-time method can rarely be used with safety. Only when the rock is free from fluorine, chlorine, sulphur, carbon, carbon dioxide, and fixed oxidisable constituents can the loss be accepted as the true index of the amount of water present, and it is rarely that a rock is met with fulfilling these conditions, especially as to the absence of ferrous iron. Blast ignition in presence of carbon dioxide alone of the above list may give a correct result, after separate estimation of the carbon dioxide, provided this emanates from carbonates of the earths and not from those of iron or manganese. The long-maintained and still upheld idea that in presence of ferrous iron a sufficiently correct result is obtainable by adding to the observed loss an amount needed for oxidising all ferrous iron is not justifiable. There can be no certainty that the oxidation has been complete, especially in the case of readily fusible rocks, and at the high temperature of the blast a partial *reduction* of higher oxides is not only possible but sometimes certain. The inability to ensure complete oxidation by simple ignition is illustrated in the case of precipitated ferric hydroxide which has been ignited in contact with its filter-paper. If the quantity was in any degree large it is sometimes decidedly magnetic, presumably from presence of magnetic oxide, which no amount of heating wholly oxidises, especially in the larger grains. Neither is evaporation with nitric acid and re-ignition sufficient to destroy the magnetic property of the oxide, as has been claimed.

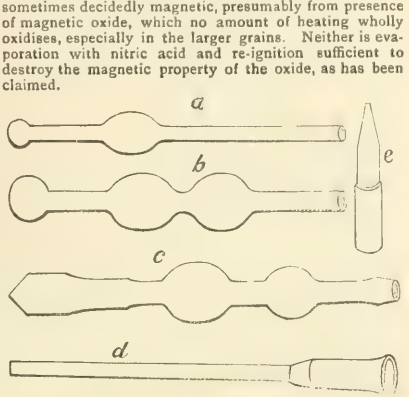


FIG. 4.—PENFIELD'S TUBES FOR WATER DETERMINATION IN MINERALS.

a, *b*, *c*, Different forms of tubes; *d*, thistle tube for introducing the powder; *e*, capillary-tipped stopper.

Direct weighing of the water evolved is then imperative in most cases, and of the numerous methods advocated, or in general use, several will now be considered.

Direct Weighing of the Water Without the use of Absorption Tubes—Penfield's Methods.

For Minerals Easily Deprived of their Water.—If no other volatile constituents than water are present, the beautifully simple method first used by Prof. G. J. Brush, and extended by Prof. S. L. Penfield (*Amer. Journ. Sci.*, 1894, Series 3, vol. xlviii., p. 31; *Zeitsch. für Anorg. Chemie*, 1894, vol. vii., p. 22), leaves nothing to be desired

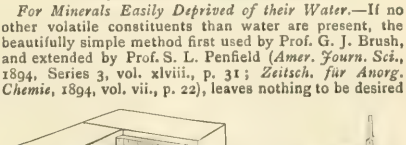

FIG. 5.—PENFIELD'S FIRE-BRICK AND CHARCOAL OVEN FOR USE IN DETERMINING WATER.

for accuracy. It consists simply in heating the powder in a narrow tube of hard glass, enlarged at the closed end, and provided with one or two further enlargements in the middle to hold the water and prevent its running back and cracking the hot glass. A capillary glass stopper fitted in with rubber tubing prevents loss of water by circulating air currents. The tube being held horizontally, the bulb is heated to any required degree by the Bunsen or blast-flame. Moistened filter-paper or cloth wound about the cooler parts of the tube insures condensation of all water. The heated end being finally pulled off, the tube is weighed after cooling and external cleansing, and again after the water has been removed by aspiration. For most rocks,

* *Bulletin of the United States Geological Survey*, No. 176.

as they contain little water, central enlargements of the tube are hardly needed.

Various forms of tubes used by Penfield are shown in Fig. 4.

Before using, even if apparently dry, "these tubes must be thoroughly dried inside, which is best accomplished by heating and aspirating a current of air through them by means of a glass tube reaching to the bottom."

How this simple tube is made to afford entirely satisfactory results with minerals, even when carbonates are present, is fully set forth in the paper cited.

Few rocks, comparatively, are altogether free from other volatile constituents. Hence, for refined work the application of this apparatus in the simple manner above set forth is limited. It may, however, be used with the addition of a retainer for fluorine, sulphur, &c., in the shape of calcium, lead, or bismuth oxides.

For Minerals not Easily Deprived of their Water.—When minerals are present which do not give up their water wholly, even over the blast, as talc, topaz, chondrodite, staurolite, &c., Penfield's simple combination of firebrick and charcoal oven, depicted in Fig. 5, must be used, either with or without a retainer for fluorine, as circumstances demand. The part of the tube in the fire is to be protected by a cylinder of platinum foil tightly sprung about its end, and the part outside by asbestos board, as well as by wet cloth or paper. A piece of charcoal is likewise laid on the tube, as well as beneath and behind, and the blast-flame is given a horizontal direction, so as to play upon the side of the apparatus. In this way a most intense temperature can be reached.

In whichever way the apparatus may be used, the water found is the total water, from which that found separately at 105° C. may be deducted if desired.

(To be continued).

CONCERNING LIPASE, THE FAT-SPLITTING ENZYME, AND THE REVERSIBILITY OF ITS ACTION.*

By J. H. KASTLE and A. S. LOEVENHART.

(Continued from p. 88).

On the Effect of Concentration of the Enzyme on the Velocity of the Reaction.

THE attempt has been made to determine the effect of concentration on the activity of hepatic and pancreatic lipase. According to some observers, the rate of hydrolysis by lipase is proportional to the concentration of the enzyme, especially if the conditions are those most favourable to the reaction. In order to determine the effect of concentration of the enzyme on its activity, concentrated extracts, usually 50 per cent, of the pancreas and liver were prepared, and from these the more dilute extracts, such as 5, 10, 20, and 40 per cent respectively, were made by dilution. Tubes were then prepared containing 4 c.c. of water, 0·1 c.c. of toluene, and 0·19 c.c. of ethylacetate. The tubes were heated for five minutes at 40° C., at the end of which time 1 c.c. of the enzyme of a given concentration was then added, after which the tubes were heated for thirty minutes. They were then removed from the bath and titrated with N/20 KOH. The following results were obtained:—

Concentration of the pancreatic extract. Per cent.	N/20 KOH required. C.c.	Per cent of hydrolysis.
5	0·13	0·33
10	0·25	0·625
20	1·08	2·70
40	2·00	5·00

* From the *American Chemical Journal*, xxiv., No. 6.

Concentration of the hepatic extract. Per cent.	N/20 KOH required. C.c.	Per cent of hydrolysis.
5	0·8	2·00
10	1·35	3·37
20	3·88	9·70
40	6·90	17·25

Still another series, with an extract which was prepared from the pig's liver that had stood for twenty-four hours on ice, gave the following results:—

Conditions of the experiments the same as in the first two series.

Concentration of the hepatic extract. Per cent.	N/20 KOH required. C.c.	Per cent of hydrolysis.
5	1·2	3·00
10	2·02	5·05
20	2·93	7·32
40	4·50	11·25

These results leave no room for doubt that the rate of change increases with the quantity of enzyme present in the solution; in fact, in one of the above series, viz., that of the liver extract, it is approximately proportional to the concentration of the enzyme. The fact, however, must be borne in mind, in the interpretation of the above results, that the fatty acid produced in the hydrolysis of the ethereal salt soon coagulates the proteid present in the solution, and, as has already been pointed out, this coagulation removes the lipase more or less completely from solution; and while the coagulum still possesses considerable lipolytic power, it is doubtful if the enzyme acts to as great advantage as when in solution. We have not yet had the opportunity of comparing the activity of the coagulum with that of the original extract. It is a factor, however, which might very materially vitiate the results, and should certainly be taken into consideration.

On the Effect of the Concentration of the Ethereal Salt on the Velocity of the Reaction.

The hydrolysis of an ethereal salt by lipase certainly presents some analogy at least to the hydrolysis of such a compound by an acid. On account of the instability of the lipase itself, however, its action rather resembles that of the hydrolysis of an ethereal salt by an acid itself so unstable as to be constantly undergoing a gradual decomposition during the change. The question therefore suggests itself in this connection—Is the amount of hydrolysis for any given interval proportional to the active mass of the ethereal salt? Hanriot and Camus (*Comptes Rendus*, 1897, cxxiv., 235) have observed that the rate of hydrolysis varies slightly with the quantity of ethereal salt present. In order to test this point further, the equation for a reaction of the first order,—

$$\frac{1}{\theta} \log \frac{A}{A-x} = k,$$

was applied to the reaction in hand. Tubes containing 4 c.c. of water, 0·1 c.c. toluene, and 0·26 c.c. ethyl butyrate were prepared and heated for five minutes at 40° C. One c.c. of a 10 per cent extract was then added and the tubes heated for the desired length of time and titrated with N/20 KOH. The following results were obtained.

Time. Minutes.	N/20 KOH required. C.c.	Per cent of hydrolysis.	*k.*
5	2·60	6·53	0·01354
10	3·45	8·66	0·00907
15	3·40	8·53	0·00592
20	3·80	9·54	0·00500
25	4·25	10·67	0·00500
30	3·75	9·41	0·00329
60	6·90	17·32	0·00316
120	10·10	25·35	0·00244
180	11·3	28·36	0·00184

One Minute Series.—Conditions the same as in the receding:—

Time. Minutes.	N/20 KOH required.	Per cent of hydrolysis.	k.
1	1·3	3·26	0·03344
2	1·8	4·52	0·02296
3	1·95	4·89	0·01657
4	2·30	5·77	0·01481
5	2·60	6·53	0·01354

The following series was tried to show the effect of varying the amount of ethyl butyrate. The tubes contained 4 c.c. of water, 0·1 c.c. toluene, and 1 c.c. of the 10 per cent liver extract used in the preceding series. The tubes were heated at 40° C. for five minutes, at the end of which time a certain quantity of ethyl butyrate was added and the tubes heated for five minutes at 40° C., and then titrated. The following results were obtained :—

Quantity of ethyl butyrate employed.		N/20 KOH required.	Quantity of ethyl butyrate hydrolysed.
C.c.	Grm.	C.c.	Grm.
0·065 =	0·0575	2·1	0·0122
0·13 =	0·1150	2·7	0·0156
0·195 =	0·1725	2·6	0·0151
0·26 =	0·2300	3·2	0 0185

According to these results, the actual amount of ethyl butyrate hydrolysed by the enzyme in a given time is very largely independent of the concentration of the ethereal salt. It was thought possible that the fact that in all of these experiments a certain amount of the butyrate remained undissolved, might offer an explanation of these results. It was thought desirable, therefore, to repeat some of the work on the concentration of the ethereal salt, using ethyl acetate in the place of ethyl butyrate, for the reason that the former is quite soluble in water. A solution of ethyl acetate was prepared containing 0·01414 grm. of the compound per c.c. 40 c.c. of this solution was placed in a glass-stoppered flask, together with 0·5 c.c. toluene, and heated in the bath at 40° C. until it had reached the temperature of the bath. 10 c.c. of 10 per cent liver extract, which had also been warmed to the temperature of the bath, were then added, and the time of the experiments was reckoned from this instant. The flask was constantly shaken, and at certain intervals 5 c.c. of the mixture were withdrawn from the flask by means of a pipette and titrated with N/20 KOH. The results are given below :—

Time. Minutes.	N/20 KOH required.	Per cent of hydrolysis.	k.
5	0·45	3·50	0·00714
10	0·75	5·83	0·00603
15	0·90	6·99	0·00484
20	1·00	7·77	0·00404
30	1·30	10·10	0·00355
45¼	1·65	12·82	0·00303
60	1·85	14·37	0·00258

The effect of varying the concentration of the ethyl acetate was tried in the following manner :—Ten per cent extract of liver used. Temperature, 40° C. Time, fifteen minutes.

Substance used in experiment.	N/20 KOH required. C.c.	Quantity of ethyl acetate originally present. Grm.	Quantity of ethyl acetate hydrolysed. Grm.
4 c.c. ethyl acetate solution and 1 c.c. of enzyme	0·9	0·05656	0·003952
3 c.c. ethyl acetate solution, 1 c.c. water, and 1 c.c. enzyme..	0·875	0·04242	0·00386:
2 c.c. ethyl acetate solution, 2 c.c. water, and 1 c.c. enzyme..	0·9	0·02828	0·003952
1 c.c. ethyl acetate solution, 3 c.c. water, and 1 c.c. enzyme..	0·775	0·01414	0·003403

It will be observed that, as in the case of ethyl butyrate, the hydrolysis of ethyl acetate by lipase is largely independent of the concentration of the ethereal salt.

In this connection the attempt has also been made to determine whether the hydrolysis of ethyl butyrate by lipase is complete. With this in view, two bottles were prepared as follows :—

No. 1 contained 40 c.c. of water, 10 c.c. of 10 per cent pancreatic extract, 1 c.c. toluene, 0·65 c.c. ethyl butyrate.

No. 2 contained 40 c.c. of water, 10 c.c. of 10 per cent hepatic extract, 1 c.c. toluene, 0·65 c.c. ethyl butyrate.

These were allowed to stand at ordinary temperature for several days. At intervals during this time, 5 c.c. of the contents were withdrawn by means of a pipette and titrated with N/20 KOH. The following results were obtained :—

Time. Hours.	N/20 KOH required. C.c.	Per cent of hydrolysis.
Five c.c. No. 1 (Pancreatic) Lipase.		
19	3·5	35·0
19	3·5	35·0
47	4·3	43·0
47	4·15	41·5
137	4·3	43·0
137	4·3	43·0
Five c.c. No. 2 (Hepatic) Lipase.		
19	7·1	71·0
19	7·25	72·5
47	9·35	93·5
47	9·55	95·5
47	9·4	94·0
137	9·2	92·0

After titration these tubes were allowed to stand for a time. In every case the contents of the tube became acid in reaction, thereby indicating that active enzyme was still present in the solution. The above results are such as to indicate that, except when relatively large amounts of the enzyme are employed, the reaction is incomplete. Whether with lipase of different origin or with varying amounts of the same enzyme the limit reached in all cases would be the same is a matter which can only be settled by further investigation. The fact that the hydrolysis is not complete under ordinary circumstances is in keeping with the more or less regular falling off in the velocity of the reaction described in the above, and is probably to be explained by the fact that the hydrolysis of an ethereal salt by lipase is a reversible process, and that the enzyme, as a catalytic agent, is concerned chiefly in bringing about a condition of chemical equilibrium between the ethereal salt and water and the products of the hydrolysis. Acids also have been found to greatly inhibit the activity of the enzyme, so that the great falling off in the rate of hydrolysis is doubtless, to some extent at least, assignable to this cause.

(To be continued).

A New Hydrate of Alumina.—V. Zunino.—It has already been observed that aluminium when plunged into mercury becomes amalgamated on the surface, and if then left exposed to the air it becomes covered with greyish-white tongue-like protuberances of hydrated alumina containing a little metallic aluminium. The author has analysed this alumina and finds it to be a new hydrate, $Al_2O_3\,5H_2O$. He concludes by remarking that aluminium amalgam, being very easily decomposed by water, might be employed with advantage in organic reductions.—*Gazz. Chim. Ital.*, (1), vol. xxx., p. 194.

(Concluded from page 94).

*11. "*Organic Derivatives of Phosphoryl Chloride, and the Space Configuration of the Valencies of Phosphorus.*"* By R. M. Caven, B.Sc.

By the interaction of ethoxyphosphoryl chloride, $OP{\cdot}OC_2H_5{:}Cl_2$, with two equivalents of aniline in ethereal solution, a chlorine atom is replaced and *ethoxyanilidophosphoryl chloride*, $OP{\cdot}OC_2H_5{\cdot}NHC_6H_5{\cdot}Cl$, results. This compound crystallises from ether in truncated pyramids, m. p. 61—62°. The remaining chlorine atom may be displaced by the action of *p*-toluidine, when the *ethyl ester* of *anilido*-p-*toluidophosphoric acid*, $OP\,OC_2H_5{\cdot}NHC_6H_5{\cdot}NHC_6H_4CH_3$, is obtained. This substance crystallises from dilute alcohol in needles, m. p. 116°.

p-Toluidine and aniline may be made to react in reverse order. Thus *ethoxy*-p-*toluidophosphoryl chloride* was obtained crystallised in oblique prisms, m. p. 74°; and the *ethyl ester* of p-*toluidoanilidophosphoric acid* was found to crystallise from dilute alcohol in needles, m. p. 116—117°.

The ethyl esters obtained by these reverse processes present similar physical and microscopic characters, and an intimate mixture of the two products melts at 116—117°. Thus the two compounds—

$$OP\begin{cases}OC_2H_5 & (1)\\ NHC_6H_5 & (2)\\ NHC_6H_4CH_3 & (3)\end{cases} \text{ and } OP\begin{cases}OC_2H_5 & (1)\\ NHC_6H_4CH_3 & (2)\\ NHC_6H_5 & (3)\end{cases}$$

are identical, and from this it appears that the two chlorine atoms in the compound $OP{\cdot}OC_2H_5{\cdot}Cl_2$ are similarly situated with regard to the rest of the molecule.

The only alternative to this would be the supposition that, the two chlorine atoms being differently situated, aniline and *p*-toluidine possess the power of appreciating this difference, and exercise a different predilection when reacting with the substance. This supposition, however, can hardly be entertained.

The chlorine atom replaced by the ethoxy-group might, however, differ in relative position from the other two chlorine atoms.

To determine whether this is so, aniline and *p*-toluidine were made to react directly with phosphoryl chloride, and the following compounds were obtained:—*Anilidophosphoryl chloride*, $OP{\cdot}NHC_6H_5{:}Cl_2$, prisms, m. p. 79°; *anilido*-p-*toluidophosphoryl chloride*, $OP{\cdot}NHC_6H_5{\cdot}NHC_6H_4CH_3{\cdot}Cl$, very fine needles, m. p. 133—134°; p-*toluidophosphoryl chloride*, $OP{\cdot}NHC_6H_4CH_3{:}Cl_2$, plates, m. p. 106°; p-*toluidoanilidophosphoryl chloride*, $OP{\cdot}NHC_6H_4CH_3{\cdot}NHC_6H_5{\cdot}Cl$, very fine needles, m. p. 133°. The two substances—

$$OP\begin{cases}NHC_6H_5 & (1)\\ NHC_6H_4CH_3 & (2)\\ Cl & (3)\end{cases} \text{ and } OP\begin{cases}NHC_6H_4CH_3 & (1)\\ NHC_6H_5 & (2)\\ Cl & (3)\end{cases}$$

present similar characteristics, and when mixed together melt at 133—134°. They are therefore identical.

It would seem then that the first and second chlorine atoms to be replaced are similarly situated, and therefore that all three chlorine atoms occupy similar positions within the molecule of phosphoryl chloride. The supposition that the chlorine atom which was at first replaced by the ethoxy-group refuses to react with bases, and is the particular atom which remains intact in these latter compounds, need scarcely be considered.

The above conclusion concerning the similarity of the chlorine atoms, if ultimately established, should be an important factor in settling the configuration of the phosphorus atom.

A tri-derivative, such as—

$$OP\begin{cases}R^{I}\\ R^{II}\\ R^{III}\end{cases},$$

in which the points of attachment of the three radicles are similarly situated in space with reference to the rest of the molecule, does not contain a plane of symmetry. It should therefore be capable of existing in right- and left-handed forms in which the phosphorus atom is the centre of optical activity. Experiments are now in progress to determine this point, and the fact that one of the elements is doubly bound to the phosphorus atom lends additional interest to the investigation, which was commenced at the suggestion of Dr. Kipping.

*12. *α-Hydroxycamphorcarboxylic Acid.*"* By A. Lapworth and E. M. Chapman.

An account was given of experiments begun with the view of preparing α-bromohomocamphoric acid, an object which has been achieved in another way (*Trans.*, 1900, lxxvii., 1063).

A method for preparing camphorquinone in large quantities, and free from camphoric anhydride, was described. *Camphorquinone*-p-*bromophenylhydrazone*, $C_{10}H_{14}O{:}N_2H{\cdot}C_6H_4Br$, is eminently suited for the detection of the quinone in small quantities; it is very sparingly soluble in nearly all organic media, and melts at 215—216°. It appears to exist only as the ketonic modification (Betti, *Ber.*, 1899, xxxii., 1995). *Camphorquinonesemicarbazone*, $C_{10}H_{14}O{:}N_2H{\cdot}CONH_2$, which is nearly colourless at ordinary temperatures, turns yellow at 210°, melts and decomposes at 228—229°.

When camphorquinone is treated with hydrogen cyanide at −10°, a nearly colourless mass is produced, which probably consists of stereoisomeric forms of *α-dihydroxycyanocamphor*,—

$$C_8H_{14}\begin{cases}C(OH)CN\\ CO\end{cases}.$$

One of these was isolated in the form of six-sided plates, which decomposed when heated, and melted at 197—198°, approximately the melting-point of camphorquinone; it had all the properties of an α-hydroxynitrile, and when dissolved in fuming sulphuric acid was converted into *α-hydroxycamphorcarboxylic amide*,—

$$C_8H_{14}\begin{cases}C(OH)CONH_2\\ CO\end{cases},$$

which forms large brilliant crystals, melting somewhat indefinitely, at 235—240°.

α-Hydroxycamphorcarboxylic acid,—

$$C_8H_{14}\begin{cases}C(OH)CO_2H\\ CO\end{cases},$$

is formed on heating the nitrile with strong hydrobromic acid for some time. It is sparingly soluble in water, and crystallises in brilliant needles or prisms which melt and decompose at 207—208°, becoming converted into Manasse's hydrocamphor (*Ber.*, 1897, xxx., 659). The acid is converted into carbon dioxide and camphorquinone by lead peroxide and acetic acid, and is slowly decomposed when heated with alkalis, being, perhaps, converted into *di*α-homocamphanic acid (*Trans.*, 1900, lxxvii., 1067).

α-Acetoxycamphorcarboxylic acid,—

$$C_8H_{14}\begin{cases}C(OAc)CO_2H\\ CO\end{cases},$$

melts at 85—86°.

It was pointed out that these compounds must contain the carboxyl group in the position in which it occurs in camphor.

*13. "*The Bacterial Decomposition of Formic Acid.*"* By W. C. C. Pakes and W. H. Jollyman.

The authors, as the result of various observations, were

led to analyse the gases produced from sodium formate in solution by certain bacteria. These experiments show that hydrogen and carbon dioxide are evolved, sodium hydrogen carbonate remaining in the medium in which the sodium formate was dissolved. The total amount of carbon dioxide, that is, the amount evolved as a gas and that in combination, was found to be equal in volume to the amount of hydrogen evolved. It is therefore possible to express the reaction by a very simple equation, either $H\cdot CO_2Na + H_2O = NaHCO_3 + H_2$ or $H\cdot CO_2H = CO_2 + H_2$. One of the chief reasons why the addition of sodium formate to media containing dextrose is of such advantage is that the alkali formed from the decomposition of the sodium formate neutralises the acids produced by the decomposition of the sugar; the fact that the medium continues to be neutral or alkaline allows the bacteria to grow for a longer period than when the medium becomes increasingly acid.

Many bacteria had no action upon the formate, and it was found that none of the more commonly occurring yeasts had any action upon the salt.

14 "*Preparation of Substituted Amides from the Corresponding Sodamide.*" By A. W. Titherley, M.Sc., Ph.D.

The behaviour of sodamide derivatives of the type $R\cdot CO\cdot NHNa$ with various halogen organic compounds was investigated, when the marked difference observed between the aliphatic and aromatic derivatives suggested a dissimilarity in their constitution.

(*a*) With alkyl haloids. In presence of benzene there is no action; alcohol, if present, takes part in the reaction, giving the amide and an ether, thus:—

$$CH_3\cdot CO\cdot NHNa + C_2H_5OH + C_2H_5I = CH_3CO\cdot NH_2 + NaI + C_2H_5OC_2H_5.$$

Sodiobenzamide in sealed tubes at 140° readily gives alkyl derivatives, $C_6H_5CO\cdot NHR$, in absence of alcohol, whilst sodacetamide under similar conditions undergoes complex decomposition, giving only a small quantity of the alkylacetamide.

(*b*) With acid chlorides in presence of benzene, sodiobenzamide behaves normally, giving diamides, $C_6H_5CO\cdot NH\cdot COR$, but sodacetamide does not give regular results. With acetyl chloride, diacetamide is formed, but with benzoyl chloride a complex change takes place, dibenzamide, tribenzamide, acetamide, diacetamide, benzonitrile, and benzoic anhydride being formed, but no acetyl benzamide.

(*c*) With halogen esters, sodiobenzamide behaves normally, but gives only small yields of direct condensation products. Ethyl hippurate was synthesised by the action of ethyl bromacetate on sodiobenzamide. Sodacetamide gives unsatisfactory results.

(*d*) With bromamides, symmetrical disubstituted acyl hydrazines were expected, in accordance with the equation $R\cdot CO\cdot NHNa + R\cdot CO\cdot NHBr = R\cdot CO\cdot NH\cdot NH\,CO\cdot R + NaBr$; but no trace of these substances was obtained, as both aliphatic and aromatic derivatives immediately undergo molecular re-arrangement, giving alkyl acyl ureas, $NHR\cdot CO\cdot NH\cdot COR$.

It was found that the sodium atom could be best replaced by alkyl radicles by heating with potassium alkyl sulphates; for example:—

With sodamide, amines are formed thus:—

$$NaNH_2 + KRSO_4 = R\cdot NH_2 + KNaSO_4.$$

With sodium organic amides, substituted amides are formed:—

$$CH_3\cdot CO\cdot NHNa + KRSO_4 = CH_3\cdot CO\cdot NHR + KNaSO_4.$$

On treatment with sodamide, the remaining hydrogen atom in the group CONHR may be replaced by sodium, and this similarly replaced by an alkyl group. The stages are:—

$$R\cdot CO\cdot NH_2 \rightarrow R\cdot CO\cdot NHNa — R\cdot CO\cdot NHR^{I} \rightarrow R\,CO\cdot NNaR^{I} \rightarrow R\cdot CO\cdot NR^{I}R^{II},$$

where R^{I} and R^{II} may be similar or dissimilar radicles.

Several new monalkyl amides and mixed dialkyl amides have been thus prepared, and their behaviour, with dry hydrochloric acid and sodamide respectively, studied. The hydrochlorides of the monalkyl amides contain base and acid in the proportion of 1 mol.: 1 mol. (compare acetamide hydrochloride), and in the aliphatic group are solid, crystalline, very easily fusible, fairly stable substances; in the aromatic group, thick viscid liquids, which dissociate readily.

Acetethylamide hydrochloride, $CH_3\cdot CO\cdot NHC_2H_5,HCl$, melts at 60°; and *acet-n-propylamide hydrochloride*, $CH_3\cdot CO\cdot NHC_3H_7,HCl$, melts at 47°; *acetisobutylamide*, $CH_3\cdot CONH\cdot C_4H_9\beta$, is a liquid boiling at 225—227°, is miscible with water, but is readily separated as an oil by adding alkali; its hydrochloride melts at 107°.

Benz-n-propylamide, $C_6H_5\cdot CO\cdot NHC_3H_7$, crystallises in cubic-shaped crystals melting at 84·5°, and boiling at 294—295°.

Benzbutylamide, $C_6H_5\cdot CO\cdot NHC_4H_9$, melts at 57°, and boils with slight decomposition at 295—296°. *Acetmethylethylamide*, $CH_3\cdot CO\cdot N(CH_3)C_2H_5$, boils at 180°; and *benzmethylethylamide*, $C_6H_5\cdot CO\cdot N(CH_3)C_2H_5$, boils at 280°. Both are liquids. The sodium derivatives, $R\cdot CO\cdot NNaR^{I}$, are white powders, appreciably soluble in benzene. In the aliphatic series they dissolve unchanged in alcohol, and the solutions give, with alcoholic silver nitrate, *orange* precipitates. The aromatic sodium alkyl amides are decomposed by alcohol.

The author discussed the tautomerism of the amides and expressed the view that in the aliphatic group the sodium compounds are true sodamide derivatives of the type $R\cdot CO\cdot NHNa$, whilst in the aromatic group they are partly sodium salts of the imidehydroxy-formula,—

$$R\cdot C\overset{NH}{\underset{ONa}{\leqslant}},$$

and partly $R\cdot CO\cdot NHNa$. Two series of silver derivatives have been obtained, one white, presumably—

$$R\cdot C\overset{NH}{\underset{OAg}{\leqslant}},$$

and the other orange,—

$$R\cdot C\overset{O}{\underset{NHAg}{\leqslant}},$$

which are capable of passing into each other and are very unstable.

The formula of benzamide itself in aqueous solution is probably—

$$C_6H_5\cdot C\overset{NH}{\underset{OH}{\leqslant}},$$

and that of acetamide, $CH_3\cdot CO\cdot NH_2$.

15. "*Note on Two Molecular Compounds of Acetamide.*" By A. W. Titherley, M.Sc., Ph.D.

Acetamide sodium bromide, $2CH_3\cdot CONH_2,NaBr$, and acetamide sodium iodide, $2CH_3\cdot CONH_2,NaI$, are well defined crystalline compounds analogous to the hydrochloride, $2CH_3\cdot CONH_2,HCl$. They were obtained as by-products in certain reactions, and may be prepared by direct union of the constituents in the presence of alcohol. On concentration or cooling they separate as needles which begin to dissociate below their melting points and are very deliquescent. On quickly heating, $2CH_3\cdot CONH_2,NaBr$ melts at 144° with separation of NaBr, and $2CH_3\cdot CONH_2,NaI$ melts at 110° with separation of NaI. Molecular compounds with other haloid compounds of potassium and sodium do not appear to exist.

16. "*Diacetamide; a New Method of Preparation.*" By A. W. Titherley, M.Sc., Ph.D.

Diacetamide may be readily prepared by the direct action of acetyl chloride (in benzene solution) on acetamide,—

$$3CH_3CONH_2 + CH_3COCl = (CH_3CO)_2NH + 2(CH_3\cdot CONH_2)HCl.$$

After filtering off the insoluble acetamide hydrochloride and removing the benzene by distillation the residue is

fractionated. No previous account appears to have been given of this reaction.

Neither acetyl nor benzoyl chloride has any action on benzamide, but the benzoyl chloride gradually decomposes acetamide, with formation of benzoic acid, benzoic anhydride, and acetonitrile.

17. "*Organic Derivatives of Silicon.*" By F. S. Kipping and L. L. Lloyd.

Experiments on the preparation of enantiomorphously related silicon compounds were commenced nearly three years ago, and a short account of this work has already appeared (*Proc.*, 1899, xv., 174); the much more important object, the separation of the isomerides, has not yet been attained.

When silicon tetrachloride is treated in dilute ethereal solution with one molecular proportion of a phenol or alcohol, it is decomposed in accordance with the equation $SiCl_4 + R^I \cdot OH = SiCl_3 \cdot OR^I + HCl$, and by submitting the product to a similar treatment, a second group, and then a third, may be introduced,—

$SiCl_3 \cdot OR^I + R^{II} \cdot OH = SiCl_2(OR^I)(OR^{II}) + HCl.$

$SiCl_2(OR^I)(OR^{II}) + R^{III} \cdot OH = SiCl(OR^I)(OR^{II})(OR^{III}) + HCl.$

Amido-compounds may be used in the above reactions in the place of alcohols or phenols with similar results.

Phenoxymethoxysilicon dichloride, $SiCl_2(OPh)(OMe)$ (b. p. 216°), and *phenoxymethoxyethoxysilicon chloride*, $SiCl(OPh)(OMe)(OEt)$ (b. p. 241°), are colourless, oily liquids readily decomposed by water; *methoxyethoxysilicon dichloride*, $SiCl_2(OMe)(OEt)$, and *methoxyethoxyisobutoxysilicon chloride*, $SiCl(OMe)(OEt)(OBu\beta)$, boiling at 128° and 160° respectively, have similar properties.

The principle on which the above reactions are based, namely, the interaction of halogen compounds and hydroxylic or amido-derivatives, is evidently capable of general application, and its use for the preparation of enantiomorphously related compounds is being investigated by one of us in the case of elements other than silicon.

18. "*Isomeric Hydrindamine Camphor-π-Sulphonates. Racemisation of α-Bromocamphor.*" By F. S. Kipping.

In examining the salt formed by the combination of *d-l*-hydrindamine with *d*-camphor-π-sulphonic acid (obtained by the reduction of *α*-bromocamphorsulphonic acid) in order to try and isolate isomeric salts analogous to those obtained from the bromo-acid (*Trans.*, 1900, lxxvii., 861), it was found that although the salt at first seemed to be homogeneous, it could be resolved into fractions having different specific rotations.

This difference in optical properties is due to the fact that the crude *d* camphor-π-sulphonic acid contains a very small quantity of the enantiomorphously related isomeride, and as the latter can hardly have been produced during the reduction of the bromocamphorsulphonic acid, it follows that *α*-bromocamphor undergoes partial racemisation during sulphonation.

This change is one of considerable complexity, and necessitates the transference of part of one of the closed chains in bromocamphor from one position to another, as in the case of the optical inversion of camphor (Kipping and Pope, *Trans.*, 1897, lxxi., 958).

Except for the separation already referred to, the salt of *d-l*-hydrindamine with camphor-π-sulphonic acid undergoes no change on fractional crystallisation, and gives a molecular rotation practically identical with that of ammonium *d*-camphor-π-sulphonate; it is therefore a *partially* externally compensated salt of the type *d*AlB,*d*AdB; it crystallises from water in large transparent rhomboidal prisms containing water of crystallisation, and melts at about 198°.

19. "*Tetramethylene Carbinol.*" By W. H. Perkin, jun.

When the chloride of tetramethylenecarboxylic acid is reduced in moist ethereal solution with sodium, it is converted into tetramethylene carbinol,—

$$\begin{array}{l} CH_2 \cdot CH_2 \\ | \quad | \\ CH_2 \cdot CH \cdot CH_2OH \end{array}$$

a colourless oil boiling at 143—144°, and having an odour resembling that of isoamyl alcohol. The determinations of the density, refraction, and magnetic rotation of this substance are given in the detailed paper.

PHYSICAL SOCIETY.

Ordinary Meeting, February 22nd, 1901.

Prof. S. P. Thompson, President, in the Chair.

A paper on "*How Air Subjected to X-Rays Loses its Discharging Property, and how it Discharges Electricity*," by Prof. Emilio Villari (Hon. Fellow), was read by the Chairman.

Air made active by X-rays in passing through a long tube coiled in many turns loses much more of its discharging power than it does in passing through the same tube if straight. During this process the tube charges itself to a certain potential. If active air is allowed to stream on masses of wire gauze or wound-up ribbons, enclosed in tubes, the metals, independent of their nature, take a positive or negative charge according to whether the active air rubs against them with force or lightly. Experiments have been performed to prove this. For instance, tubes of copper or lead, if short and straight, take negative charges, but if long and coiled they take positive charges. These phenomena cannot be attributed to chemical actions, but seem to be produced by a special rubbing of the active air upon metallic surfaces, as the result of which they assume one of the charges, and the other charge ought to manifest itself in the air. This is not the case, the charge of the air being often of the same kind as that of the metals. It has previously been shown by the author that active air by streaming against an electrified body is reduced either to ordinary air or to air charged with the electricity which disappears. Hence it may be supposed that the active air in rubbing upon the metallic surfaces develops the two electricities, one of which manifests itself upon these surfaces, and the other goes to reduce the active air to ordinary air, and therefore does not become manifest. The electroscope used in the experiments consisted of a fixed brass-plate, and a gold leaf, whose position was determined by means of a telescope with an eye-piece scale.

The Chairman said he had observed the fact that metals were charged sometimes positively and sometimes negatively by active air.

Mr. Watson asked if any experiments had been performed on the viscosity of gases rendered active by X-rays.

A paper on "*The Propagation of Cusped Waves and their Relation to the Primary and Secondary Focal Lines*," by Prof. R. W. Wood, was read by Mr. Watson.

This paper is a discussion of the reflexion of a plane-wave by a hemispherical mirror, the reflected wave being likened to a volcanic cone. The cusp of the wave, or the rim of the crater, traces the caustic, and is continuously passing through a focus. This accounts for the increased illumination along the caustic. The wave-fronts were drawn by constructing the orthogonal surface, which in section is an epicycloid. The evolute of this curve is the caustic, and the reflected wave-fronts form a family of parallel curves which are the involutes of the caustic. The wave-front between two focal lines is expanding along one meridian, and contracting along a meridian at right angles to it; in other words, the wave is convex along one meridian and concave along the other. The outer slope of the volcanic cone representing the reflected wave corresponds to the position of the wave-front between the focal lines. A useful piece of apparatus can be made by silvering the outside of a hemispherical glass vessel,

The concave mirror thus formed should be mounted on a stand and a small electric lamp arranged so that it can move along the axis of the mirror. A spherical wave starting at the focus of a hemispherical mirror is reflected as a saucer-shaped wave, the curved sides of the saucer coming to a focus in a ring surrounding the nearly flat circular bottom. If the lamp is placed at the focus the luminous ring and the uniformly illuminated area within it can be shown on a ground glass screen. If the lamp be moved to a point midway between the focus and the the mirror a ring of intense brilliance, with very little light within it, is formed.

A paper on "*Cyanine Prisms*," by Prof. R. W. Wood, was read by Mr. Watson.

Prof. Wood has already described a method of making prisms of solid cyanine by pressing the fused dye between plates of glass. Until recently angles of about half a degree were the largest that could be used with advantage on account of the small quantity of green light transmitted. A new supply of the dye has been found to transmit a large quantity of green light with an angle of over one degree. By viewing the filament of an incandescent electric lamp through one of these prisms the anomalous spectrum is seen, the colours being arranged in the order:—Green, blue, violet, red, orange. Prof. Wood has crossed one of these prisms with a photographic copy of a diffraction grating having 2000 lines to the inch. On viewing a naked arc lamp the diffraction spectra are deviated by the prism, the red ends being turned up, and the blue-green ends turned down.

The Chairman said he had been trying to obtain some cyanine, but had not succeeded. Rosaniline has an anomalous dispersion, but cannot be fused. The acetate of rosaniline might, however, be used.

The Society then adjourned until March 8th.

CORRESPONDENCE.

ARSENIC IN SULPHURIC ACID.

To the Editor of the Chemical News.

Sir,—With reference to the evidence of Dr. Campbell Brown before the Liverpool Coroner at a recent inquest on a death from arsenical poisoning:—

The percentage of arsenic (As_2O_3) found in the samples supplied to Messrs. Bostock was excessively high; the following are the figures:—

1·92, 2·36, 2·24, and 2·5 per cent.

In all my experience as a chemist and practical vitriol maker, I have never come across such high percentages as these.

The most impure acid in any factory is that concentrated in the "Glover tower," where it meets all the dust and gases from the kilns; this acid seldom contains more than from 0·5 to 1 per cent of arsenic (As_2O_3). Acid from the chambers contains from 0·02 to 0·1 per cent.

It would be instructive to know how the vitriol in question was manufactured, and from what kind of pyrites.

It was interesting to note that Dr. Campbell Brown found the arsenic depositing in crystals on the sides of the carboys.

White arsenic (As_2O_3) is only sparingly soluble in cold strong vitriol, but much more readily so in hot, from which it deposits in crystals on the sides and bottom of the vessel on cooling.

I have never noticed any crystals deposited on the sides of the carboys used for ordinary strong "commercial" acid.—I am, &c.,

Geo. H. Allibon, F.C.S.

Belfast, February 18, 1901.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Note.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. cxxxii., No. 5, February 4, 1901.

Origin of Chemical Combination. Allotropic Forms of Silver.—M. Berthelot.—The author's method of examining the different allotropic forms of silver consists in measuring the heat brought into action when the metal in its different states is dissolved in an equal weight of mercury. Mercury is employed as a liquid calorimeter, and used at ordinary temperatures. The differences between the quantities of heat thus observed are equal to the heats of transformation of one state into another. The various allotropic forms of silver on which the above experiments were made were:—(1) Beaten silver in thin sheets; (2) silver produced by the transformation of the beaten silver when kept in a current of oxygen for about twenty hours at 500° to 550°; (3) crystalline silver in the form of needles (prepared by the slow electrolysis of silver nitrate dissolved in 10 parts of water); (4) silver precipitated by a sheet of copper by means of silver nitrate in dilute solution. This precipitate is then washed and dried—one portion at the ordinary temperature, the other at 120°; (5) the silver prepared as in No. 4, but heated to a dull red heat.

Researches on the Compounds of Silver and Mercury.—M. Berthelot.—The research described in the former paper suggested to the author the idea of examining the heat of formation of the various amalgams of silver; some being crystalline, and obtained when silver is precipitated from its nitrate by means of mercury, the others prepared by pounding the two metals together in a mortar. In all cases it is found that the chemical affinity of silver for mercury is very slight. A series of crystalline amalgams can be formed simply by varying the relative proportions of the two metals—for 1 atom of mercury, from 1 atom of silver up to 50 atoms. The crystals of these amalgams seem to form in this case in the same manner as in other cases of mixtures of isomorphous salts, which crystallise together in all proportions.

Borates of Magnesium and the Metals of the Alkaline Earths.—L. Ouvrard.—In a former paper, the author describes his researches on the preparation of the tribasic borates of a certain number of metals. Since then he has applied the same method to magnesium and the metals of the alkaline earths—metals which appear to less easily lend themselves to the preparation of crystalline products. Magnesium dissolves easily in melted boric anhydride. Lime or its carbonate dissolves equally well at a red heat in a mixture of boric anhydride and fluorhydrate of potassium fluoride, but the well-defined product is only obtained by using three molecules of lime to one of each of the other compounds. Strontia and baryta behave in an almost similar manner with regard to the above mixture. By their addition in suitable proportions, $B_2O_3.3SrO$ and $B_2O_3.3BaO$ separate out on cooling in the form of crystals which act on polarised light and are less acted upon by water than the corresponding calcium salt, very slightly attacked by dilute acetic acid, but very soluble in mineral acids.

Electrolysis of Oxy-acids. Preparation of β-Amyloxypropionic Acid and the Diamyline of Butanediol-1.4.—J. Hamonet.—The author applies to the preparation of some glycols or their ethers the decomposition of the alkaline salts of the oxy-acids by means of the electric current. If the ether-oxide group of the molecule is in the β-position, the reaction takes place almost according to the equation $2ROC_nH_mCO_2K = K_2 + 2CO_2 + (ROC_nH_m - C_nH_mOR)$; but if this group is in the α-position, a great portion of the ether is hydrolysed,—

$RCH(OC_5H_{11})CO_2H + H_2O = (RCHOHCO_2H) + C_5H_{11}OH.$

In the present paper, only the reactions which take place according to the first equation are considered. By a modification of the above method, β-amyloxypropionic acid, $C_5H_{11}OCH_2CH_2CO_2H$, was prepared, and from this, again, amyl-β-chloropropionate was prepared—a substance which is easily transformed into amyl-β-amyloxypropionate by the addition of sodium amylate dissolved in amyl alcohol.

MISCELLANEOUS.

Arsenic in Beer.—We have received the report of the Public Analyst to the City of Manchester for the quarter ending December 31st, 1900. Among other articles examined we note that 52 samples of beer were tested for arsenious acid; of these, 13 were genuine, while the others contained arsenious acid in quantities varying from one-seventh of a grain per gallon to traces only.

The Sulphocyanacetic Acids.—G. Frerichs and H. Beckurts.—When we react with NCSK on chloracetylurethane we obtain two isomers—

$CH_2.CONH.COOR$ and $CH_2CONH.COOR$
| |
$N=C=S$ $S-C\equiv N$

Isosulphocyanacetylurethane. Sulphocyanacetylurethane.

The salts obtained by Claesson by reacting with NCSK on CH_2ClCO_2M, as well as the ethers derived from them, correspond not only with the normal sulphocyanacetic acid, but also with its isomer, isosulphocyanacetic acid. The amides, on the contrary, correspond only with the normal acid. The salts, as well as the ethers, give with warm alkaline lyes yellowish-red solutions, which give off HCN and H_2S when acidulated, and do not form thioglycolic acid, CH_2SH-CH_2COOH; these are the characteristics of the iso-derivatives. The corresponding acetic amide, treated in the same manner, does not give off HCN, but forms thiogycolic acid; it has the character of a derivative of the normal acid, S being attached directly to the radical which prevents its disengagement in the form of SH_2.—*Arch. d. Pharm.*, vol. ccxxxviii., pp. 9—15.

MEETINGS FOR THE WEEK.

MONDAY, 4th.—Society of Arts, 8. (Cantor Lectures). "The Bearings of Geometry on the Chemistry of Fermentation," by W. J. Pope.
—— Royal Institution, 5. General Monthly Meeting.
—— Society of Chemical Industry, 8. Adjourned Discussion on the "Occurrence and the Detection of Arsenic in Manufactured Products." "A New System for the Manufacture of Borax and Nitrates," by Dr. W. Newton, F.I.C. (time permitting).

TUESDAY, 5th.—Royal Institution, 3. "The Cell as the Unit of Life," by Allan Macfadyen, M.D., B.Sc.
—— Society of Arts, 8. "Early Playing Cards and their Decoration," by Richard Steele.

WEDNESDAY, 6th.—Society of Arts, 8. "Modern Artillery," by Lieut. Arthur Trevor Dawson, late R.N.
—— Society of Public Analysts, 8. "The Determination of Dissolved Oxygen in Water in presence of Nitrites and Organic Matter," by S. Rideal, D.Sc., F.I.C. THE
DAVY FARADAY RESEARCH LABORATORY
OF
THE ROYAL INSTITUTION.

Directors:
The Right Hon. LORD RAYLEIGH, M.A., D.C.L., LL.D., F.R.S.
Professor DEWAR, M.A., LL.D., F.R.S.

Superintendent of the Laboratory:
Dr. ALEXANDER SCOTT, M.A., D.Sc., F.R.S.

This Laboratory was founded by Dr. LUDWIG MOND, F.R.S., as a Memorial of Davy and Faraday for the purpose of promoting, by original research, the development and extension of Chemical and Physical Science.

The Laboratory is open free of charge to Workers of either sex, and any nationality, prosecuting individual investigations; and the extensive collection of Physico-Chemical Apparatus presented by the Founder is available for their use, together with such materials, chemicals, electricity, &c., as the Directors may authorise.

Assistants and a trained mechanician are attached to the Laboratory to aid Workers in the prosecution of their researches.

All persons desiring to be admitted as Workers must send evidence of scientific training, qualification, and previous experience in original research, along with a statement of the nature of the investigation they propose to undertake.

MICHAELMAS TERM.—Monday, October 1, to Saturday, December 15.
LENT TERM.—Monday, January 7, to Saturday, March 30.
EASTER TERM.—Monday, April 22, to Saturday, July 27.

Forms of application can be had from the Assistant Secretary, Royal Institution, Albemarle Street, W.

The Laboratory, Corporation St., Lancaster.

SPECIALITIES:—
COMBUSTIONS—C, H, and N (DUMAS).
FURFURAL DETERMINATIONS and the ANALYSIS AND DETERMINATIONS OF RADICALS IN CARBON COMPOUNDS, and other routine work necessary in Chemical Research.

Research work undertaken in Organic and Agricultural Chemistry, and other preliminary investigations for Chemical Experts, Scientific Investigators, College Professors, Manufacturers, &c. Work involving the use of large Experimental Digester and Vacuum Pans undertaken.

References, List of Charges, and other information on application.

VOL. LXXXIII., No. 2154.

THE BOILING-POINT OF LIQUID HYDROGEN, DETERMINED BY HYDROGEN AND HELIUM GAS THERMOMETERS.*

By JAMES DEWAR, M.A., LL.D.,
Professor of Chemistry at the Royal Institution, and Jacksonian Professor, University of Cambridge.

(Concluded from page 98).

ANOTHER thermometric substance at our disposal, as suitable for determining the boiling-point of hydrogen as hydrogen had been in determining that of oxygen and other gases, is helium. The early experiments of Olszewski and my own later ones showed that pure helium is less condensible than hydrogen, and that the production of liquid or solid products by cooling Bath helium to the temperatures of boiling and solid hydrogen was only partial, and resulted from the presence of other gases undefined at the time the experiments were made. The mode of separating the helium from the gases given given off by the King's Well at Bath is fully described in my paper on "The Liquefaction of Air and the Detection of Impurities" (*Proc. Chem. Soc.*, 1897; CHEMICAL NEWS, lxxvi., 272).

If the neon, present as impurity in the Bath helium which was used, should reach its saturation pressure about the boiling-point of hydrogen, the values given by this thermometer of the boiling-point of hydrogen would be too low. In order to avoid this, the crude helium extracted from the Bath gas was passed through a U-tube cooled by liquid hydrogen to condense out the known impurities—oxygen, nitrogen, and argon. In my paper "On the Application of Liquid Hydrogen to the Production of High Vacua" (*Roy. Soc. Proc.*, 1898; CHEMICAL NEWS, lxxix., 73), it was shown that at the temperature of boiling hydrogen, oxygen, nitrogen, and argon have no measurable tension of vapour, and that the only known gases uncondensed in air after such cooling were hydrogen, helium, and neon. This same neon material occurs in the gas derived from the Bath wells. A sample of helium prepared as above described, which had been passed over red-hot oxide of copper to remove any hydrogen, was found by Lord Rayleigh to have a refractivity of 0·132. The refractivity of Ramsay's pure helium being 0·1238, and that of neon 0·2345, it results that my helium contained some 7·4 per cent of neon, according to the refractivity measurements. This would make the partial tension of the neon in the helium thermometer cooled in the liquid hydrogen to be about 4 m.m., and this being taken as the saturation pressure the boiling-point of neon is about 34° absolute. The initial pressure (No. 9) was taken rather less than an atmosphere, and the temperature of the boiling-point of hydrogen was given by this thermometer as −252·68°. A further observation (No. 10) was taken on another occasion with the same thermometer, and the value found was −252·84°. The fact that the boiling-point of hydrogen, as determined by the helium thermometer, is in substantial agreement with the results obtained by the use of hydrogen itself is a conclusive proof that no partial condensation of the neon had occurred.

Of the remaining experiments in Table I., No. 3 was made in order to show the effect of a very small initial pressure, one-sixth of an atmosphere. The results were unsatisfactory, owing to the sticking of the long columns of mercury giving uncertain pressure readings. In this

§ Dry carbonic acid.

* A Paper read before the Royal Society, February 7, 1901.

case an error in the reading of a low pressure has six times as great an effect as if the initial pressure had been about an atmosphere. If the temperature deduced for the boiling-point of oxygen is corrected, and the same factor of correction applied to the observed liquid hydrogen boiling-point, then it becomes $-251{\cdot}4^{\circ}$.

It is of particular moment to have some estimate of how far errors in the observed quantities employed in Chappuis's formula affect the final value of T.

In the case of an error in t, on differentiating equation (2) we get—

$$dT = T_1 \frac{-x(273+T_1)}{(273+t-xT_1)^2}\, dt \quad . \quad . \quad . \quad . \quad (4).$$

If $x = 1/50$, $t = 13^{\circ}$, $T_1 = -180^{\circ}$; then $dT = 0{\cdot}00339\ dt$, or it would need an alteration of $2\frac{1}{2}^{\circ}$ in t to alter T by 1/100th of a degree at the boiling-point of oxygen. In the same circumstances when $T_1 = -250$, $dT = 0{\cdot}00136\ dt$, so that an alteration of between 7° and 8° in the value of t would only affect the boiling-point of hydrogen by 1/100th of a degree.

From equation (4) the error in T varies with x very nearly. Thus for the second thermometer where $x = 1/115$, a variation of t to the extent of 6° would only affect the boiling-point of oxygen by 1/100th of a degree; and it would require an alteration of 17° in t to affect the boiling-point of hydrogen to the same extent.

In the case of an error in P, a similar process gives—

$$dT = \theta \frac{(\alpha-\delta)P}{(\alpha P_0 - \delta P)^2} \frac{273+t}{273+t-xT_1}\, dP \quad . \quad . \quad (5).$$

If $x = 1/50$, $t = 13^{\circ}$, $P_0 = 760$ m.m., $T_1 = -180^{\circ}$; $dT = 0{\cdot}3563\ dP$, so that an error of 1 m.m. in P would only alter the boiling-point of oxygen by a third of a degree. In the same circumstances at -250°, $dT = 0{\cdot}3516\ dP$, which is practically the same result at the boiling-point of hydrogen as at that of oxygen.

For the second thermometer, these two equations became—

at -180°, $dT = 0{\cdot}3575\ dP$,
at -250°, $dT = 0{\cdot}3548\ dP$.

In each of the last four results if $P_0 = \frac{1}{n} \times 760$ m.m. the formulæ become respectively—

$dT = n \times 0{\cdot}3563\ dP$, and $dT = n \times 0{\cdot}3516\ dP$,
$dT = n \times 0{\cdot}3575\ dP$, and $dT = n \times 0{\cdot}3548\ dP$;

in other words, any error in reading P is magnified in its effect on T directly in proportion as P_0 is diminished. This affords some explanation of the weakness of the results in Experiment No. 3.

In like manner, from an error in P_0, we get—

$$dT = -\frac{P}{P_0}\frac{dT}{dP}\, dP_0 \quad . \quad . \quad . \quad . \quad . \quad (6).$$

Here if $x = 1/50$, $t = 13^{\circ}$, $P_0 = 760$ m.m., $T_1 = -180^{\circ}$;—

$$dT = -0{\cdot}1188\ dP_0,$$

or an error of 1 m.m. in P_0 would only alter the boiling-point of oxygen by a ninth of a degree; but with the same data at -250°, $dT = -0{\cdot}0264\ dP_0$, so that the boiling-point of hydrogen would only be altered by a tenth of a degree for a change of 4 m.m. on an initial pressure of about one atmosphere.

In this case also if $P_0 = \frac{1}{n} \times 760$ m.m. we get similar results to those in the case of P, namely,—

For $x = 1/50$, $dT = -n \times 0{\cdot}1188\ dP_0$ and
$dT = -n \times 0{\cdot}0264\ dP_0$.

For $x = 1/115$, $dT = -n \times 0{\cdot}1192\ dP_0$ and
$dT = -n \times 0{\cdot}0266\ dP_0$.

The general result of an error in either P_0 or P is, that the more reliable experiments are those in which the initial pressure is as high as possible. Hence Nos. 4, 9, 10 are in this respect the most reliable for hydrogen. Also, it is of much more importance that P should be accurate than that P_0 should be so: in fact, for hydrogen an error in P has fourteen times as much effect as the same error in P_0.

We can verify these results from Table I. In Experiment No. 2, where $P_0 = \frac{1}{2} \times 760$ nearly, we have two readings—one at the boiling-point, the other in solid hydrogen—namely, 19·7 m.m. and 14·4 m.m., whose difference is 5·3 m.m. This corresponds to $dT = 3 \times 0{\cdot}3516(-5{\cdot}3)$ degrees, or $5{\cdot}59^{\circ}$. The calculated temperatures for these pressures are $-253{\cdot}37^{\circ}$ and $-258{\cdot}66^{\circ}$, whose difference is $5{\cdot}29^{\circ}$, a satisfactory agreement.

If we compare Experiments Nos. 4 and 9, in both of which the same value of α is used, we can pass from the former to the latter by the formula—

$$dT = -0{\cdot}0266\ dP_0 + 0{\cdot}3548\ dP,$$

in which $dP_0 = -11$ m.m. and $dP = -0{\cdot}5$ m.m., whence $dT = 0{\cdot}152^{\circ}$, the observed result is $-252{\cdot}683^{\circ} + 252{\cdot}806^{\circ}$ or $0{\cdot}123^{\circ}$, which is also satisfactory and explains how so great a drop as 11 m.m. in P_0 has, nevertheless, so slight an effect on the result.

An alteration in the value of x has but little relative effect on the results. As before we have—

$$dT = T_1 \frac{(273+t)(273+T_1)}{(273+t-xT_1)^2}\, dx \quad . \quad . \quad . \quad . \quad (7).$$

If $x = 1/50$, $t = 13^{\circ}$, then—

at $T_1 = -180^{\circ}$, $\quad dT = -57{\cdot}085\ dx$,
at $T_1 = -250^{\circ}$, $\quad dT = -19{\cdot}4205\ dx$,

and for the second thermometer ($x = 1/115$) in like circumstances, and—

$$dT = -57{\cdot}895\ dx.$$
$$dT = -19{\cdot}802\ dx.$$

For instance, if x were altered from 1/50 to 1/80 the result would be to raise the boiling-point of oxygen by $0{\cdot}43^{\circ}$ and that of hydrogen by $0{\cdot}15^{\circ}$.

Finally, the alteration of α for any particular gas, being in any case small, affects the value of T practically only in its main factor T_1. To hundredths of a degree therefore the change in T is inversely proportional to the change in α; or, in other words, is directly proportional to the corresponding absolute zero.

For instance, in Experiment No. 11 had we used the same value of α as for hydrogen the boiling-point of dry CO_2 would have been $-79{\cdot}35^{\circ}$.

Table II. shows what alterations would be required for each of the thermometers, in the values of t, P, P_0, and x to alter the boiling-point of oxygen or that of hydrogen by 1/10 or 1/100 of a degree. The table is calculated for $t = 13^{\circ}$; and in the cases of P and P_0 the initial pressure is taken to be about $1/n$th of an atmosphere.

TABLE II.

		Thermometer No. 1.	Thermometer No. 2.	Alteration of T.
t	at B.P. of O..	$2\frac{1}{2}^{\circ}$	6°	1°
	at B.P. of H..	$7\frac{1}{2}^{\circ}$	17°	$\frac{1}{100}$
P	at B.P. of O..	$\frac{0{\cdot}280}{n}$ m.m.	$\frac{0{\cdot}280}{n}$ m.m.	$\frac{1^{\circ}}{10}$
	at B.P. of H..	$\frac{0{\cdot}285}{n}$ m.m.	$\frac{0{\cdot}282}{n}$ m.m.	
P_0	at B.P. of O..	$\frac{0{\cdot}842}{n}$ m.m.	$\frac{0{\cdot}839}{n}$ m.m.	$\frac{1^{\circ}}{10}$
	at B.P. of H..	$\frac{3{\cdot}79}{n}$ m.m.	$\frac{3{\cdot}76}{n}$ m.m.	
x	at B.P. of O..	0·88 per cent	2·00 per cent	$\frac{1^{\circ}}{100}$
	at B.P. of H..	2·57 "	5·81 "	

Thus, for example, if the initial pressure in either thermometer were about half an atmosphere, an error of 1/7 m.m. in reading P would alter T by a tenth of a degree.

If we take the average values given by these experiments as being the most probable, then the boiling-point of oxygen is $-182{\cdot}5°$, and that of hydrogen is $-252{\cdot}5°$, or $20{\cdot}5°$ absolute. The temperature found for the boiling-point of oxygen agrees with the mean results of Wroblewski, Olszewski, and others. If the boiling-point of oxygen is raised to $-182°$, which is the highest value it can have, then an equal addition to the hydrogen value must follow, making it then $-252°$, or 21° absolute. In a future communication the temperature of solid hydrogen will be discussed.

I am indebted to Mr. J. D. H. Dickson, M.A., of St. Peter's College, Cambridge, for help in the theoretical discussion of the results, and to Mr. Robert Lennox, F.C.S., for able assistance in the conduct of the experiments.

SOME PRINCIPLES AND METHODS OF ROCK ANALYSIS.*

By W. F. HILLEBRAND.

(Continued from p. 102).

V. *Water—Total or Combined* (continued).

Direct Weighing of the Water in Absorption Tubes.

Penfield's Procedure.—The simplest of these methods as to apparatus, and one permitting, by the use of auxiliary arrangements such as are shown and described on page 90, the determination of the hygroscopic as well as any other fraction of the water, is the following glass-tube arrangement (Fig. 6) of Dr. Penfield's (*Amer. Journ. Sci.*, 1894, Series 3, vol. xlviii., p. 37; *Zeit. für Anorg. Chemie.*, 1894, vol. vi., p. 22), whereby the brick and charcoal oven already referred to (Fig. 5), comes again into play, but without the half brick shown in that figure.

The tube is of about 15 m.m. internal diameter, and is fitted with two platinum cylinders at A, one inside, the other outside, where the heat exposure is to be most intense.

These are made from pieces of platinum foil, about 0·07 m.m. in thickness and 8 by 11 c.m. in diameter, which have been previously bent around glass tubes of such a size that when applied to the combustion tubing, the spring of the metal will hold them in place. A large platinum boat, 7 to 8 c.m. long and 11 to 12 m.m. in diameter, with a cross-section like *b*, should be used, since this will readily hold a grm. of mineral mixed with 5 grms. of sodium carbonate. . . . The tube is placed in the angle formed by the charcoal lining, some pieces of charcoal are placed at the sides in front, leaving an opening through which the flame may be directed, and an additional piece is laid on top. The tube can readily be brought to a full white heat, and by forcing a slow current of dry air through the apparatus the carbon dioxide resulting from the decomposition can be removed, and the water carried over into the weighed absorption tube. The glass fuses between the platinum casings, and in a number of experiments that have been tried there has not been a single instance where the glass tube has broken or shown any indication of breaking. After heating the tube will not crack if it is left to cool slowly on the charcoal, but it cannot be used a second time. . . . At the high temperature to which the glass is subjected it of course becomes very soft and the ends must be properly supported; also the rubber connections and absorption apparatus must be carefully screened by asbestos board. By constructing a cover for the boat no material need be lost by spattering, and after making the water determination the contents may be used for the remainder of the analysis.

* *Bulletin of the United States Geological Survey*, No. 176.

The inner cylinder of platinum serves to prevent the glass from collapsing as it softens, whereby distortion of the boat would result, and its withdrawal for further examination of its contents would be impossible.

Gooch's Apparatus.—Of more elaborate apparatus, designed to be used with fluxes, the tubulated platinum crucible invented by Dr. Gooch (*Amer. Chem. Journ.*, 1880, vol. ii., p. 247; CHEM. NEWS, 1880, vol. xlii., p. 326), is capable of affording most excellent service, and it is the one by which far the larger number of water determinations in this laboratory have been made.

Fig. 7, which hardly needs detailed description, shows it in a modified form, which differs from the original forms of Gooch in that the tubes for connecting with both the drying and absorption vessels are constructed wholly of platinum instead of lead glass, the vertical one being bent horizontally at right angles for convenient attachment to the drying towers, and the side one also bent at right angles, but downward, and having its end slightly drawn in at E (Fig 7) so as to admit of easy insertion in the rubber stopper of a U-shaped calcium-chloride tube as shown in Fig. 9. With tubes of the lengths shown in the figure there is absolutely no danger of their ends becoming hot enough by conduction to scorch or soften the rubber stopper or other connection.

The extra first cost of the platinum extension to these tubes over the lead-glass ends of Gooch's original and modified forms need hardly enter as a factor into the question of employment of this apparatus. The glass ends often break, and only a rich lead glass, not easily obtainable, can be used, since it alone will not crack at the joint with the platinum after cooling. In its present form the whole apparatus weighs approximately 88 grms.

As an adjunct to its convenient use there is needed an ordinary upright iron ring stand, with two small sliding rings, and a sliding ring-burner provided with entering ducts for gas and air-blast. Across the uppermost ring there is an arrangement of stout platinum wire (S, Fig. 8), forming at the centre of the ring a secure seat for the upturned flange of the crucible proper. Both rings and burner can be clamped firmly at any height.

The rock powder having been placed in the cylindrical crucible (C, Fig. 7), is there mixed with not more than 3 or 4 grms. of fully dehydrated sodium carbonate,* or more of lead chromate if carbon is to be likewise determined. The crucible is sunk in its seat S (Fig. 8), in the upper ring R' and the tubulated cap T (Fig. 7) is fitted on and attached to the calcium chloride drying towers—preceded by one containing potassium hydroxide if carbon dioxide is likewise to be estimated—on the one side, and to a sulphuric-acid bulb tube B (Fig. 9) on the other. Powdered sodium tungstate—free from arsenic, which would soon ruin the crucible lips—is now poured into the flanged lip L (Fig. 7) in which the cap rests, and a metal vessel of cold water having been raised up by the lower ring R'' (Figs. 8 and 9) until the platinum crucible is sufficiently immersed, the flame of an ordinary blast lamp is turned on to melt the tungstate. As soon as this is fused the flame is removed, and the salt solidifies and makes an air-tight joint, the test of which is the permanence of the column of sulphuric acid in the bulb tubes caused by the contraction of the air in the platinum apparatus as it cools.

After drying by a current of air at 105° C. for two hours, more or less (see below), by means of an air or toluene bath as shown in Fig. 8, the absorption tube A (Fig. 9) is interposed between the sulphuric acid bulbs and the apparatus, being fitted to the latter by its stopper, which is at other times closed by a glass plug, and while a slow current of air continues to pass, the gradual heating and subsequent fusion of the flux is brought about by the

* This has been heated for a length of time to near its fusing point over a free flame or in an air-bath, to decompose the bicarbonate it usually contains, and then placed in a desiccator. Thus heated it is not very hygroscopic. Penfield found that 2·5 grms. of it, spread out on a watch-glass, gained only 0·0002 grm. in fifteen minutes. Potassium carbonate and potassium-sodium carbonate are too hygroscopic by far to be available.

blast-fed sliding ring-burner R''' (Figs. 8 and 9). The sodium-tungstate joint is shielded from the flame by small pieces of asbestos board P (Fig. 9), cut out so as to fit the crucible. When fusion is complete, as shown in the case of sodium-carbonate flux by the decided slackening of the gas current through the safety bulbs attached to the drying tube, the flame is extinguished, and a current of air is allowed to continue until the apparatus is cold.

This apparatus suffers from the drawback of being slightly permeable to combustion gases at high temperature. The defect can be overcome by causing the flame to play upon an outer ordinary platinum crucible, kept permanently filled with sodium-potassium carbonate.

FIG. 6.—TUBE FOR WATER DETERMINATION ACCORDING TO PENFIELD.

A, Outer protecting covering of platinum foil. A second similar foil on the inside prevents the glass from collapsing when heated to softness. *b*, Cross section of platinum boat.

This protective crucible, however, is soon ruined for other purposes, being distorted by the alternate expansion and contraction of the carbonate.

It has been found that if the operation is carried out expeditiously and the final full heat applied for but a few minutes, the error due to penetrating water gases is inappreciable. This hastening may be rendered safer by using rather finely powdered calcium chloride in the central section of the U-shaped absorption tube to avoid large air

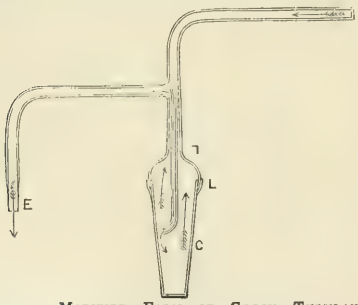

FIG. 7.—MODIFIED FORM OF GOOCH TUBULATED PLATINUM CRUCIBLE FOR THE DETERMINATION OF WATER. (One-fourth natural size. Weight about 88 grms.).

channels. Through this, or any apparatus based on similar principles, the air current should always be forced, not drawn. A warm blast directed upon the exit tube near its entrance into the absorption tube greatly shortens the time required, and is to be recommended.

In this apparatus only the water expelled above 100° to 110° should as a rule be determined, and to effect drying of the mixed mineral powder and sodium carbonate, after luting the tubulated cap on the cylindrical crucible with sodium tungstate, the tube is sunk through a round hole in the cover into a small cylindrical air-bath (Fig. 8), which can be heated from beneath by the same ring burner which is subsequently to fuse the flux. A slow current of air is then forced through, and the drying satisfactorily accomplished.

The reason why it is unsafe to attempt estimation of "hygroscopic" moisture in this apparatus is, that the luting of the two parts must be done by direct application of a flame to the tungstate, and considerable water vapour may enter the apparatus, and be in part retained by the dried sodium carbonate.

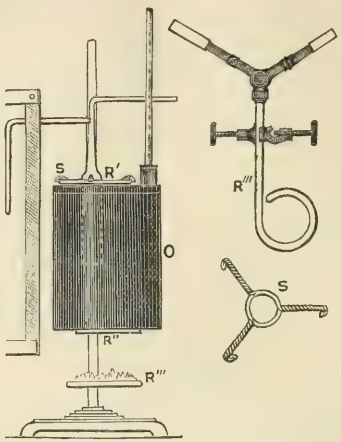

FIG. 8.—DETAILS OF GOOCH CRUCIBLE FOR DETERMINING WATER.

S, Seat of stout platinum wire resting on ring, R', and serving as a support for the crucible; R''', blast-fed ring burner; R'', support for air or toluene bath, O.

Chatard's Apparatus.—The platinum apparatus devised by Dr. Chatard (*Amer. Chem. Journ.*, 1891, vol. xiii., p. 110; *Bull. U. S. Geol. Survey*, 1891, No. 78, p. 84), overcomes the permeability of the metal to gases and affords sharp results, moreover permitting of determining by direct

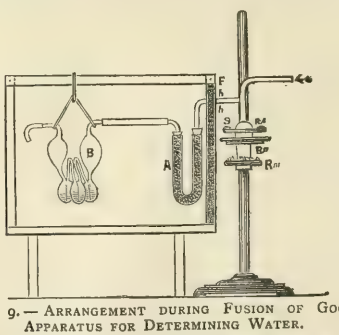

FIG. 9.—ARRANGEMENT DURING FUSION OF GOOCH APPARATUS FOR DETERMINING WATER.

R''', Blast-fed ring burner; F, protective asbestos board shield resting on ring, R''; F F, board forming end of frame and covered with asbestos board to prevent being set on fire by the heat of the blast (this serves at the same time as an efficient shield for the absorption-tube A; in it there is bored a round hole at *h h*, through which passes the outlet tube from the crucible); B, sulphuric acid bulb serving to show the rate of gas current through the absorption-tube and at the same time to prevent back entry of moisture from the air into A.

absorption not only the hygroscopic water, but that which may be driven off at any desired temperature, either with or without fluxes. It is, however, perhaps even more

costly than the Gooch apparatus, and the supposed non-liability to injury by warping, because of the protective layer of borax and asbestos, can hardly be considered as proved.

Merits of the Above Three Forms of Apparatus.—All of these apparatus, except the glass tube of the modified Brush method, permit of the estimation of other constituents besides water in the same portion if necessary, and by the use of lead chromate or potassium chromate, instead of sodium carbonate, graphite, or the carbon of organic matter, can be simultaneously determined with the water.

To one accustomed to its use, and with a drying and suspension attachment permanently set up, the Gooch apparatus, considering its limitations above set forth, offers perhaps the most handy and convenient means for the determination of water in rocks. Its high first cost, in comparison with the glass tube, is fully made up in time by its durability.

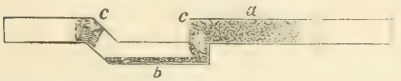

Fig. 10.—Glass Tube for Determination of Water (Jannasch).

b, Mixture of mineral powder with borax; *c c*, plugs of glass-wool; *a*, layer of lead chromate or lead oxide. Total length of the tube, 33 c.m.; inside diameter, 12—14 m.m.

Jannasch's Methods.—This zealous deviser of methods for mineral analysis has published in the *Zeitschrift für Anorganische Chemie* and in the *Berichte der Deutschen Chemischen Gesellschaft* several papers dealing with the problem of water determination in minerals, and in his text-book ("Praktischer Leitfaden der Gewichtsanalyse,") Leipzig, von Veit and Co., 1897), these are collected in more or less modified form.

For the majority of silicates he finds dehydrated borax powder a most efficacious flux, usually at a very moderate temperature. The fusion is accomplished either in a platinum boat, within a glass tube, or in a tube of the form and dimensions shown in the accompanying Fig. 10.

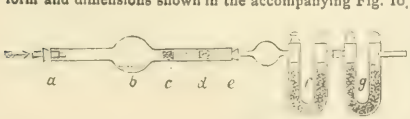

Fig. 11.—Glass Tube for Determination of Water in Special Cases (Jannasch).

Length from *a* to *e*, 26 c.m.; inside diameter, somewhat over 1 c.m.; volume of bulb *b*, 25 c.m.^{3}; *c d*, retaining layer of lead oxide between plugs of glass-wool; *f*, calcium chloride absorption tube; *g*, protective tube.

For rocks or minerals containing not much fluorine a retaining layer of granular lead chromate, or of previously fused and powdered lead oxide, is used as shown at *a*. Plugs of glass-wool are used at *c, c*. Whether or not the boat is employed the borax is first introduced, and, together with the retainer, is thoroughly dried out in an asbestos oven by a hot-air current. Then, after cooling, the mineral powder is added, and thoroughly mixed with the borax. Heat is applied by a flat flame to the mixture, which soon melts and forms a clear fusion, when the action is complete. The blast may be used in extreme cases. The layer of retainer must be kept warm by an auxiliary flame, and the absorption tube must be removed before the glass breaks as soon as this is done. Carbon dioxide can simultaneously be determined by attaching a soda-lime tube to the calcium-chloride tube. For one-half to 1 grm. of silicate Jannasch uses 1½ to 2 grms. of borax.

Regarding the borax method, its inventor insists upon the following points as essential to success, especially when the blast can not be applied:—Most thorough mixing of flux and mineral powder, and a most impalpable fineness of the latter.

The borax itself is prepared by heating pure crystallised borax in a platinum dish till a small portion has melted. That remaining unfused is powdered and again heated in the dish to dull redness for fifteen minutes, with constant stirring. The powder is placed in a tube with tightly fitting glass stopper, and kept over sulphuric acid. It must not be kept long without re-heating, because of being hygroscopic.

Another form of tube used by Jannasch for special purposes is shown in Fig. 11. Minerals, such as topaz, which is not fully decomposed by the borax method, and which contains a large amount of fluorine, are fused at *b* with about six times their weight of lead oxide. A layer of lead oxide between *c d* serves to retain any fluorine escaping from the fusion.

(To be continued).

CONCERNING LIPASE, THE FAT-SPLITTING ENZYME, AND THE REVERSIBILITY OF ITS ACTION.*

By J. H. KASTLE and A. S. LOEVENHART.

(Continued from p. 103).

The Reversibility of the Action of Lipase.

In spite of the vast amount of work which has been done upon the enzymes, we possess at present no unifying conception as to the manner of their action. For the solution of this problem, we must probably look to the study of the kinetics of enzyme action, and one of the first questions to present itself in this connection is: Are the enzymes reversible in their action? If so, then an accumulation of the products of their action should have an increasingly inhibiting effect on the further progress of the change, until finally equilibrium would be established between the initial substance and the products of the change.

O'Sullivan and Thompson (*Journ. Chem. Soc.*, 1890, lvii., 926), in their exhaustive study of the action of invertase on cane-sugar, could not observe any inhibiting effect from the presence of the products of the change. On the other hand, Sheridan Lea (*Journ. of Physiology*, 1890, xi., 226), found the digestion of starch by salivary diastase to be more rapid and much more complete when the products of the digestion were removed by dialysis than when the digestion was performed under identical conditions, but without this precaution. He obtained similar results in his investigation of tryptic digestion. As to the effect of peptone on peptic digestion, the views are somewhat contradictory. Kühne (*Lehrbuch d. Phys. Chemie*, 1866, S. 39), states that peptone has a retarding effect on peptic digestion, while the opinion of Chittenden and Ely (*Journ. of Physiology*, iii., 327), contradicts this. Tamman (*Ztschr. Physiol. Chem.*, 1892, xvi., 271; *Ztschr. Physikal. Chem.*, 1895, xxviii., 426), from his studies of this phase of the problem, arrived at the following conclusions:—

1. Hydrolyses produced by enzymes are incomplete, especially if the quantity of material acted on is large (invertase and rennin are exceptions to this).

2. The incompleteness of the action is due to the accumulation of the products of the fermentation.

3. Removal or dilution of these products, or elevation of the temperature, allows the fermentation to continue.

It would appear that the results obtained by Tamman are easily explicable on the supposition that the enzymes are reversible in their action, the reaction ceasing when

* From the *American Chemical Journal*, xxiv., No. 6

the products of the hydrolysis reach a definite concentration in consequence of equilibrium being established. As Tamman failed to get any indication experimentally that the enzymes are capable of effecting the synthesis of the substances they are capable of hydrolysing, he was forced to explain his results in another way. He advanced the view that the products of the hydrolysis act on the enzyme, transforming it into an inactive modification, and that on removal of these products it is converted into the active modification again.

Oppenheimer ("Die Fermente und ihre Wirkungen," Leipzig, 1900, S. 55), accepting Tamman's results as final, sought to supply a unifying conception of the action of enzymes. He believes the enzymes are capable of inducing only exothermic reactions—that they are only capable of setting free potential energy, and that none of the endothermic, that is, synthetic processes taking place within the organism, can be classed as enzymic, but must be attributed to the peculiar activity of living protoplasm. (The same view has been expressed by Nasse; *Maly's Jahrsbr.*, 1894, S. 718). He admits, however, that this view is completely at variance with the recent work of Hill (*Journ. Chem. Soc.*, 1898, lxxiii., 634), who has proved that the action of maltase on maltose is reversible—first, by showing that maltase can effect the synthesis of maltose from glucose, and, secondly, by showing that the action of maltase on maltose tends to an equilibrium, which is the same whether we start with glucose or an equivalent quantity of maltose.

It is believed that the results reached in this investigation of lipase throw still further light on the subject and greatly strengthen the belief that all enzyme action would probably prove to be reversible if proper conditions of concentration, &c., could be attained.

In many instances, however, it will probably not be practicable to secure the proper conditions, for as in the rennin coagulation of caseinogen solutions, one of the products of cleavage seems to undergo instantaneous rearrangement in the presence of soluble calcium salts, and is thereby removed from the field of activity, thus rendering reversibility impossible. Then again, in some cases, for example, the action of invertase on cane-sugar, the reaction seems to be so nearly complete in one direction that it is doubtful whether reversibility could be demonstrated experimentally. While the catalysis of ethers by strong acids is practically complete, still these are typical reversible reactions. In attempting to determine whether lipase is reversible in its action, it was decided to test its power to effect the synthesis of ethyl butyrate, inasmuch as this substance possesses the following advantages over a true fat:—First, it possesses such a characteristic odour that this alone serves as a very delicate and unmistakable test for its presence. Secondly, in order to effect the synthesis of a fat, it would be necessary, or at least highly desirable, to have the extract of the enzyme free from fat. Up to this time we have not been able to prepare a pancreatic extract free from fat without greatly diminishing its lipolytic power. In the synthesis of ethyl butyrate, however, it would not be necessary to remove the fat, and hence it would be possible to employ the most active pancreatic extract obtainable. Finally, a demonstration of the power of lipase to effect the synthesis of ethyl butyrate would be as conclusive as the synthesis of a fat, for the reason that the compounds are exactly analogous from a chemical point of view.

Experiment 1.—5 c.c. N/100 butyric acid, 2 c.c. of 13 per cent alcohol, and 1 c.c. of diluted glycerin extract of pig pancreas were sealed in a test-tube, and heated at 48·5° for thirty-six hours. When opened it had distinctly the odour of ethyl butyrate.

Experiment 2.—A mixture of 180 c.c. of N/40 butyric acid and 72 c.c. of 30 per cent alcohol was divided into two equal parts. To part 1, 25 c.c. of a 10 per cent glycerin extract of pig pancreas was added; 25 c.c. of the same glycerin extract which had been brought to boiling, and then cooled, was added to part 2. The flasks were left open at ordinary temperature. In a few minutes the flask containing the fresh enzyme had developed a decided odour of ethyl butyrate. The flask was then corked, and allowed to stand a week, when the odour of ethyl butyrate was still perceptible. The flask containing the boiled enzyme was also corked, and was allowed to stand a week under the same conditions. At no time could the odour of ethyl butyrate be detected in the control experiment. Exactly similar experiments were carried out in the presence of toluene water with similar results. Two flasks were also made up, each containing 0·25 grm. of β-naphthol. Here, also, the odour of ethyl butyrate was apparent in the flask containing the active enzyme, while in the flask containing the boiled enzyme there was never the faintest odour of the ethereal salt. Similar results were obtained with glycerin extracts of the cow pancreas. In these experiments, the only test for the production of the ethereal salt was the odour, and although this is very delicate and unmistakable, it seemed desirable to obtain, if possible, larger quantities of the substance. With this in view, the following experiment was made:—

400 grms. of pig pancreas (which had been removed from the animal one and a half hours), was thoroughly ground up with sand and extracted with water, the extract being made up to 2000 c.c. This was divided into two parts of 1000 c.c. each. One part was placed in a balloon flask (A) of 4 litres capacity, while othe other part was boiled for three minutes. After cooling, enough water was added to supply that lost in boiling. It was then placed in a flask (B) similar to (A). To each of these flasks 2 grms. of powdered thymol were added as antiseptic. Each of the flasks was provided with a three-hole rubber stopper, through which passed: 1. A separating funnel; 2, a tube reaching to the bottom of the flask with a small aperture at the end and connected with an apparatus for giving a current of air; and 3, a tube connecting the flask with a condenser. A distilling bulb, with its delivery tube drawn out to a capillary opening, and packed in ice, was used as a receiver. The inner tube of the condenser extended to the bottom of the receiver, and the connection between receiver and condenser was made tight with rubber tubing. 3800 c.c. of practically N/10 butyric acid (5 c.c.=9·2 c.c. N/20 KOH) was made up. This was divided into two equal parts, and to each part was added 100 c.c. of 95 per cent alcohol, and 4 grms. of powdered thymol. One part of this mixture was added to flask (A), and the other simultaneously to flask (B). It was allowed to flow into the flasks very slowly through the separating funnels, four and a half hours being consumed in the operation. The flasks were kept in water-baths at laboratory temperatures 23° to 27°, and both under identical conditions, with respect to sunlight, &c. The initial acidity of the boiled and unboiled extract was the same, viz., 1 c.c.=0·3 c.c. N/20 KOH. The initial activity of the enzyme was taken, and found to be high. In a tube containing 4 c.c. of water, 1 c.c. of extract, 0·26 c.c. ethyl butyrate, and 0·1 c.c. toluene, and heated at 40° C. for fifteen minutes, 6·45 per cent of the ethyl butyrate was hydrolysed. The flasks were allowed to stand forty hours with occasional shaking, both flasks being shaken equally. In order to separate any ethyl butyrate which might have been produced, the flasks were then heated on the water-bath, the distillation being carried on in a slow current of air. About 25 c.c. of the distillate were collected in each case.* The odour of the distillate from flask (A) indicated plainly and unmistakably the presence of ethyl butyrate; it also contained some alcohol and butyric acid, but the odour of these could not be detected on account of the butyric ether. In the distillate from the blank (B), the presence of even a trace of the ether was considered very doubtful by all who examined it, while the odour of alcohol and butyric acid were distinct. The distillate obtained from (A) was re-distilled from a water-bath (this time no

* Previous experiment had shown that on distilling a mixture of ethyl butyrate and a large amount of water practically all the ethereal salt passes over in the first portions of the distillate.

current of air was used), and 5 c.c. of a clear distillate was collected. This was still faintly acid with butyric acid and contained some alcohol.

A small portion of this distillate was reserved for experiment and the remainder was poured into water. The mixture at once became turbid, and a light ethereal oil rose to the surface. Altogether about 1 c.c. of impure ethyl butyrate was obtained in this experiment. Hence about 5 per cent of the butyric acid present had been transformed into the ethereal salt. This quantity was too small for purification, and hence no analysis of it was attempted. Its characteristic odour, however, together with its other properties, and its mode of formation left no room for doubt regarding its composition. A small amount of it was saponified with caustic soda, and the solution evaporated to dryness. On adding sulphuric acid to the residue the odour of butyric acid was perceptible at once.

(To be continued).

THE ACTION OF ALCOHOL AT 95° ON METALS WITH WHICH IT COMES IN CONTACT.

By Dr. MALMÉJAC.

The alcohol used in these experiments was perfectly pure, titrating exactly 95° at a temperature of 15° C., and leaving no residue on evaporation.

Samples of 250 c.c. of this alcohol were placed in flasks of white glass closed with corks, on the 5th of July, 1900; each flask also containing 30 grms. of the following metals:—Copper, iron, tin, lead, zinc, galvanised iron.

For six months these samples were all shaken up at certain periods for the same length of time. On the 5th of January, 1901, we observed at the bottom of the flasks containing the tin, the lead, the zinc, and the galvanised iron a white deposit mixed with the metal, which was itself covered with a sort of cloud of the same colour, and in the flask containing the iron there was a deposit of rust.

With these samples we made the following experiments:—

1st Experiment.

60 c.c. were taken of each, after well shaking. These were evaporated separately on the water-bath in small glass dishes, and the following results were obtained:—

1. Copper	No appreciable residue.
2. Iron	Deposit of rust.
3. Tin	Decided residue.
4. Zinc..	"
5. Lead	"
6. Galvanised iron	"

The cloudiness caused by shaking the solutions (except in the case of the copper), before evaporation, caused us to expect this result.

2nd Experiment.

60 c.c. of each of the filtered liquids were taken. All, except the lead, gave a limpid solution after filtration; the lead solution, even after being filtered several times through double filter-papers, retained a milky appearance.

These various liquids were evaporated on the water-bath in the same way as the former ones, and gave the following results:—

1. Copper	No residue.
2. Iron	Decided residue.
3. Tin	Hardly observable residue.
4. Zinc..	Very decided residue.
5. Lead	Voluminous residue.
6. Galvanised iron	Very decided residue.

On dissolving these different residues in acidulated water, the various metals submitted to the experiment can be detected in the solutions.

It is thus evident that alcohol at 95°, when put in contact with metals for six months, dissolves a small portion of them. This reaction should be, therefore, remembered whenever we have to keep alcohol in metallic receptacles. As the weights of the residues were not determined very accurately we have thought it as well not to publish them. —*Journ de Pharm. et de Chim.*, Series 6, vol. xiii., No 4.

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Ordinary Meeting, February 21st, 1901.

Dr. Armstrong, Vice-President, in the Chair.

Messrs. Hugh Ramage, R. W. Cohen, and A. W. Nunn were formally admitted Fellows of the Society.

The following certificates were read for the first time:—Edward George Paul Bousfield, St. Swithin, Hendon; Albert Ernest Dunstan, 24, Lidfield Road, Stoke Newington, N.; Alfred James Hyder, 22, Gunton Road, Upper Clapton, London, N.E.; William Henry Coutts Jemmett, Tintern, Gap Road, Wimbledon; William Shepperson, Longfield, Gt. Missenden, Bucks; Charles Edmund Shaw Sherratt, 24, Argyll Road, Normacott, Staffs.

It was announced that the following changes in the Officers and Council were proposed by the Council:

As *President*: Professor J. Emerson Reynolds, Sc.D., M.D., F.R.S., *vice* Professor T. E. Thorpe, C.B., Ph.D., D.Sc., LL.D., F.R.S.

As *Vice-Presidents*: Professor Herbert McLeod, F.R.S., and Professor H. A. Miers, M.A., F.R.S., *vice* Professor G. D. Liveing, M.A., F.R.S., and Professor J. M. Thomson, LL.D., F.R.S.

As Ordinary Members of Council: Dr. A. W. Crossley, Professor J. J. Dobbie, M.A., D.Sc., Dr. M. O. Forster, and Mr. S. U. Pickering, M.A., F.R.S., *vice* Professor J. Norman Collie, Ph.D., F.R.S., Mr. Gowland, Mr. C. T. Heycock, M.A., F.R.S., and Dr. Messel.

Mr. F. J. M. Page, Mr. E. W. Voelcker, and Mr. A. C. Chapman were appointed to audit the Society's accounts.

Mr. F. J. Lloyd was appointed to act with the Officers, and Dr. Chattaway, who had been appointed by the Council, in drawing up a Report to the Council on the replies which have been received to the question as to the suggested change in the day and hour of the Ordinary Meetings.

Of the following papers, those marked * were read:—

*20. "*Isomeric Hydrindamine Mandelates and Phenylchloroacethydrindamides.*" By F. S. Kipping and H. Hall.

Although many salts of *d-l*-hydrindamine with different optically active acids have now been submitted to fractional crystallisation (Kipping, *Trans.*, 1900, lxxvii., 861), the resolution of the base into enantiomorphously related compounds has not yet been accomplished; this fact, and the formation in some cases of isomeric salts which appear to be partially racemic, led the authors to try to obtain some direct evidence of the asymmetry of the base.

The fractional crystallisation of *d-l-hydrindamine d-l-mandelate*, $C_9H_{11}N,C_8H_8O_3$, was therefore undertaken in order to ascertain whether the two racemic or externally compensated salts, *d*BdA, *l*BlA, and *d*BlA, *l*BdA, could be separated, but the several fractions proved to be identical, owing possibly to the conversion of one isomeride into the other, *d*BdA,*l*BlA $\rightleftarrows$ *d*BlA,*l*BdA.

From *d-l*-hydrindamine and *d-l*-phenylchloroacetyl chloride, however, two isomeric *phenylchloroacethydrindamides*, $C_6H_5{\cdot}CHCl{\cdot}CO{\cdot}NH{\cdot}C_9H_9$, melting at 150—151° and 124—125° respectively, were obtained; in this case, the isomerides are not mutually convertible in solution, and their formation shows that the base is externally compensated.

d-l-*Hydrindamine* d-*mandelate*, prepared from the pure *d*-acid, is not resolved into different fractions when it is crystallised from alcohol; it is therefore a partially externally compensated salt, *d*Al*B*, *d*A*d*B.

The hydrindamine salts derived from racemic mandelic acid and from pure *d*-mandelic acid respectively are indistinguishable except in optical properties; they both melt at 139—141°, whether heated separately or mixed together in different proportions; they have also the same, or almost the same solubility, for when a mixture of the two is fractionally crystallised, the several deposits have practically the same specific rotations.

It may be concluded therefore that the three optically different compounds, *d*A*d*B, *d*Al*B*, *l*Al*B*, form isomorphous mixtures, and that the salts of the active and inactive acids do not represent true partially racemic or racemic compounds.

The use of externally compensated acid chlorides for the detection of asymmetry, and of the active chlorides for the separation of enantiomorphously related compounds, is being further investigated.

*21. "*Isomeric Benzylhydrindamine Bromocamphorsulphonates and some Salts of* d-l-*Hydrindamine*." By F. S. Kipping and H. Hall.

Benzylhydrindamine, $C_9H_9{\cdot}NH{\cdot}C_7H_7$, prepared by treating *d-l*-hydrindamine with benzyl chloride, unites with α-bromocamphorsulphonic acid, forming a mixture of two isomeric salts, $C_{16}H_{17}N,C_{10}H_{14}BrO{\cdot}SO_3H$, which are separable by fractional crystallisation.

The more sparingly soluble "α-salt" forms transparent plates, melts at 206—207°, and has a specific rotation $[\alpha]_D = +50°$ in ethyl alcohol.

The more readily soluble "β-salt" crystallises in ill-defined prisms, melts at 186—187°, and has a specific rotation $[\alpha]_D = +51{\cdot}5°$ in ethyl alcohol; in chloroform, the specific rotation of the β-salt seems to be slightly greater than that of the isomeride.

Both salts give an optically inactive base when decomposed with barium hydroxide solution, and they both contain an acid optically identical with ordinary *d*-α-bromocamphorsulphonic acid. Since they both contain an asymmetric carbon group, as well as a nitrogen atom which is directly united with (H),(C_9H_9),(C_7H_7), and with the ion of the bromo-acid, they might be regarded as salts of the two different externally compensated bases, $+C+N^v$, $-C-N^v$, and $+C-N^v$, $-C+N^v$, or they may be considered to be analogues of the isomeric hydrindamine bromocamphorsulphonates, &c., which have been recently described (Kipping, *Trans.*, 1900, lxxvii., 861).

d-l-*Hydrindamine* d-*camphorsulphonate*,—
$$C_9H_{11}N,C_{10}H_{15}O{\cdot}SO_3H,$$
prepared from the base and Reychler's camphorsulphonic acid, like the salt obtained with *d*-camphor-π-sulphonic acid, is not resolved into isomerides on fractional crystallisation; it forms long prisms melting at 165—166°, and is very readily soluble in water.

d - l - *Hydrindamine* d - *hydroxy* - cis - π - *camphanate*, $C_9H_{11}N,C_{10}H_{14}O_5$, unlike the corresponding salt of l-*cis*-π-camphanic acid, also remains homogeneous on fractional crystallisation; it forms transparent prisms $(+\frac{1}{2}H_2O)$ melting at 202—203°.

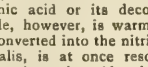
*22. "*Constitution of Bromocamphoric Anhydride and Camphanic Acid.*" By A. Lapworth and W. H. Lenton.

The fact that ordinary bromocamphoric anhydride on treatment with alkalis is in part converted into lauronolic acid by loss of hydrogen bromide and carbon dioxide has led to the view that the bromine atom is in the β position with regard to one of the carboxyl groups (Aschan, *Ber.*, 1894, xxvii., 2112), as it is with β-bromo-acids that this property is almost exclusively associated.

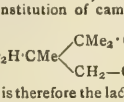
In the belief that the behaviour of the anhydride in this respect is misleading, the authors have made numerous experiments which have resulted in the following observations;—

Camphanic acid, on treatment with phosphorus pentabromide, is re-converted into bromocamphoric anhydride, showing that the lactonic oxygen atom occupies the position of the bromine atom in the anhydride.

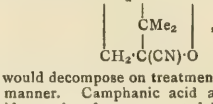
It is difficult to oxidise camphanic acid with any but powerful agents, and when attacked it is usually converted into camphoronic acid or its decomposition products. When its amide, however, is warmed with phosphorus chlorides it is converted into the nitrile, and this, on treatment with alkalis, is at once resolved into hydrogen cyanide and camphononic acid, which, apart from all views as to the constitution of camphor, must have the structure,—



Camphanonitrile is therefore the lactone of an α-hydroxynitrilic acid, namely,—



which would decompose on treatment with alkalis in the above manner. Camphanic acid and bromocamphoric anhydride are therefore represented by the formulæ suggested by Bredt, namely,—



and the formation, from them, of lauronolic acid has not the significance which has been attached to it.

*23. "*The Action of Acetylchloro- and Acetylbromoaminobenzenes on Amines and Phenylhydrazine.*" By F. D. Chattaway and K. J. P. Orton.

In studying the action of nitrogen chlorides and nitrogen bromides on amines and phenylhydrazine, the authors have used the acetylchloro- and acetylbromo-amino-2 : 4-dichlorobenzene recently prepared by them, as these substances are readily obtained pure. The operations have generally been carried out in chloroform solution, avoiding as far as possible the presence of water.

The reaction with the aliphatic amines is represented by the equation—

$$R{\cdot}NH_2 + C_6H_3Cl_2{\cdot}NClAc = R{\cdot}NHCl + C_6H_3Cl_2{\cdot}NHAc.$$

The chloroamino derivatives thus formed can be isolated.

The initial reaction with the aromatic amines (anilines and toluidines) is similar. The halogen, however, immediately wanders from the nitrogen into the para- and ortho-positions if these are unoccupied. When the hydrogen atoms in the positions 2, 4, and 6 are already substituted, no such intramolecular transformation can take place, but the halogen amino-derivatives of such anilines (as *s*-trichloroaniline) are very unstable, and decompose, yielding substituted azobenzenes. The azo-formation takes place to some extent when acetylchloroaminobenzenes react with the less substituted anilines and toluidines.

Two reactions take place between phenylhydrazine and halogen amino-compounds. The one, when phenylhydrazine is in excess, is represented by the equation,—

$$4C_6H_5{\cdot}NH{\cdot}NH_2 + 2(:NX) = = C_6H_5N_3 + C_6H_5NH_2 + 2C_6H_5{\cdot}NH{\cdot}NH_2{\cdot}HCl + 2(:NH);$$

the other, when the halogen amino-compound is in excess, by the equation,—

$$C_6H_5NH{\cdot}NH_2 + 3(:NX) = C_6H_5X + N_2 + X_2 + 3(:NH).$$

In the authors' opinion, the formation of these substances is not a result of oxidation, but depends on the intermediate formation of halogen hydrazino-derivatives.

The following hitherto undescribed substances have been prepared: — *Aceto*-4-*chloromethylanaline*, $C_6H_4Cl{\cdot}NCH_3{\cdot}COCH_3$, m. p. 92°, white plates from petroleum; *o-chloromethylaniline*, $C_6H_4Cl{\cdot}NH{\cdot}CH_3$, a colourless oil, b. p. 218° (760 m.m.); *2-chloro-5-bromoacetanilide*, $C_6H_3ClBr{\cdot}NH{\cdot}COCH_3$, needles, m. p. 141°; 3-*bromo*-4-*chloroacetanilide*, $C_6H_3ClBr{\cdot}NH{\cdot}COCH_3$, rhombs, m. p. 130°; 2:4:6, 2':4':6'-*hexachloroazobenzene*, $C_6H_2Cl_3{\cdot}N{:}N{\cdot}C_6H_2Cl_3$, dark red needles, m. p. 188°.

•24. "*The Preparation of Orthochloroaniline.*" By F. D. Chattaway and K. J. P. Orton.

The authors described a convenient method of preparing orthochloroaniline by the chlorination of acetanilide.

The chlorination is effected by adding the calculated quantity of a strong solution of bleaching powder to a solution of acetanilide (1 part) in glacial acetic acid (3 to 4 parts). Orthochloroacetanilide, which forms from 5 to 8 per cent of the product, is partly separated from the para-derivative by fractional crystallisation from alcohol. The *o*-chloroaniline is finally freed from *p*-chloroaniline by distilling in steam from sulphuric acid.

•25. "*The Bacterial Oxidation of Formates by Nitrates.*" By W. C. C. Pakes and W. H. Jollyman.

In previous communications the authors have described the actions of a group of bacteria upon solutions containing sodium formate, and of another group upon solutions containing sodium or potassium nitrate.

Many of the bacteria which decompose the formate are also found to decompose the nitrate, such, for instance, as the *B. coli communis*, *B. enteritidis* of Gärtner, and the *Pneumobacillus* of Friedländer, each of which converts formic acid into carbon dioxide and hydrogen, and reduces nitric to nitrous acid.

If any of these bacteria be cultivated in a medium containing both formate and nitrate (1 per cent of each), it it will be found that no gas will be evolved. After the lapse of several days, the fluid will be found to contain sodium hydrogen carbonate and sodium nitrite. When the medium contains an excess of sodium formate as compared with the sodium nitrate, gas is evolved which, upon analysis, proves to consist of carbon dioxide and nitrogen.

When the same bacteria are cultivated in media containing *d*-glucose and sodium nitrate, a similar effect is produced, gas is evolved which consists of carbon dioxide and nitrogen, or carbon dioxide, nitrogen, and hydrogen, the latter being found if the sugar is in excess as compared with the nitrate.

The authors have not yet been able to determine whether a similar result would be obtained when the organism used did not act upon both, but they have succeeded in showing that the *B. pyocyaneus* (which does not decompose formate) acts in a medium containing both salts almost as if the formate were absent; they have not as yet been able to find a bacterium which decomposes formate, but which does not reduce nitrates.

26. "*Condensation of Phenols with Esters of the Acetylene Series.* Part IV. *Benzo-γ-pyrone and its Homologues.*" By S. Ruhemann and H. W. Bausor, B.A.

Ruhemann and Stapleton have shown (*Trans.*, 1900, lxxvii., 1184), that phenoxyfumaric acid under the influence of concentrated sulphuric acid condenses to benzo-γ-pyronemonocarboxylic acid, which, on distillation, yields benzo-γ-pyrone. The authors of the present paper have applied these reactions to the cresoxyfumaric acids, and thus obtained the corresponding tolu-γ-pyronecarboxylic acids and tolu-γ-pyrones.

27. "*The Influence of Solvents on the Rotation of Optically Active Compounds.* II. *The Influence of Isobutyl Alcohol and Secondary Octyl Alcohol (Methylhexylcarbinol) on the Rotation of Ethyl Tartrate.*" By T. S. Patterson.

In continuation of work already published (*Trans.*, 1901, lxxix., 167), experiments were described whose object was to determine the influence of *iso*butyl and octyl alcohols as solvents upon the rotation of ethyl tartrate. It was found that both liquids lower the specific rotation of the dissolved active substance, the latter having the greater effect. In both cases, concentrations of distinct minimum rotation occur. This phenomenon was briefly discussed.

It was also shown that ethyl tartrate in *iso*butyl alcohol has a molecular-solution-volume greater than that in *n*-propyl alcohol, but less than that in octyl alcohol, which is in agreement with the generalisation deduced from the results of the former investigation.

28. "*Influence of a Heterocyclic Group on Optical Rotation; the Ethyl and Methyl Salts of Dipyromucyltartaric Acid.*' By P. F. Frankland and F. W. Aston.

The authors have investigated the influence on optical rotation of the heterocyclic furfurane group by preparing diethyl dipyromucyltartrate and determining its rotation. The molecular rotation, $[M]_D\,20° = -321{\cdot}44°$, $[M]_D\,99{\cdot}5° = -266{\cdot}54°$, is, at 20°, intermediate between that of diethyl di-*m*-toluyltartrate ($[M]_D 20° = -306{\cdot}3°$) and diethyl di-*p*-toluyltartrate ($[M]_D\,20° = -484{\cdot}4°$), and at 100° intermediate between that of diethyl dibenzoyltartrate ($[M]_D\,100° = -251{\cdot}6°$) and diethyl di-*m*-toluyltartrate ($[M]_D\,100° = -281{\cdot}7°$). Thus the influence of the pyromucyl radicle is similar to that of the aromatic acid, but unlike that of the fatty acid radicles, the derivatives of ethyl tartrate with two equivalents of the former being strongly lævorotatory, whilst those with the latter are more strongly dextrorotatory than ethyl tartrate itself. The pyromucyl derivative again resembles the corresponding aromatic derivatives in having its lævorotation diminished by rise of temperature, whilst the corresponding derivatives with fatty acid radicles have their dextrorotation increased under the same circumstances.

The authors also described a novel method of continuous automatic esterification which has been advantageously employed by them in the preparation of methyl and ethyl tartrates.

NOTICES OF BOOKS.

Laboratory Instructions in General Chemistry. Arranged by Ernest A. Congdon. Philadelphia. 1901. 100 pp., 8vo. 56 Illustrations. Interleaved.

The author of this book is Professor of Chemistry at the Drexel Institute, Philadelphia, and the "Laboratory Instructions" embody ten years' experience in teaching classes. Much of the material is original; the work can be used in connection with any standard text-book.

The first lessons deal with such simple operations as manipulations with glass-tubing, demonstrations of the differences between physical and chemical changes, and experiments to illustrate divers chemical reactions; then follow easy preparations, as of oxygen, hydrogen, &c., and the usual experiments on metals. The whole course is graded carefully, the instructions are explicit and adequate; moreover, the student is occasionally cautioned against injurious actions.

A valuable feature of the book is found in the appendix of twenty pages containing simple and ingenious experiments for illustrating the laws of the conservation of matter, of definite and multiple proportions, of the influence of temperature and pressure on the volumes of gases, as well as the determinations of molecular weights (by three methods), of equivalent weights, and of atomic weights. Except in this appendix the apparatus required is simple and comparatively inexpensive.

The book is admirably adapted to the needs of beginners, and could be used both with large classes or for home study. It is well illustrated from drawings in the note-book of Mr. D. Owen Hales, a student in the Drexel Institute, and the paper and typography do credit to the publishers, P. Blakiston, Son, and Co. H.C.B.

CORRESPONDENCE.

NUMBERING CRUCIBLES.

To the Editor of the Chemical News.

Sir,—Mr. A. A. Kelly's suggestion (Chemical News, vol. lxxxiii., p. 95), that porcelain crucibles be marked with platinic chloride, was made some time ago in the Chemical News, by Blount, I believe. He scratched the side with a diamond, put on the platinic chloride, lightly wiped away the excess, and ignited.

While admiring the practically indestructible marking in metallic platinum, may I suggest that the crucible be marked with ordinary writing ink and then fired. The letter, number, or approximate weight of the crucible is much more easily made, and stands out distinctly in brown lines for as long a time as such pieces of apparatus usually last.—I am, &c.,

Horace Jervis.

52, Bannon Street, Sheffield.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Note.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. cxxxii., No. 6, February 11, 1901.

Generation of Hydrocarbides by means of Metallic Carbides.—M. Berthelot.—Metallic carbides can be divided into several groups; their decomposition by means of water or dilute acids giving rise to different hydrogen carbides, such as acetylene, ethylene, formene, and liquid carbides less well known. A study of these metallic carbides and their transformation into hydrocarbides has been rendered more simple by the discovery of acetylides prepared from acetylene, and also by M. Moissan's researches on the production of metallic carbides in the electric furnace. The present paper gives an account of further researches on the thermo-chemical conditions under which hydrogen carbides are generated. The results show that metallic carbides do not, when decomposed by water, give rise to oxides of composition corresponding to that of the carbide.

Observations on the Solution of Solid Metals in Mercury and more generally in other Molten Metals.—M. Berthelot.—Observations made during the reaction of a molten metal, such as mercury, on other metals, show that there exist a number of phenomena resembling those produced during the reaction of water on colloidal bodies, organic or mineral, having the characteristics of emulsions, and which do not tend to confirm the notion of a definite coefficient of solubility.

Formation and Decomposition of Acetals.—Marcel Delépine.—In previous thermo-chemical researches on the acetals of monovalent and plurivalent alcohols, the author stated that the generating reaction ought to be limited by the inverse reaction of water on the acetal formed, $R{-}CHO + 2R'(OH) \gtrless R{-}CH(OR')_2 + H_2O$. The point now considered is that the laws ruling the formation and decomposition of acetals approach in a singular manner the processes of etherification and saponification; or rather that the acetals are the ethers of the corresponding aldehyde, and they behave as a kind of bibasic acid. If their stability with regard to water or alkalis is observed, these substances are seen to resemble ether-oxides, their other properties rendering them comparable with ether-salts.

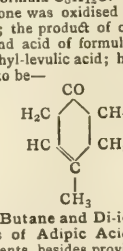
The Elimination of Methane in the Atmosphere.—V. Urbain.—Methane is evolved in abundance from the surface of the earth. Independently of the sources of this gas which exist in all countries, this carbide is a constant product of the fermentation of substances containing cellulose. The author's researches lead him to believe that plants play the same part towards methane that they do towards carbon dioxide. The author proves this by sealing plants hermetically in glass vessels containing about 1300 c.c. of air together with known volumes of methane, and examines the methane undecomposed at the end of definite periods of time.

Action of Ethers of Monobasic Fatty Acids on Mixed Organo-magnesium Compounds.—V. Grignard.—Continuing former researches, the author now examines the action of organo-magnesium compounds on ethers of the monobasic fatty acids, particularly formic and acetic ethers. It is known that organo-zinc compounds, apart from zinc allyl, only react on formic ethers, and then with poor yields. The use of mixed organo-magnesium compounds allows of the simplification and generalisation of a large number of synthetic methods for which formerly organo-zinc compounds were used.

Absorption of Light by Indophenols.—P. Bayrac and C. Camichel.—In no experiment were the authors able to limit the red band found in the absorption-spectrum of the indophenols, at the infra-red side, nor even to observe the culminating point of the curve (the point where the transparence of the solution ceases to increase). They tried also to define the extremities of the band by the condition that the coefficient K has the same very slight value for the two extremities.

Acid and Alcoholic Compounds of Phenylcarbazide with Phenylhydrazine.—P. Cazeneuve.—The acid and alcoholic compounds of phenylcarbazide have been prepared with acids of the fatty series, CH_2O_2, $C_2H_4O_2$, $C_3H_6O_2$, $C_4H_8O_2$, $C_5H_{10}O_2$. The reaction has been made with propionic and normal butyric acid and valerianic acid and valeriane: also with oxalic acid. Crystallised from excess of alcohols, phenylcarbazide of phenylhydrazine gives alcoholic compounds, less stable, however, than the acid combinations; the former being decomposed by the heat of boiling water, and many of them effloresing in the air.

Ketones of Wood Oils: Dimethylcyclohexenone.—A. Béhal.—In a former research the author isolates a series of ketones from wood oil. He now undertakes the separation and examination of another of these ketones. It boils at 194°, its oxime melts at 102·5°, and it gives a benzoyl derivative fusing at 129°. Analysis assigns to it the formula $C_8H_{12}O$. To determine the constitution, the ketone was oxidised by means of permanganate of potash; the product of oxidation giving acetic acid and a second acid of formula $C_6H_{10}O_3$, which was found to be α-methyl-levulic acid; hence the constitutional formula appears to be—



Di-bromated Butane and Di-iodated Butane (1 . 4). New Synthesis of Adipic Acid.—J. Hamonet.—The author's experiments, besides proving the constitution of di-bromated butane and di-iodated butane (1 . 4), furnish a new synthesis of adipic acid.

Nitrate of Uranium.—Œchsner de Coninck.—The author determines the densities of some solutions of uranium nitrate in dilute nitric and sulphuric acid. He then measures the solubility of uranium nitrate in absolutely pure methyl alcohol (prepared from methyl oxalate) in ordinary ether, in ethyl acetate, and in concentrated formic acid.—*Comptes Rendus*, cxxxii., No. 2.

MISCELLANEOUS.

Royal Institution.—A General Monthly Meeting of the Members of the Royal Institution was held on the 4th inst., Sir James Crichton-Browne, Treasurer and Vice-President, in the Chair. Dr. F. H. Anderson, Mr. Alfred Baldwin, M.P., Sir William J. Bell, Mr. R. M. Cocks, Mr. W. Duppa Crotch, Mr. R. S. Dean, Lady Farrer, Major-General Viscount Frankfort de Montmorency, K.C.B., Mr. G. Hartridge, Captain T. B. Heathorn, R.A., Lady Hope, Mr. R. H. Household, Mr. L. S. Little, Mr. F. L. Lucas, Mrs. W. T. Makins, Miss E. M. Marindin, Mr. C. Schiff, and Mr. F. Owen were elected Members. The special thanks of the Members were returned to Mr. Hugh Leonard, F.S.A., for his donation of £100, and to Sir William J. Farrer for his donation of £50, to the Fund for the Promotion of Experimental Research at Low Temperatures.

The Use of Chloride of Lim eas a Purifying Material for Acetylene.—F. B. Ahrens.—Acetylene, purified by passing over materials containing chloride of lime, contains a small quantity of carbonic acid, which, however, causes no inconvenience; but it also contains variable quantities of chlorised organic derivatives, which constitute a source of danger. It also happens that the purifying material (a mixture of sawdust and chloride of lime), may become heated spontaneously and thus become useless. The author has observed that this heating, and consequently the disengagement of chlorine, does not occur when chloride of lime is used alone. He attributes the heating to a reaction between the hypochlorite and the lignine of the sawdust. The temperature attained by the mass depends on the relative proportions of the chloride of lime, water, and sawdust. On mixing 20 grms. of chloride of lime with 10 grms. of sawdust, and 9 c.c. of water, the temperature reaches 130° in seven minutes. The author concludes that sawdust can be replaced by Kieselguhr, powdered coke, brick-dust, or chromate of lead. If sawdust is retained, then a very large proportion should be used with only a small quantity of water.—*Zeits. f. Angew. Chem.*, p. 777.

NOTES AND QUERIES.

** Our Notes and Queries column was opened for the purpose of giving and obtaining information likely to be of use to our readers generally. Arsenic in Coal.—Could any reader give information as regards a good method for the detection and estimation of arsenic in coal?—ANALYST.

MEETINGS FOR THE WEEK.

MONDAY, 11th.—Society of Arts, 8. (Cantor Lectures). "Electric Railways," by Major Philip Cardew, R.E., &c.

TUESDAY, 12th.—Royal Institution, 3. "The Cell as the Unit of Life," by Allan Macfadyen, M.D., B.Sc.

—— Society of Arts, 8. "Some Examples of Romanesque Architecture in North Italy," by Hugh Stannus.

WEDNESDAY, 13th.—Society of Arts, 8. "The Proposed High Speed Electrical 'Monorail' between Liverpool and Manchester," by F. B. Behr, Assoc.Inst.C.E.

THURSDAY, 14th.—Royal Institution, 3. "Greek and Roman Portrait Sculpture," by Prof. Percy Gardner, Litt.D.

—— Society of Arts, 4.30. "The Growth and Trend of Indian Trade—A Forty Years' Survey," by Henry John Tozer, M.A.

FRIDAY, 15th.—Royal Institution, 9. "Through the Heart of Africa from South to North," by Major Alfred St. Hill Gibbons, F.R.G.S.

SATURDAY, 16th.—Royal Institution, 3. "Sound and Vibrations," by the Rt. Hon. Lord Rayleigh, F.R.S., &c.

MACMILLAN & CO.'S BOOKS
FOR
CHEMICAL STUDENTS.

JUST PUBLISHED.

PRACTICAL ORGANIC CHEMISTRY
for ADVANCED STUDENTS.
By JULIUS B. COHEN, Ph.D.
Globe 8vo, 3s. 6d.

Second Edition Now Ready.

THE SCIENTIFIC FOUNDATIONS of ANALYTICAL CHEMISTRY
Treated in an Elementary Manner.
By Professor WILHELM OSTWALD, Ph.D. Translated with the Author's sanction by GEORGE M'GOWAN, Ph.D.
Extra crown 8vo, 6s. net.

CHEMICAL NEWS.—"We can strongly recommend the book both to advanced chemists and to analytical students."

INTRODUCTION TO PHYSICAL CHEMISTRY. By JAMES WALKER, D.Sc., Ph.D., Professor of Chemistry in University College, Dundee. 8vo, 10s. net.

ELEMENTARY PHYSICS AND CHEMISTRY. In Three Stages. By Prof. R. A. GREGORY, F.R.A.S, and A. T. SIMMONS, B.Sc. (Lond.) Globe 8vo, 1s. 6d. each.

A PRIMER OF CHEMISTRY. By Sir HENRY E. ROSCOE, F.R.S. Illustrated. With Questions. Pott 8vo, 1s.

CHEMISTRY FOR ORGANISED SCHOOLS OF SCIENCE. By S. PARRISH, B.Sc. A.R.C.S. (Lond.). With Introduction by Dr. FORSYTH. Globe 8vo, 2s. 6d.

INORGANIC CHEMISTRY FOR ADVANCED STUDENTS. By Sir HENRY ROSCOE, F.R.S., D.C.L., LL.D., and ARTHUR HARDEN, Ph.D. M.Sc. (Vict.). With Fifty-four Illustrations in the Text. Globe 8vo, 4s. 6d.

AN INTRODUCTION TO THE SCIENCE AND PRACTICE OF QUALITATIVE CHEMICAL ANALYSIS, *INORGANIC.* By CHAPMAN JONES, F.I.C., F.C.S. (Lond. and Berlin), &c. Crown 8vo, 6s.

PRACTICAL INORGANIC CHEMISTRY FOR ADVANCED STUDENTS. By CHAPMAN JONES, F.I.C., F.C.S. (London and Berlin), Senior Demonstrator of Chemistry in the Royal College of Science, London. Globe 8vo, 2s. 6d.

A TREATISE ON CHEMISTRY. By H. E. ROSCOE, F.R.S., and C. SCHORLEMMER, F.R.S.
New Edition completely revised by Sir H. E. ROSCOE, assisted by Drs. H. G. COLMAN and A. HARDEN.
VOLUME I.—THE NON-METALLIC ELEMENTS. 8vo., 21s.
VOLUME II.—THE METALS. 8vo., 31s. 6d.
*** The two volumes as they now stand form the only complete work, up to date, on Inorganic Chemistry in the English language.
VOL. III. Organic Chemistry. Parts I., II., IV., and VI., 21s. each. Parts III. and V. 18s. each.

INORGANIC CHEMISTRY FOR BEGINNERS. By Sir HENRY ROSCOE, F.R.S. Assisted by JOSEPH LUNT, B.Sc. Globe 8vo, 2s. 6d.

LESSONS IN ELEMENTARY CHEMISTRY, INORGANIC AND ORGANIC. By Sir H. E. ROSCOE, F.R.S. Sixth Edition, thoroughly revised, 4s. 6d.

A JUNIOR COURSE OF PRACTICAL CHEMISTRY. By FRANCIS JONES, F.R.S.E., F.C.S., Chemical Master in the Grammar School, Manchester. With a Preface by Sir H. E. ROSCOE, F.R.S. (Eighth Edition). Globe 8vo, 2s. 6d.

AN INTRODUCTION TO THE STUDY OF CHEMISTRY. By W. H. PERKIN, Jr., Ph.D., F.R.S., Professor of Organic Chemistry in the Owens College, Manchester, and BEVAN LEAN, D.Sc., B.A. (Lond.). Globe 8vo, 2s. 6d.

MACMILLAN & CO., Ltd., LONDON.

CORPORATION OF LONDON.

APPOINTMENT OF PUBLIC ANALYST.

Sale of Foods and Drugs Acts, 1875 to 1899.

The CORPORATION OF LONDON hereby Gives Notice that it will meet in the Council Chamber of the Guildhall, in the City of London, on Thursday, the 25th April, to APPOINT a PUBLIC ANALYST for the said City under the above Acts and the General Order of the Local Government Board, dated March 7th, 1900, in regard to the "Appointment of Public Analyst—Regulations as to Competency."

The remuneration will be at the rate of 10s. per analysis, the minimum remuneration to be on the basis of 400 analyses per annum, including water, such number to include samples of water and other articles that may be submitted by any Committees of the Corporation, or by the City of London Union, and, in addition, 10s. per sample for every sample of water or food, &c., analysed beyond the number of 400.

The Public Analyst must provide his own Laboratory, Chemicals, &c.

The Appointment will be subject to the approval of the Local Government Board.

Applications for the appointment (accompanied by copies of three testimonials) should be addressed "Town Clerk, Public Health Department, Guildhall," and delivered on or before the 18th March.

MONCKTON.

Guildhall, March 1st, 1901.

NORTHERN POLYTECHNIC INSTITUTE,

HOLLOWAY, LONDON, N.

The Governors are prepared to Appoint a PRINCIPAL. The salary offered is £500 per annum. Application must be made before March 30th, on forms which, together with detailed information, may be had on application to the undersigned.

Personal canvassing of the Governors will be regarded as a disqualification.

W. M. MACBETH,
Clerk to the Governors.

March 6th, 1901.

CHEMICAL ASSISTANTSHIPS IN THE GOVERNMENT LABORATORY.

The Principal is prepared to Appoint several ASSISTANTS in the GOVERNMENT LABORATORY. Applicants, who need not be members of the Civil Service, must have had a good Chemical training and be proficient in ordinary Mineral and Organic Analysis.

Salary, from £100 to £120 per annum.

For further particulars apply by letter to—

THE PRINCIPAL,
Government Laboratory,
Clement's Inn Passage,
Strand, W.C.

UNIVERSITY COLLEGE OF WALES,

ABERYSTWYTH.

PROFESSORSHIP OF CHEMISTRY.

The Council invite APPLICATIONS for the POST of PROFESSOR of CHEMISTRY at the above College.

Applications, together with testimonials, must be in the hands of the undersigned (from whom further particulars may be obtained) on or before Tuesday, March 19th, 1901.

T. MORTIMER GREEN, Registrar.

The Laboratory, Corporation St., Lancaster.

SPECIALITIES:—

COMBUSTIONS—C, H, and N (DUMAS).

FURFURAL DETERMINATIONS and the ANALYSIS AND DETERMINATIONS OF RADICALS IN CARBON COMPOUNDS, and other routine work necessary in Chemical Research.

Research work undertaken in Organic and Agricultural Chemistry, and other preliminary investigations for Chemical Experts, Scientific Investigators, College Professors, Manufacturers, &c. Work involving the use of large Experimental Digester and Vacuum Pans undertaken.

References, List of Charges, and other information on application.

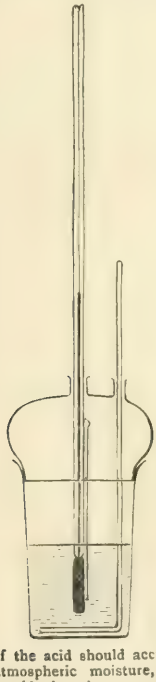
AN IMPROVED MELTING-POINT APPARATUS.

By F. W. STREATFEILD, F.I.C., and J. DAVIES.

In determining the melting-point of organic compounds, which melt at a temperature above 100° C., it is customary to use the well-known apparatus consisting of a thermometer suspended in a beaker of concentrated sulphuric acid, and provided with a glass stirrer.

Certain inconveniences are, however, experienced when employing this somewhat crude arrangement. Some of these are:—1. Annoyance from acid fumes when working at a high temperature. 2. Danger of projection of hot



acid, especially if the acid should accidentally boil. 3. Absorption of atmospheric moisture, and consequent weakening of the acid when the apparatus is not in use.

The drawbacks referred to are avoided by employing the little device shown in the accompanying sketch.

It consists of a light dome-shaped glass cover of such diameter that it rests lightly on the rim or flange of an ordinary narrow beaker. The cover is furnished with two narrow necks, one for the insertion of the thermometer (which is suspended from a retort stand), and the other for the admission of a glass stirrer.

The glass cover is raised by sliding it up the stem of the thermometer, in order to attach the melting-point tube, which is made to adhere to the thermometer by capillarity, induced by moistening the tube and thermometer with sulphuric acid.

It will be found that the cover forms an efficient condenser for the acid fumes, and practically protects the bath from atmospheric moisture.

The apparatus was kindly made for us by Messrs. A. Gallenkamp and Co., of Sun Street, Finsbury, E.C.

City and Guilds Technical College,
Leonard Street, Finsbury, E.C.

NOTE ON THE ESTIMATION OF HIPPURIC ACID.

By W. A. CATES, A.I.C.

The estimation of hippuric acid in urine can be conveniently effected by the method of Bunge and Schmiedeberg, in which the residue from the evaporated urine is treated successively with absolute alcohol, acetic ether, and petroleum ether. The hippuric acid so obtained is dissolved in hot water, and the solution evaporated to crystallisation. The crystals are transferred to a small weighed filter-paper, dried in the water-oven, and weighed. For every c.c. of the filtrate 0·0015 grm. is added.

The latter part of the process can be considerably shortened if, after the treatment with petroleum ether (which removes benzoic acid, oxy-acids, phenol, and fat), the crystalline residue be taken up in hot water and titrated direct with N/10 NaOH, using phenolphthalein as indicator. The end point is very satisfactory despite the fact that a certain amount of urinary pigment is always extracted along with the hippuric acid, while the results agree well with those obtained by the gravimetric process.

A standard solution of hippuric acid was made by dissolving 0·5 grm. pure hippuric acid in 100 c.c. water on the water-bath; 40 c.c. N/10 NaOH were then added, and, after cooling, the whole was made up to 200 c.c., and the excess of alkali estimated by titration with N/10 HCl, using two drops of 1 per cent phenolphthalein as indicator.

50 c.c. of this solution used 3 c.c. N/10 HCl, showing that 7 c.c. of the N/10 alkali had been used up. Theoretically 6·98 c.c. should have been saturated, reckoning that 1 c.c. of N/10 NaOH corresponds to 0·0179 grm. hippuric acid.

250 c.c. of the urine of a patient who had been taking piperazine quinate yielded:—

Gravimetrically	..	0·1891 grm. hippuric acid
Volumetrically	..	0·1895 ,, ,, ,,

In another case, 200 c.c. of urine ten days old, which had undergone ammoniacal fermentation, and therefore presumably contained but a trace of hippuric acid, was mixed with 50 c.c. (containing 0·125 grm. hippuric acid) of the above standard solution. There was recovered:—

Gravimetrically	..	0·131 grm. hippuric acid
Volumetrically	..	0·1268 ,, ,, ,,

Of the two processes, the volumetric is probably the more accurate, as with most urines sufficient urinary pigment would be extracted to weigh a few m.grms., whereas this would not affect the volumetric estimation.

Hydrocinchonine.—E. Jungfleisch and E. Léger.—A comparison of the two bases, hydrocinchonine and cinchonifine, establishes their identity. The differences apparently revealed at first disappear after a more thorough examination of hydrocinchonine. To procure hydrocinchonine, it is necessary to apply the treatment described in a former paper to cinchonine. In all cinchonines there is a very large proportion of hydrocinchonine, which decidedly modifies the properties of cinchonine itself.—*Comptes Rendus*, cxxxii., No. 7.

THE ESTIMATION OF PHOSPHORUS IN STEEL AND IRON.

By FRED. IBBOTSON and HARRY BREARLEY.

If one may judge from the number of inquiries respecting the estimation of $Am_3PO_4.12MoO_3$ by transforming the molybdenum contents of it into $PbMoO_4$, the operation has been appreciated in the best of all ways; that is, it has been tried.

Shortly after the publication of the method (Chem. News, lxxxii., 55), we were informed that when applied to pig-irons the results were low, and it was suggested that the graphite should not be filtered off until after the oxidation with permanganate. A day or two later we were otherwise informed, that although very satisfactory for steels, "in the case of pig-irons the $PbMoO_4$ method gave results nearly twice as great as the ordinary phosphomolybdate method." With this letter there came four samples of pig-iron, together with the phosphorus percentages as given in the first column of the following table. These had their phosphorus determined in two ways: (1) By filtering off the graphite, and (2) after oxidising with permanganate.

Analysis received. (Long method).	Graphite removed. Before.	After.
0·038	0·034	0·037
0·058	0·056	0·054
0·044	0·045	—
0·049	0·048	0·047

Steels containing 2 to 3 per cent of chromium frequently will not dissolve completely in nitric acid (1·20), even when digested with permanganate. On adding 5 c.c. dilute sulphuric acid (1 to 3) the reaction re-commences after a few seconds with a slight explosion, and is quickly ended. In such cases an additional 2 or 3 c.c. AmHO should be added before precipitating the phosphoric acid. The addition of a little hydrofluoric acid (Chem. News, lxxxii., 269), also clears away the insoluble portion. Perhaps the simplest of all expedients is to dilute the solution which will no longer attack the residue with about its own bulk of hot water; the reaction then re-commences with vigour.

On the few occasions when arsenic has been present in considerable amounts in the steel, and in a few other cases where it has been purposely added, we have not found it to be precipitated along with the phosphorus when the latter was separated rapidly by shaking. This observation has been repeatedly made by advocates of rapid precipitation processes.

There is a considerable demand in large steel-works laboratories for methods by which from twenty to forty estimations of a particular element can be made daily by one person. In relation to this fact, the $PbMoO_4$ process of estimating phosphorus cannot perhaps be considered rapid in comparison with some others, with which, however, we believe it to compare more favourably in point of accuracy. A single estimation to be trustworthy needs at least half-an-hour from the time the drillings are weighed out. A series of results, however, can be obtained in much less time proportionately; for example, thirty estimations have been made in a working day of seven hours by an experienced operator. The ability, however, to deal rapidly with a large number of samples in a systematic and intelligent way is a faculty possessed in greatly different degree by different persons. It also depends very considerably on the peculiar fitness of the apparatus for the operation. Both these considerations are usually overlooked by incredulous persons who think the possibilities of most rapid processes are exaggerated.

The excuse for the following particulars, if they should appear commonplace, is that the desired speed cannot be attained except by attending to them. The reader is supposed to be familiar with the process.

Taylor pattern flasks holding about 300 c.c. are very suitable for use throughout the estimation. The shaking after the addition of the Am_2MoO_4 reagent can be omitted, as each sample will stand at least half-an-hour on the hot plate before its turn comes to be filtered. A smooth funnel $3\frac{1}{4}$ inches in diameter allows the whole of the solution and precipitate to be at once poured on the filter. The flask is washed out twice, and then the filter twice more, each time allowing all the solution to run through. With pulp filters the filtration is very rapid, and the washing particularly effective, since the precipitate and pulp both lie at the throat of the funnel; a wash-bottle having no jet on the delivery tube is used. The yellow precipitate is conveniently dissolved by strong ammonia dropped from a burette. The mixture of ammonium acetate and chloride being kept hot, and the filter being washed with hot water, allows the final precipitation to be made without any further heating. When all are precipitated as lead molybdate the filtration and washing are carried out as before. On each occasion so many filters are used as keep the time fully occupied; more than this invites confusion. The filters are transferred to marked porcelain crucibles, and placed six or eight at a time straight into the hot muffle if needs be. Under this very severe treatment the precipitate never spatters.

It needs little effort to realise that to go through these operations unaided thirty times a day is very hard work. The toil may be lessened in the following manner, but the speed is not increased much, and it is easier for the final precipitate to contain accidental impurities:—After dissolving the yellow precipitate in ammonia and washing the filter, pour the solution at once into 50 c.c. of an acetic acid solution of lead acetate (PbA_2 crystals 8 grms., acetic acid B.P. 400 c.c., all made up to a litre). The white precipitate formed is a mixture corresponding to $Pb_3(PO_4)_2+24PbMoO_4$, and contains 0·644 per cent phosphorus. It is ignited as before, and weighed.

RADIO-ACTIVE MATERIAL.

By F. GIESEL.

According to the publication in No. 16 of the *Berichte* on "Radio-active Lead and Radio-active Rare Earths," it appears that K. A. Hofmann and E. Strauss are of opinion that they have obtained the above elements absolutely pure, but in the radio-active state.

It is in this connection that I wish to observe that, with the present knowledge of radio-active material, it will be scarcely possible to detect chemically, amongst the metals separated from about 100 grms. of mineral, an impurity so slightly active, which enables them to affect the photographic plate within twenty-four hours. It is therefore not surprising if we find most of the separated products of radio-active minerals, also lead and the rare earths, more or less active.

Commercial uranium salts also show activity, which does not necessarily arise from uranium. Curie would not have succeeded in distinguishing between radium and barium had not tons of pitch-blende of the highest activity been worked up. Even by working on these lines it has not yet proved possible to learn anything with certainty about polonium and actinium.

The active material thus far obtained, not once pure, but only purified, exhibits collectively a far more intense activity than the active metals of Hofmann and Strauss. But radium, for example, would call forth a display of this activity, even when the impurity present lies far beyond the reach of detection by sulphuric acid.

The chief difficulty of separation and detection of radio-active material lies in the generally rare occurrence of minerals of known activity containing uranium and thorium.

Insoluble sulphates, such as those of barium and lead, carry with them very readily active material, as Debierne has demonstrated in the case of actinium, and I myself with uranium nitrate. Consequently, barium radium sulphate frequently contains differently active radium material, which is discovered on purification in the sulphuretted hydrogen and ammonia precipitations. Although this purification was preceded by addition of 2 kg. of radium barium bromide, yet after the radium was practically completely removed by crystallisation, and the barium mostly so, a slight precipitate from the mother-liquor was again obtained with ammonia, which was very strongly active. When the latter was dissolved in hydrochloric acid, and sulphuretted hydrogen passed for some time into the solution, the result obtained was first a yellowish, then a dirty brown precipitate, which when dried weighed 3 m.grms., and was as active as preparations rich in radium. The rare earths, afterwards precipitated as oxalates, had a relatively weak action, but giving forth distinctly the phosphorescent glow.

The presence of polonium appeared to predominate, for the rays exhibited the same high power of absorption and similar characteristics in the magnetic field. This product, after one month, as yet shows no diminution in the intensity of its radiation.

I have now attempted, but in vain, to detect in 2 m.grms. of the substance, bismuth as oxychloride. On the contrary, sulphuric acid produced a precipitate which pointed to lead, but was much less active than the ammonia precipitate which followed next. The filtrate from this, when evaporated, was also active. But, strangely enough, the total action of all the separate products did not amount to the activity of the original 2 m.grms.

Even when greatly enriched products of large quantities of mineral are at one's command, yet, for the reasons given above, chemical tests are useless.

I should further like to mention an observation of Walkhoff, viz., that radium rays cause skin-wounds as do Röntgen rays.

I have applied for two hours to the inner surface of the arm 0·27 grm. of radium-barium-bromide in a double celluloid capsule. At first only a faint redness appeared; after two to three weeks much inflammation was caused, and finally, the outer skin came off, after which it quickly healed.

I noticed a similar action of the rays on living plant leaves; the chlorophyll disappears, and the leaf gradually acquires an autumnal yellow till the colour of the affected spot is brown. This action appears to depend upon molecular re-arrangement which causes a decay in the cell; intense radium rays similarly affect salts, glass, paper &c., the latter becoming brown and brittle.—*Berichte der Deutschen Chemischen Gesellschaft*, 1901, No. 19.

ON CERIUM.

By W. MARCKWALD.

The often repeated statements in present day literature, that cerium consists of at least two elements, have led me to publish herewith a research undertaken by me some time ago with the intention of finally deciding this important question. In this case, as in many other paths, laboratory experiments are superseded by technical methods of working; I will therefore describe the course I adopted, instead of merely stating the results obtained. I started with raw commercial cerium carbonate (50s. per 100 kg.), of which 250 kg., mixed into a paste with water (to avoid frothing over), were dissolved in a just sufficient quantity of raw hydrochloric acid. The heavy metals present were then precipitated by addition of potassium sulphide solution, and from the clear decanted solution in large wooden vessels the cerium was partially precipitated by means of alkaline chloride of lime solution (90 per cent of the required chloride of lime). The deep yellow precipitate was pressed and washed. By going carefully to work this product now contains but little didymium, but relatively much (more than 2 per cent) lanthanum and yttrium. By washing with dilute nitric acid, part of the didymium, &c., was removed. By dissolving in concentrated nitric acid, cerium nitrate is obtained (with evolution of chlorine), from which solution ceriammonium nitrate could be almost quantitatively produced by neutralising with ammonium nitrate. But as the two ceriammonium nitrates crystallise with equal facility, and do not dissociate upon addition of foreign substances, the total solid after being pressed was mixed with hot oxalic acid solution and a little hydrochloric acid, whereupon it is quickly converted into heavy oxalate (with evolution of cabonic acid), from which the remaining impurities, iron, calcium, &c., can be easily removed by washing. The oxalate was treated with great excess of soda, and the washed carbonate dissolved in nitric acid. The completely colourless solution still distinctly showed the absorption bands of didymium in thick films; but not by observation in the eprouvette. This proves that a strongly dispersing system of prisms is not suited to the observation of the absorption spectra, because the weak absorption shadows of dilute solutions are easily overlooked, while a direct vision spectroscope shows the absorption bands in the form of deep black lines, with the advantage of being able to see the whole spectrum simultaneously. One quickly learns to identify the spectrum from the general character of the appearance, without being obliged to measure laboriously the individual lines.

The nitrate solution, treated with ammonium nitrate and evaporated, yielded the salt $Ce_2(NO_3)_6,xNH_4NO_3+Aq$, crystallising in silky shiny needles 20 c.m. long, also the salt $Ce_2(NO_3)_6,3NH_4NO_3,10Aq$, crystallising in large rhombic plates. (Only the latter served for fractional crystallisation).

Both salts are only slightly hygroscopic, and crystallise very easily by the retention of didymium in the mother-liquor. The yttrium earths and lanthanum remain obstinately attached to the salt, a phenomenon which I have also observed upon re-crystallisation of the cerium salt. This double nitrate was now subjected to a systematic fractional crystallisation, and in the course of seven months more than two hundred crystallisations were carried out. Widely removed fractions were tested by Auer's basic method, a part converted into the salt of the dioxide and treated with hot water, but all fractions thus obtained were not in the least distinguishable from cerium preparations which could have been obtained with sufficient care according to the older methods. Also the illuminating power of the incandescent bodies prepared from them was the same. At the same time I may mention that none of the fractions gave a pure white cerium dioxide upon heating; the oxide showed instead a pale yellow glow. Again, the means recommended by Wyrouboff and A. Verneuil for purifying cerium salts gave a cerium nitrate, which upon heating left a yellowish oxide, when reducing mediums were kept away (for which a white heat was necessary). According to this method no preparation free from didymium can be obtained. A little didymium is invariably precipitated with the least basic fractions.

As regard lanthanum and the yttrium elements, these were undoubtedly removed after three crystallisations. In working with compounds containing as much as 4 per cent yttrium, erbium, and above all ytterbium, this method is of no use.

For removal of the latter, the freshly precipitated oxalates are dissolved in strong potash solution (soda is less suitable on account of the less solubility of sodium oxalate). In accordance with published accounts, all the elements of the cerium and yttrium groups dissolve readily in concentrated solutions of the alkaline carbonates. If this solution is poured into a large quantity

of hot water, the carbonates of the elements of the cerium group are precipitated, while those of the yttrium group remain in solution. They can be precipitated as oxalates by acidifying or as hydrates by strong potash, and then further purified by conversion into the sodium double sulphate. (It is incomprehensible why hitherto potassium sulphate, which is eight times as dear, has been used for this purpose). The solubility of the yttrium elements in ammonium carbonate renders it less suitable for the separation. Further, it is necessary by the potassium carbonate method to decant quickly after the deposition of the cerium carbonates if loss is to be avoided.—*Berichte der Deutschen Chemischen Gesellschaft*, 1901, No. 19.

ON THE SEPARATION OF FERRIC CHLORIDE IN AQUEOUS HYDROCHLORIC ACID FROM OTHER METALLIC CHLORIDES BY ETHER.

By FRANK N. SPELLER.

A METHOD for the "Separation of Iron from the Elements by a New Process" was outlined by J. W. Rothe in 1892 (Abstract in CHEMICAL NEWS, vol. lxvi., p. 182), founded on the fact that ferric chloride in aqueous hydrochloric acid solution, when shaken with ether and allowed to settle, remains in the ethereal solution, whereas the other chlorides are almost entirely insoluble, and are retained by the lower aqueous solution.

In endeavouring to apply this method to the analysis of nickel-steel, difficulties were met with, which led the writer to conduct certain experiments to arrive at a better understanding of the conditions under which the separation of ferric chloride takes place.

A solution of ferric chloride containing 0·8 grm. of iron in 100 c.c. HCl (1·193 sp. gr.) was made up. 10 c.c. of this solution was run into a suitable burette, and an excess of ether (20 c.c.) added. The liquids were well shaken together for two or three minutes, then allowed to stand for about thirty minutes until entirely separated at a temperature from 17° to 18° C. A portion of the upper solution was then removed and the iron therein determined.

Similar experiments, varying the specific gravity of the acid, gave the results (calculated to per cent of total iron) shown in Table I.

TABLE I.—*The Deportment of Ferric Chloride with Ether and Aqueous Hydrochloric Acid of the following Strengths.* (*Ferric Chloride contains* 0·8 *grm. Iron in* 100 *c.c.*).

Specific gravity, aqueous hydrochloric.	Per cent of total iron in— Aqueous solution.	Ethereal solution.
1·193	99·0	1·0
1·164	97·5	2·5
1·158	92·84	7·16
1·151	74·0	26·0
1·123	7·2	92·8
1·115	2·4	97·6
1·111	2·0	98·0
1·105	1·95	98·05
1·103	1·95	98·05
1·091	3·3	96·7
1·0825	10·0	90·0
1·069	47·5	52·5
1·06	87·0	13·0
1·0525	98·4	1·6
1·0424	99·6	0·4

Evidently, hydrochloric acid of a specific gravity from 1·100 to 1·115 allows of the most complete separation of iron under the above treatment.

Table II. includes results obtained by varying the quantity of iron in solution and, in some cases, the volume of HCl (1·105) in which the ferric chloride was dissolved. It was ascertained by preliminary experiments that 5 c.c. of ether was necessary for the separation of each decigrm. of iron where the volume of the HCl solution does not exceed 15 c.c.

TABLE II.

Grm. of iron in solution.	Volume aqueous hydrochloric solution.	Residual iron in aqueous solution after shaking with ether.
	C.c.	Grm.
0·08	18	0·00155
0·3	15	0·00151
0·3	20	0·0051
0·3	25	0·0067
0·2	10	0·00204
0·3	10	0·00096
0·5	10	0·00082

In using this principle for the first time in the analysis of copper-nickel mattes, in 1897, it was noticed that considerably more iron was left in aqueous solution when dealing with mattes low in that metal. Sufficient work has not been done to explain the fact, but a concentration (of about 1 grm. of iron in 20 c.c.) appears to be necessary to the most complete extraction.

Nickelous, cobaltous, cupric, manganous, chromic, and aluminium salts in solution in aqueous hydrochloric acid (1·105), when shaken with ether, are insoluble in the ethereal solution. Chromic acid, which may be present with the metallic chlorides, appears to be quite soluble in ether, but is quickly reduced by the latter, and separates in the lower (aqueous) solution a few minutes after shaking.

A volume of 10 c.c. aqueous hydrochloric solution of known strength was shaken in a burette with 15 c.c. of anhydrous ether (re-distilled with $CaCl_2$), and after standing for about thirty minutes at a temperature of 17—18° C., readings at the top of the aqueous and ethereal solutions were taken. The volume of ether in the upper solution subtracted from that originally used gave the apparent solubility, calculated in Table III. to per cent of original volume of aqueous hydrochloric solution.

TABLE III.—*Apparent Solubility of Ether in Aqueous Hydrochloric Acid* per se, *and in the presence of certain Metallic Chlorides. Temperature*, 16—18° *C.*

Spec. grav. Aqueous hydrochloric solution.	Cubic centimetres of ether dissolved by 100 c.c. of— Aqueous HCl *per se*.	Aqueous HCl with Fe_2Cl_6.	Aqueous HCl with $CuCl_2$.	Aqueous HCl with $CoCl_2$.	Aqueous HCl with $NiCl_2$.
1·177	140	139	131	144	107
1·151	—	89	94·2	102·5	83·3
1·140	89	71·5	79·1	—	—
1·131	—	52·8	65·7	72	52
1·123	64	43·3	54	—	—
1·111	—	—	40	—	—
1·115	—	35	—	46	33
1·103	30	26·1	—	33·8	25
1·093	—	21·5	26·5	25·5	21
1·087	—	19·5	—	—	—
1·075	19	16	18·4	—	—
1·063	15·5	13·6	15·6	16·8	14
1·055	14·4	12	14	14	14

Ether, while dissolving 3 per cent of its volume of water, has a very slight affinity for the hydrochloric acid; 10 c.c. of a solution of ether which had been well shaken with an equal volume of aqueous HCl (1·1033) was found to contain only 0·0019 grm. HCl, hence the apparent solubility given in Table III. may be said, with very small error, to have a very simple relation to the real solubility, which it approaches very closely under similar conditions.

In analytical work, the writer has applied this principle in the following manner:—A solution of the chlorides of the metals is obtained to which sufficient concentrated nitric acid is added to completely oxidise the iron present.

It is then evaporated in a 6-oz. wide-necked Erlenmeyer flask on a flat iron plate, the temperature of which can be very easily controlled by rows of small gas jets underneath; this is continued until a thick syrupy consistency is obtained, then taken up with the least possible quantity of hydrochloric acid, 1·105 *specific gravity*.

The solution thus treated is transferred to a suitable separatory cylinder, with a well-ground stopper and tapered out to a rather small orifice below the tap. Ether is added, about 5 c.c. for every decigrm. of iron in solution, and the liquids shaken together for three or four minutes, after which the cylinder is placed in an upright stand. At the expiration of ten minutes, the lower (aqueous) solution may be drawn off; it being quite easy to separate the two liquids to the last drop, owing to the marked contrast in colour.

The residual iron in the aqueous solution should be very small, and in most cases—when in the presence of copper, nickel, and cobalt—may be removed by a single ammonium precipitation, or by adding more ether and again shaking in the same cylinder in which the first separation was performed, when all but a bare trace of iron will be removed.

Most of the above work was carried on from time to time in the Chemical Laboratories of the School of Science, Toronto University, where the interest manifested in the subject by Dr. W. H. Ellis, Professor of Applied Chemistry, gave the writer the advantage of many helpful suggestions.

ON THE DOUBLE CHLORIDES OF URANYL AND THE ALKALINE METALS; AND THE HYDROCHLORATE OF CHLORIDE OF URANYL.

By J. ALOY.

Compounds of Chloride of Uranyl and the Alkaline Chlorides KCl *and* NaCl.

The double chlorides of uranyl and the alkaline metals have up to the present only been prepared in the hydrated state by the evaporation of a suitable mixture of the constituent parts. I have succeeded in obtaining them in the anhydrous state by the direct action of the fumes of the chloride UO_2Cl_2 on the alkaline chlorides.

In a tube of combustion glass arranged over a gas-furnace, I first placed a quantity of non-pyrophoric oxide UO_2, then a series of boats containing the well-dried alkaline chloride; I then passed a current of pure dry chlorine gas through the tube. As soon as the air was completely driven out I heated the part of the tube where the boats were to redness, and gradually extended the heat to the oxide UO_2. The chlorine soon combines with the oxide, which takes a yellow colour on account of the formation of chloride of uranyl; when the transformation is complete the current of gas is increased, and the temperature raised; the fumes of the chloride of uranyl are brought into contact with the alkaline chloride, with which they combine, forming a fusible mass consisting of the double salt.

Chloride of uranyl being very slightly volatile, I was compelled to use a considerable excess of the oxide UO_2 to obtain a definite compound.

The double chlorides of uranyl and the alkaline metals are of a golden-yellow colour; they melt at a red heat without giving off any fumes. They are very soluble in water, and dissolve with considerable ease in aqueous alcohol.

Analysis.—The composition of these double salts was established by determining the weight of UO_2Cl_2 combined with the chlorides, KCl and NaCl, and then estimating the uranium and the total chlorine in aqueous solution.

Double Chloride of Uranyl and Potassium.

	I.	II.
Weight of KCl used	0·622	1·301
Weight of combined UO_2Cl_2; found ..	1·38	2·80
Weight of combined UO_2Cl_2; theoretical for $UO_2Cl_2.2KCl$	1·4	2·9

In 100 parts of material dissolved:—

	Found. I.	Found. II.	Theory.
Uranium as U_3O_8	48·9	48·2	48·7
Chlorine as AgCl	28·3	29·0	28·9

Double Chloride of Uranium and Sodium.

	I.	II.
Weight of NaCl used	0·512	0·601
Weight of combined UO_2Cl_2; found ..	1·44	1·82
Weight of combined UO_2Cl_2; theoretical for $UO_2Cl_2.2NaCl$..	1·5	1·9

In 100 parts of material dissolved:—

	Found. I.	Found. II.	Theory.
Uranium as U_3O_8	51·8	52·0	52·1
Chlorine as AgCl	30·9	31·0	30·8

The above figures correspond with the formulæ $UO_2Cl_2.2KCl$ and $UO_2Cl_2.2NaCl$. The alkaline earthy chlorides do not combine with chloride of uranyl under the same conditions.

Hydrochlorate of Chloride of Uranyl, $UO_2Cl_2.HCl,2H_2O$.—Chloride of uranyl is easily soluble in water, and this solubility is increased by the presence of hydrochloric acid. A saturated hydrochloric solution of this salt, made at 15°, deposits crystals of hydrochlorate of chloride of uranyl when cooled down to −10°.

These crystals are very brillant, and decompose with rapidity, giving off abundant fumes of hydrochloric acid when exposed to the air.

The analysis of this salt is difficult on account of its great instability; to effect it I adopted the method devised by M. Recoura. After forming a fairly large quantity of the hydrochlorate in a test-tube, I added strongly baked kaolin, and then inverted the tube; the salt, thus freed from the mother-liquor, was separated from the kaolin by cutting with a file, and then placed as rapidly as possible in a closed tared glass tube. I then dissolved the substance in water, and estimated the uranium and the chlorine.

I found for 100 parts of material:—

	Found. I.	Found. II.	Found. III.	Theory for $UO_2Cl_2.HCl,2H_2O$.
Uranium as U_3O_8 ..	56·1	56 5	57·0	57·7
Chlorine as AgCl ..	26·5	26·0	—	25·6
Water, by difference	8·8	8·9	—	8·6

These figures correspond to the formula $UO_2Cl_2.HCl.2H_2O$. According to M. Engel's law each molecule of HCl carries two molecules of water.—*Bull. Soc. Chim.*, Series 3, vol. xxv., No. 3.

"The Scottish Electrician."—Electricians are to be congratulated upon the issue of a new journal, *The Scottish Electrician*. Considering the present magnitude of electrical science, it is not surprising that there should be a desire to have a journal of this class published in Edinburgh. For the present it is proposed to issue it monthly, but a more frequent issue is contemplated in the near future if circumstances justify the step. If the high standard of matter that is to be found in the first number is maintained, we predict a very large measure of success for the new venture. The offices of publication are at 37, Queensferry Street, Edinburgh.

CONCERNING LIPASE, THE FAT-SPLITTING ENZYME, AND THE REVERSIBILITY OF ITS ACTION.*

By J. H. KASTLE and A. S. LOEVENHART.

(Concluded from p. 115).

The Reversibility of the Action of Lipase (continued).

THE first distillate from flask (B), viz., that obtained in the control experiment, was treated in exactly the same manner as that from flask (A), *i.e.*, the first distillate was distilled a second time, and the first 5 c.c. of distillate, No. 2, collected. This second distillate had only a trace of the odour of ethyl butyrate, and when poured into water it dissolved without turbidity, and no ethereal oil separated on standing. The conduct of the second distillate from (A) and (B) towards lipase was also tested. Tubes were prepared containing 4 c.c. of water, 1 c.c. of enzyme, 0·1 c.c. toluene, and 0·26 c.c. of the second distillate from (A) or (B).

The following results were obtained :—

With hepatic extract; time, fifteen minutes; temperature, 40° C.

	N/20 KOH required.
	C.c.
(1) 2nd distillate (A)	0·65
(2) ,, ,, (A)	0·70
(1) ,, ,, (B)	None.
(2) ,, ,, (B)	0·05

With pancreatic extract; time, fifty minutes temperature, 40° C.

	N/20 KOH required.
	C.c.
(1) 2nd distillate (A)	0·65
(2) ,, ,, (B)	None.

Control experiments on the second distillate from (A) using the boiled enzyme, showed no hydrolysis even after long standing. These results prove the presence of an ethereal salt in the second distillate from (A), but none, or at best only traces thereof, in the second distillate from (B).

From these experiments it would seem that lipase is reversible in its action upon ethyl butyrate at least.

The fact that lipase is reversible in its action will doubtless afford an explanation of a number of somewhat obscure physiological processes. For example, Schmiedeberg (*Arch. f. Exp. Path. and Pharm*, 1881, xiv., 379), has shown that the kidney of the pig is capable of splitting hippuric acid into benzoic acid and glycocol, and that it is also capable of effecting the synthesis of hippuric acid from these substances. He attributes the splitting of the hippuric acid to a soluble enzyme which he calls histozyme, and which he succeeded in extracting from this organ, and also from the liver. On the other hand, he believes the synthesis of the hippuric acid to be due to the absence of histozyme, and to be induced by some other agency. According to him, the processes of decomposition and synthesis going on in the living organism, are brought about by entirely different agencies. The formation of hippuric acid being a reversible reaction, however, it would seem more probable that the histozyme simply has the power to hasten the establishment of the equilibrium between benzoic acid and glycocoll. According to this view, if benzoic acid and glycocoll are passed through the kidneys, a certain quantity of hippuric acid would be built up under the influence of the histozyme, whereas if hippuric acid itself were passed through this organ a certain quantity of it would be hydrolysed by the histozyme. The fact that lipase can effect the synthesis of an ethereal salt, like ethyl butyrate, will doubtless throw some light on two exceedingly interesting and important physiological processes, viz., the absorption of fats, and the ripening of fruits. Without entering minutely into the physiological aspects of fat-absorption, it may be observed in passing that serious objections have been urged against the various theories which have been put forward from time to time to account for the absorption of fats in the intestinal tract. It has been pointed out by Rachford (*Journ. Physiology*, 1891, xii., 92), that the pancreatic juice is capable of hydrolysing all the fat of a fatty meal in the period of pancreatic digestion. In the living intestine therefore the hydrolysis should be complete, inasmuch as the removal of the products of the hydrolysis by absorption prevents the establishment of equilibrium. On the other hand, the products of the hydrolysis in their transition through the epithelial cells come in contact with a lipolytic enzyme, the presence of which in these cells has been demonstrated in the above (see *ante*, p. 64). The lipase now finds itself in contact with only fatty acid and glycerin, and hence in acting catalytically to bring about the chemical equilibrium, it effects the synthesis of a fat. This would offer a satisfactory explanation of the presence of fat granules in these cells. As the fatty acid and glycerin diffuse out of these cells through the basement membrane, the fat in these cells would speedily disappear were it not that these substances were constantly being absorbed from the lumen of the intestine. When absorption ceases, however, the fat present in the epithelial cells is at once hydrolysed by the lipase present. This hydrolysis is in all probability complete for the reason that the products of the hydrolysis, viz., glycerin and fatty acid, are being constantly removed by diffusion. According to this view, therefore, no fat ever enters or leaves the epithelial cells as such, but as fatty acid and glycerin.

These two substances then enter the central lacteal, where equilibrium is again established, and there is a large production of fat. This view derives support from the fact that fats and soaps exist side by side in the blood (Hoppe Seyler, *Ztschr. Physiol. Chem.*, viii., 503), in the serum of which Hanriot (*Comptes Rendus*, 1896, cxxiii., 753), has demonstrated the presence of a very powerful lipolytic enzyme. It is our intention to look for a lipolytic enzyme in the lymph and lymphatic tissue when the opportunity presents itself.

As is well known, lipase is by no means confined to the animal organism. It has been found by numerous observers in the resting and germinating seeds of various plants, but hitherto it has been looked upon as being concerned solely with the splitting of fats, especially during the period of germination.

On the other hand, Sachs ("Plant Physiology," 1887, p. 347), long ago pointed out that "the presence of fats in the seedling can only be explained by assuming that glycerin and the fatty acids travel from cell to cell, and are continually becoming re-united for the formation of fat," and quite recently Charabot (*Bull. Soc. Chem.*, [3], xxiii., No. 5), has also reached the conclusion that, in the plant, ethereal salts results from the direct action of the free acids on the alcohols. In view of these facts, and of the results described in the above, it would seem logical to conclude that lipase can effect the formation as well as the decomposition of fats and ethereal salts in the plant, and that this ferment plays an important part not only in the utilisation and translocation of these important reserve materials, but also in the storing up of these substances in the seed and fruit.

Summary of Results.

The results reached in this investigation may be briefly summarised as follows :—

1. It has been found that ethyl butyrate is so easily hydrolysed by lipase as to make it a very useful substance in the investigation of a number of problems connected with the chemical action of this enzyme.

2. By means of ethyl butyrate it has been possible to prove the presence of lipase in a number of organs and

* From the *American Chemical Journal*, xxiv., No. 6.

tissues in the animal organism, notably in the liver, stomach, and small intestine.

3. It has been shown that lipase is almost completely removed from its solutions by repeated filtration at ordinary pressure.

4. It has also been shown that lipase is a much more stable enzyme than has hitherto been supposed.

5. It has been shown that animal lipase hydrolyses ethereal salts most rapidly at 40° C., and that at 65° to 70° C. the enzyme is destroyed

6. The conduct of lipase towards a few members of an homologous series of ethereal salts has been studied. It has been found that the stability of these ethereal salts towards lipase decreases with increase in molecular weight of the combined acid. The converse of this was found to be true for the hydrolysis of these ethereal salts by acids.

7. The effect of about twenty of the commoner antiseptics on lipase has been studied. By far the greater number of these substances have been found to exert a harmful effect on the enzyme. This was found to be particularly true of sodium fluoride and hydrofluoric acid and acids generally.

8. A study of the kinetics of the reaction has given the following results :—

First the velocity of the reaction is not proportional to the active mass of the ethereal salt. Secondly, the velocity of the reaction is nearly proportional to the concentration of the enzyme. Thirdly, the reaction is incomplete. This holds for all ordinary concentrations of the enzyme and the ethereal salt. With very concentrated or energetic extracts of the lipase or with very small amounts of ethereal salt the hydrolysis certainly approaches completion. Finally, the coefficient of velocity as calculated according to the equation for a reaction of the first order, is not constant, but shows a regular falling off as the reaction proceeds.

9. By means of lipase we have effected a synthesis of ethyl butyrate from butyric acid and alcohol, thereby proving that the hydrolysis of an ethereal salt as effected by this enzyme is a reversible reaction. Finally, the bearing of this result on fat absorption and the storing up and translocation of fatty reserve material in the plant has been briefly discussed in the above.

SOME PRINCIPLES AND METHODS OF ROCK ANALYSIS.*

By W. F. HILLEBRAND.

(Continued from p. 113).

VI. *Silica, Separation from Alumina, &c.*

Alternative Methods of Decomposition.

Preliminary Remarks.

THE practice of separating alumina, &c., by the usual methods, after first attacking the rock powder by hydrofluoric and sulphuric acids—silica being estimated in a separate portion — while attractive in principle, was abandoned by the writer after fair trial, owing to the disturbance sometimes occasioned by incomplete expulsion of fluorine, and to a less degree by the presence of sulphates instead of chlorides. With exception of the comparatively few analyses made thus, the sodium-carbonate method has always been employed. In the case of rocks rich in fluorine strict accuracy would require the separation of silica to be made as in the Berzelian method for fluorine estimation (see footnote, p. 128), but in practice it is not often necessary to resort to this tedious procedure, since the amount of fluorine is usually small, and it can by no possibility cause a loss of much more than three-fourths its own weight of silica by volatilisation as silicon fluoride when the sodium-carbonate fusion is evaporated directly with hydrochloric acid. Probably the loss is less, since some fluorine perhaps escapes as hydrofluoric acid. However this may be, the error is of comparatively slight importance, since it attaches to the constituent always present in greatest amount.

Various fluxes other than alkali carbonates have been recommended for breaking up silicates insoluble in ordinary acids, such as lead and bismuth oxides, lead carbonate, borax, and boric oxide. Professor Jannasch and his pupils have been especially active of recent years in this line of work, as evidenced by their numerous published papers. One of the advantages these fluxes possess over the alkali carbonates is their removability after serving their purpose, thus allowing the various separations to be made more perfectly and without the annoying interference of several grms. of foreign fixed salts, which are most troublesome in that part of the analysis devoted to the separation of silica, alumina, iron, lime, and magnesia.

Another of their advantages is that with some of them it is possible to estimate in one portion the alkalis, in addition to those constituents usually determined in the silica portion. Where the material is limited, as it so often is in mineral analysis, this is a most important advantage, sufficient to outweigh all possible objections; but in rock analysis, where the supply of material is usually ample, it is rarely worth considering. A still further point in their favour is that it is probably more easy to obtain them entirely free from fixed impurities than an alkali carbonate.

There are, however, objections to their use. With some of them an extraordinary amount of time must be devoted to grinding the mineral to an impalpable powder, and the flux itself may need considerable hand pulverisation. Once introduced, they must be removed before the analysis can be proceeded with, and this removal takes much time and is always a possible source of error.

In mineral analysis these objections are entitled to far less weight than in rock analysis, since the object sought —usually the deduction of a formula—warrants the expenditure of much time and painstaking care. Finally, it has been found that one or more of these fluxes are not available for altogether general use, since certain minerals do not fully succumb to their attack under simple conditions, as andalusite with boric oxide, and others with lead oxide (Jannasch). Therefore however well adapted one or the other of these methods may be for the analysis of homogeneous minerals, it is very improbable that the vivid anticipations of Professor Jannasch, to the effect that the boric-oxide method will soon supersede the alkali-carbonate-fusion method in rock as well as in mineral analysis, will be speedily realised. Nevertheless, the boric-oxide-fusion method, owing to its evident merit, will be described in detail after brief reference to a means of bringing refractory silicates into solution without employing any solid reagent.

Decomposition of Refractory Silicates by Hydrochloric Acid under Pressure.

Jannasch (*Ber. Deutsch. Chem. Gesell.*, 1891, vol. xxiv., 273, and *Zeit. für Anorg. Chem.*, 1894, vol. vi., p. 72), pours upon the finely ground rock powder contained in a platinum tube of about 26 c.m.³ capacity a somewhat diluted hydrochloric acid (4 acid to 1 water), places over the open end a cap which does not hermetically close the tube, inserts the latter in a larger one of potash glass likewise partially filled with the diluted acid, seals the glass tube, and places it in turn in an inclined position in a steel Mannesmann tube containing ether or benzine to equalise the pressure, and heats to any desired temperature up to 400° C.

The chief drawback seems to be a somewhat incomplete decomposition, doubtless due to the necessarily inclined position of the tube, which causes the powder to collect at the lower end, and thus renders decomposition less complete than if the material were spread evenly throughout the length of the tube. Further, the acid

* *Bulletin of the United States Geological Survey*, No. 176.

strongly attacks the platinum unless the air in both the platinum and the glass tubes is replaced by carbon dioxide. Even when this is done, several m.grms. of platinum are found in the silicate solution.

Nevertheless, to those possessing the necessary platinum and steel tubes the method can render efficient service in special cases when economy of material is imperative.

*The Boric Oxide Method of Jannasch and Heidenreich.**

Preparation of the Boric Oxide.—This demands, if the alkalis are to be estimated in the same portion as silica, &c., an absolutely alkali-free boric acid, which can be prepared by two or three re crystallisations of a good commercial article. The purified crystals are dehydrated and fused in a large platinum crucible. This is then suddenly cooled to cause the anhydride to crack into pieces of a size convenient for powdering, which are to be kept in a tight glass and powdered as needed, since the anhydrous oxide is hygroscopic.

Treatment of Easily Decomposable Silicates.—To this flux Jannasch and Heidenreich find that nearly all silicates readily succumb over the ordinary blast-lamp. The fusion is made in a large crucible holding 40—65 c.m.^{3}, and the proportion of flux to be used is gauged according to the nature of the silicate, ranging from 3 to 8 and more parts to 1 of mineral. This last must be finely powdered, especially the most resistant, the authors recommending the expenditure of one-half to one hour's time for the grinding of one-half to 1 grm. of powder. A low burner heat is applied for five to ten minutes till water is expelled, which is then gradually increased till the gas is fully turned on. Bubbling and rising in the crucible is prevented as far as possible by using a short platinum rod which does not reach above the edge of the crucible. When the mass has been in quiet fusion for a time in the covered crucible the blast-flame is applied. The average duration of the entire operation is twenty to thirty minutes, but depends much on the character of the mineral.

Treatment of Refractory Silicates.—For those minerals which, like andalusite, cyanite, and topaz, are not fully decomposable by the heat of the ordinary blast-flame, Jannasch and Weber (*Ber. Deutsch. Chem. Gesell.*, 1899, xxxii., p. 1670), use a flame fed by oxygen instead of air. The blast-lamp, of 2½ m.m. opening, is supplied with gas from at least five or six ordinary gas-cocks, and the flame is made broad and free from luminosity. The mineral having been first heated as above described, but with a much larger proportion of flux—as high as 30 to 1—a few grms. additional of boric oxide are added and the oxygen-blast is applied till, in ten or fifteen minutes, the fusion is as transparent as glass.†

Further Treatment after Fusion.—From this point the further treatment is the same in both cases, and as modified by Jannasch and Weber (*loc. cit.*) is as follows:

The hot crucible is cooled in cold water, and the contents are turned into a very large porcelain or platinum dish, to which, after covering with a glass, a saturated solution of hydrochloric acid gas in methyl alcohol is added.‡ The cover being then removed, the liquid is heated to boiling over asbestos board by an inch-high flame, stirring constantly, or it is left without attention over a lower flame or on a water-bath heated short of boiling. The crucible is cleansed in a similar manner, and its contents are added to the dish. In ten to fifteen minutes, with occasional addition of the methyl chloride, solution is complete, and the liquid is then boiled down to a small volume and evaporated to dryness on the bath. The residue is then digested on a bath at 80° to 85° C. three or four times in succession, with the ether solution, in order to remove the last traces of boron as boric ether. Care should be taken to wash down from the sides of the dish, with methyl-chloride solution, the boric acid formed and deposited thereon during the evaporation.

Possible Objections to the Boric-oxide Method.—Very much is claimed by Jannasch for this method, but with all its undoubted merit there are two points which may militate against it in time. The boric ether, driven off in such enormous quantities, at once decomposes in contact with moisture, and boric acid settles over all objects with which it comes in contact. The hood must become thickly coated. Hence a special hood for these evaporations alone seems to be called for, otherwise boric acid may at any time fall into other dishes, and cause untold trouble. The second objection attaches to the use of the oxygen flame when alkalis are to be estimated in the fusion, and the ability to so determine them is one of Jannasch's chief claims in favour of the method, for it can not be doubted that at the high temperature of this flame alkalis are volatilised in part. Borax can be slowly but wholly volatilised over the ordinary blast, hence there is great reason to fear sufficient loss at this much higher temperature to give rise to serious errors at times.

(To be continued).

* *Zeitschr. fur Anorg. Chem.*, 1896, vol. xii., p. 208.

† An interesting and important observation reported by Jannasch and Weber is that when the oxygen blast has been used for silicates carrying fluorine or mixed with fluorides, the fluorine seems to be wholly expelled as boric fluoride, without loss of silica. If this should prove to be generally true, an easy way is at last afforded for estimating silica in such cases, where even its detection, when present in small amount, has heretofore been difficult.

‡ Made by passing dry HCl into cooled CH_4O for from one to two hours.

PROCEEDINGS OF SOCIETIES.

PHYSICAL SOCIETY.

Ordinary Meeting, March 8th, 1901.

Dr. R. T. GLAZEBROOK, Foreign Secretary, in the Chair.

A PAPER on "*A Theory of Colloidal Solutions*" was read by Dr. F. G. DONNAN.

Assuming that a colloidal solution is not a true molecular intermixture, but a two-phase system, consisting of exceedingly minute aggregates of the colloid distributed throughout the solvent, the object of the paper was to examine how such a state of affairs might be imagined to come about. By applying the fundamental notions of Laplace's theory of capillary forces to the statical (mechanical) equilibrium at the interface, it was shown that under certain conditions matter in bulk might disintegrate into a homogeneous liquid medium, and yet not attain a state of molecular division, remaining distributed in the form of very thin filaments or sheets whose thickness is comparable with the sphere of molecular attraction. True solution, or molecular intermixture, is regarded, on the other hand, as arising from the kinetic flux of molecules across the interface.

Dr. GLADSTONE said that the study of colloids was one which had been too much neglected. It involves both a knowledge of physics and of chemistry. A colloid is an unstable body, and is always altering its composition. Water of combination is given off on heating, even if the surrounding atmosphere is saturated, and the colloid cannot take up the water again. It is impossible to separate colloids and crystalloids—they merge into one another. The transition forms are not uncommon.

Dr. LEHFELDT asked if it had been proved that colloids have osmotic pressure.

Prof. THRELFALL said that in colloidal solutions some of the substance was not in suspension. Dr. Martin had filled a filter with silicic acid under pressure, and found that it allowed sugar solution to pass through, but stopped colloidal solutions. The author had used opacity as a test for colloids, but silicic acid could be got transparent. There are two kinds of opalescence. One cannot be removed, and exists because the substance is a two-phase system. The other can be removed with difficulty by

filtering, and leaves a transparent substance. The want of transparency should be used cautiously as an argument.

Dr. Donnan, in reply to Dr. Gladstone's remarks on the transition from crystalloids to colloids, said that a substance might be a crystalloid with one medium and a colloid with another. In reply to Dr. Lehfeldt, he said that the only evidence in favour of osmotic pressure of colloids is that colloidal solutions diffuse. He agreed with Prof. Threlfall that opacity should be used carefully as an argument, but stated that his theory referred to a two-phase system.

Mr. Appleyard then exhibited three pieces of apparatus. The first was a slide-wire bridge for measuring conductivities of wires. The slide-wire instead of forming two arms of the bridge forms only one, and the length used is proportional to the conductivity to be measured. If the arm which contains the standard wire used is altered it becomes necessary to alter the divisions of the scale on the slide-wire. This is done by a mechanical arrangement.

The second piece of apparatus was a mechanical gauge for measuring the diameters of spheres. The sphere to be measured is placed between a metal face plate and a piece of glass at the end of the short arm of a pivoted lever. The end of the long arm of the lever moves over a graduated scale, which is calibrated to show directly the diameter of the sphere.

The third piece of apparatus was a galvanometer fitted up for lamp and scale work. The illumination was produced by a 4 volt ¼ candle power lamp, and it was shown that very good results could be obtained from this by using a large condensing lens.

Prof. Threlfall said he had usually used a straight piece of the lamp filament itself, instead of using the lamp in conjunction with a cross-wire.

A paper by Prof. R. W. Wood on "*The Production of a Bright Line Spectrum by Anomalous Dispersion and its Application, the Flash Spectrum*," was postponed until the next meeting at Burlington House, when the subject will be experimentally illustrated by Mr. Watson.

The Society then adjourned until March 22nd, when the meeting will be held in the Chemical Laboratories of University College, London.

NOTICES OF BOOKS.

Arsenical Poisoning in Beer Drinkers. By T. N. Kelynack, M.D., M.R.C.P., and William Kirkby, F.L.S. With 16 Illustrations. London, Paris, and Madrid: Baillière, Tindall, and Cox. 1901. Pp. 125.

The importance of this subject has induced the authors to publish in part their notes on the recent epidemic of arsenical poisoning in Manchester and district; they have therefore given in this volume what they consider to be the more important results of their investigations. These results may be summarised as follows:—(1) That arsenic in quantities sufficient to account for the symptoms complained of was separated from the beer which was actually being consumed by the affected cases; (2) arsenic was found in the secretions of the patients presenting symptoms of arsenical poisoning; (3) arsenic was isolated from the beer received direct from the breweries supplying the local retailers; (4) arsenic was found in varieties of glucose and invert sugar used in the brewing of the very beer in which the arsenic had been detected, and such as was being taken by the affected persons; and (5) arsenic was detected in the tissues of affected cases.

A considerable portion of the book deals with the clinical side of the question, and a number of actual cases are illustrated from photographs of patients, showing pigmentation, dropping of the feet and wrists, transverse ridging of nails, paralysis, wasting, &c.

In the third—or chemical—part of the book, we find a very significant quotation from Dr. A. Wynter Blyth's book ("Foods; Their Composition and Analysis," published in 1896); it runs as follows:—"It is possible for arsenic to be found in beers manufactured from glucose, for in certain kinds of the latter arsenic is occasionally discovered, the substance probably having been introduced by the use of an arsenical sulphuric acid in the process of manufacture." However, the author tells us that, until within the last two months (the preface is dated December 20, 1900), as far as their researches have been carried, no evidence is to be found as to the presence of arsenic in beer.

Part IV. comprises a valuable bibliography of the literature of the subject, and will be of great use to those interested in arsenical poisoning.

In spite of the haste necessitated in compiling this book, owing to the urgency of the matter, the authors are to be congratulated on the excellence of the work they have produced.

The Case Law of the Workman's Compensation Act, 1897. By R. M. Minton-Shenstone, Barrister-at-Law. Second Edition. London: Effingham Wilson; and Sweet and Maxwell. 1900. Pp. 100.

This volume is intended to supplement Part III. of "Accidents to Workmen," which, the author tells us in his preface, has had a very great distinction conferred upon it by being cited and adopted in the Court of Appeal and the House of Lords; this is without precedent for a legal work while in its first edition, and during the lifetime of the author.

The effect of the year's decisions has been briefly summarised, and will be interesting reading for employers of labour. There are also given in the appendices, printed in bold type, the full text of both the Acts dealing with compensation to workmen, viz., the Acts of 1897 and of 1900, in the latter of which the benefits of the former Act were extended to workmen in agriculture.

Analytical Tables for Complex Inorganic Mixtures. Arranged by F. E. Thompson, A.R.C.S. (Lond.), F.C.S.; Teacher of Chemistry at Science and Art Institute, Walsall; Municipal Technical School, Dudley; and Sutton Coldfield Grammar School. Stafford: *Chronicle* Press.

The tables are specially devised for the use of students working for the advanced stage of practical inorganic chemistry of the Board of Education, and will doubtless be found useful to those engaged in preparing students for this and similar examinations. Systematically and clearly arranged, although they do not differ essentially from tables to be found in the majority of text-books, they have the advantage of being in a very convenient form for use, as they are mounted on cloth-lined boards, bound so as to readily open and remain so, and are strong enough to resist the ordinary wear and tear of the laboratory.

The price, 1s. 6d., is moderate enough to bring them within the reach of each individual student.

Dual British and Metric Table Book. By S. Jackson, M.A. (Oxon.), formerly Scholar of Merton College, Oxford, Author of "The Metric System in Theory and Practice." London: Allman and Son, Limited.

The aim of the author of this Table-book is to show, by comparison, the superiority of the metric over the British system of weights and measures. That such a comparison demonstrates this superiority is a question which we do not feel called upon to discuss, but we cannot help thinking that it is injudicious to introduce English terminations to the French terms; the words *liter*, *meter*,

centimeter are not in any way improved by the alteration, while the adoption of *gram* instead of *gramme* is a decided disadvantage, on account of its similarity to grain.

The second part of the book, giving the equivalents of French and English weights and measures, will be found useful to merchants and others unacquainted with the metric system.

We have also received a set of Conversion Tables of Weights and Measures and Foreign Moneys, prepared by the Philadelphia Commercial Museum, 233, South Fourth Street, Philadelphia, in a very compact and handy form, which, though primarily intended for use in the United States, is likely to be found of very general use to the same end. Unfortunately, we again note that the gramme is rendered *gram* and the litre *liter*, &c.

CORRESPONDENCE.

RADIO-ACTIVITY AND ATOMIC WEIGHT.

To the Editor of the Chemical News.

Sir,—The recent researches on radio-active matter seem to indicate that the phenomenon is most marked with elements of high atomic weight; radium, actinium, thorium, and the quite recently discovered radio-active lead, are instances in point. It is, however, very probable that *all* elements are more or less radio-active, but that increase of atomic weight increases the intensity of the action, so that at present our apparatus is only delicate enough to register the heaviest elements.

A glance at Mendeleeff's Periodic Table of the Elements will show the following gradual change with atomic weight of the properties of the elements:—The lightest elements of any series are sharply defined and clear cut in their properties; they effect a condition of chemical repose or equilibrium in one particular state of combination, and this point of maximum stability is quite sharp and definite. In any other state of combination they are unstable.

As, however, the atomic weight increases, this sharpness in combination becomes blurred, and the heavier members of the group often appear to be able to assume with ease more than one state of combination. This shifting and blurring of the point of maximum stability in combination is always apparent with increase of atomic weight in any one group of the Periodic Table.

Now, it is generally accepted that chemical combination is related to presence of ions in the molecules. Thus, *ferrous* iron contains only two *ions*, while *ferric* iron contains three. If we change the iron from the *ferric* state to the ferrous state we lose one *ion*.

Interpreting the above principle in this light, it would appear that an increase in the atomic weight of the elements in any group leads to an increased tendency to change the number of *ions* in the molecule; or, at any rate, it would indicate that *ions* are more easily thrown out and taken in by a heavier atom than by a lighter atom.

Hence, we arrive at the conception of very heavy metals continually casting out into space light ions, until finally their supply runs short or diminishes. If, now, the radio-active metal be treated with another body full of such particles, although the latter body may not of itself throw away many of its ions, nevertheless the heavy element will abstract from it a sufficient quantity to replenish its store, and thus the radio-activity increases again.

The above view indicates the possibility of a connection between readiness of change of valency and radio-activity.—I am, &c.,

Geoffrey Martin.

Bristol, March 2, 1901.

NUMBERING CRUCIBLES.

To the Editor of the Chemical News.

Sir,—Mr. Horace Jervis's suggestion (Chemical News, vol. lxxxiii., p. 118), that porcelain crucibles be marked with ordinary ink and then fired, is very good; but I have found that marking crucibles with an ordinary blue lead pencil (thus obviating the trouble of running ink) and then firing, is better; this produces red lines.—I am, &c.,

W. C. Kriescher.

Villiers Road, Skewen, Neath,
March 11, 1901.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Note.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. cxxxii., No. 7, February 18, 1901.

Secondary Radio-activity of Metals. — Henri Becquerel.—During the author's experiments on the radio-activity of radium, he noticed the extraordinary power of penetration of a portion of the emitted rays. He has further examined this phenomenon and finds that it is apparently a secondary radiation produced by a further excitement, due to the incident radiation which itself is absorbed; this latter being less penetrating than the original radiation. This appears to be a phenomenon corresponding to that of phosphorescence or fluorescence with regard to light. The penetrability of the secondary radiation, feebler than that of the exciting radiation, is analogous to the same property of the secondary rays derived from the Röntgen rays, which were discovered by M. Sagnac.

A New Gaseous Compound: Sulphuryl Fluoride, SO_2F_2.—H. Moissan and P. Lebeau.—The authors have obtained an apparently gaseous new body belonging to the same series as sulphur hexafluoride. It is very stable, and, on account of its slight affinity for other substances, can be compared to sulphur hexafluoride. Its formula, deduced from its density, analysis, and reactions, is SO_2F_2. It can be considered as a hexafluoride, SF_6, in which a portion of the fluorine is replaced by oxygen. From its formula it apparently corresponds to a known compound —sulphuryl chloride. In reality, the sulphuryl group, if it exists in this new gas, forms part of a much more stable molecule, for which the reactions become more complicated. Once more the experiments described in this paper show that if fluorine is incontestably at the head of the family of halogens, it is a little removed from this group, having special properties and characteristics which separate it from chlorine and bring it at the same time nearer to oxygen.

Alcoylcyanomalonic Ethers and their Derived Alcoylcyanacetic Acids.—A. Haller and G. Blanc.—The authors' researches appear to show that cyanomalonic ether contains a methinic group, CH, and that derivatives are formed bp the substitution of alcoholic radicles for the atom of hydrogen in this group, at least in all the derivatives which were examined; starting from alcoylcyanomalonic ethers, the radicles are joined to the carbon atom in the group CH.

Specific Absorption of X Rays by Metallic Salts.—Alexandre Hébert and Georges Reynaud.—The authors examined a number of chlorides, bromides, iodides, and sulphates of the following metals with regard to their powers of absorbing X rays:—Ammonium, barium, cadmium, calcium, cobalt, copper, lithium, magnesium, manganese, nickel, potassium, sodium, strontium, and zinc. Further observations were made on a series of nitrates

The results obtained show with more certainty, and also more generally than hitherto, that the absorbing power of these substances for X rays increases with the molecular weight. In a compound, it is the element whose atomic weight is the highest which gives to the compound its absorbent properties; this element, moreover, having the power of being electro-positive or electro-negative.

Diphenylcarbodiazine.— P. Cazeneuve.— Diphenylcarbazone is capable of losing two atoms of hydrogen under a very simple oxidising influence, giving diphenylcarbodiazine, a substance hitherto unknown. In order to prepare this body, the author made use of the reaction of silver acetate on phenylhydrazine urea or on diphenylcarbazone.

A New Derived Alcohol of Limonene. — P. Genvresse.—Limonene, under the action of peroxide of nitrogen, gives an alcohol having totally different properties from limonene. This has been called limonenol, and has the formula $C_{10}H_{16}O$. This substance is more difficult to prepare than its isomer, owing to the action of nitrogen peroxide on limonene being much more energetic than on pinene. Limonenol is a secondary alcohol in the same way as pinenol. Treated with the chromic mixture, it gives a ketone—limonenone.

Transformation of Dimethylacrylic Acid into Dimethylpyruvic Acid.—L. Bouveault and A. Wahl.— Ethyl-α-aminodimethylacrylate, $CH_3>C=C(NH_2)-CO_2C_2H_5$, dissolves in dilute cold acids without decomposition, but if the hydrochloric solution is heated to 100° an oily layer separates, whilst crystals of ammonium chloride separate out from the aqueous portion. The decomposition takes place according to the equation $C_7H_{13}NO_2+HCl+H_2O=NH_4Cl+C_7H_{12}O_3$. The new compound is obtained by distillation *in vacuo* of the oily layer after washing with water. This substance boils at 65—69° under 15 m.m. pressure, and possesses a pleasant ethereal odour.

Action of Monohalogen Acids of the Fatty Series on Pyridine and Quinoline.—L. J. Simon and L. Dubreuil.—In general, the reaction of the monohalogen acids of the fatty series on pyridine or quinoline depends on the relative proportions of the acid and the base. If two molecules of base to one of acid are employed, the reaction gives a basic chlorohydrate almost quantitatively,

$$2(R{-}CHBr{-}CO_2H)+3R'N+H_2O=$$
$$=\left(\begin{array}{c}R{-}CH{-}CO\\ |\qquad\quad|\\ R'{-}N{-}O\end{array}\right)_2 HBr.H_2O+R'NHBr.$$

When the quantity of tertiary base diminishes, as when equimolecular quantities are employed, the quantity of basic bromohydrate diminishes, while a neutral bromohydrate appears whose constants of solubility are quite different.

Pyrogallolsulphonic Acids. — Marcel Delage. — Pyrogalloldisulphonic acid is prepared by the action of fuming sulphuric acid on pyrogallol, and analysis shows it to have the formula—

$$C_6H(OH)_2(OH)(SO_3H)_2+4H_2O.$$

The author prepares the barium and calcium salts of this acid.

Bulletin de la Société Chimique de Paris.
Series 3, Vol. xxiii., Nos. 18 and 19.

This number contains no original chemical matter of interest.

Nos. 20 and 21.

Action of Hydrogen on Sulphides of Arsenic.—H. Pélabon.—Already noticed.

Selenides of Iron.— M. Fonzes-Diacon.— Already noticed.

General Method for the Preparation of the Mixed Carbonic Ethers of the Phenols and Alcohols.—E. Barral.—Already noticed.

Some Mixed Carbonates of Pentachlorophenol and Alcohols.—E. Barral.—Already noticed.

Some Pentachlorophenates. — L. Jambon. — The author has prepared a number of pentachlorophenates by the two following methods:—(1) By boiling finely-ground pentachlorophenol for about an hour, with a base such as ammonia, a solution of soda, potash, or baryta, &c. The boiling solution is filtered, allowed to crystallise, and the crystals collected and drained very quickly, as they absorb carbonic acid from the air. In this manner the pentachlorophenates of lithium, ammonium, strontium, barium, sodium, potassium, calcium, and aniline were prepared. (2) By the double decomposition of an alkaline pentachlorophenate and a soluble salt; this is a convenient method for preparing those which are insoluble, or nearly so, in water; but by this method it is necessary to operate in a warm, *absolutely neutral* solution; otherwise, if the solution is alkaline, insoluble pentachlorophenates, containing equally insoluble oxides, may be formed, or, if the solution is acid, there will be an excess of pentachlorophenol. The author then goes on to describe the properties and composition of a large number of these bodies.

Some Iodised Derivatives of Methylphenylketone. —A. Collet.—These bodies were obtained by heating on a water-bath to about 60—70° an alcoholic solution of chlorised or bromised ketones with a slight excess of iodised potassium in a fine powder, with frequent stirring. The warm liquid is filtered to remove the chloride or bromide of potassium formed; the iodised ketone is deposited on cooling in more or less yellowish crystals. One or two re-crystallisations in boiling alcohol, especially in the presence of animal black, suffices to purify the product. The author then describes the bodies obtained.

The Acidimetric Estimation of Protocatechuic Acid.—H. Imbert.—0·1725 grm. of the acid, dried at 105°, was dissolved in 50—100 c.c. of warm water. On cooling, the liquid was titrated with a 5·6 per cent solution of potash. 11·7 c.c. of this solution were required, which, supposing the acid to be monobasic, would indicate the presence of 0·180 grm. of acid; or, in other words, one molecule of the acid requires 1·04 molecules, and not 1·5 molecules of potash. The same operation was repeated with soda, and one molecule of the acid required 1·05 molecules of alkali. The reddish violet colour produced on adding 1·5 molecules of the base must not be taken as the end of the reaction in the presence of phthalein. The true end of the reaction is found by touching a drop of the solution, on a white tile, with a drop of an alcoholic solution of the indicating reagent; in this manner the faintest rose tint can be observed.

The Nitration of *m*-Chlorotoluene.—F. Reverdin and P. Crépieux.—By digesting *m*-chlorotoluene at the ordinary temperature with nitric acid of 1·52 density, a mixture of mononitrated derivatives is obtained. If the nitration is performed in the presence of sulphuric acid, a dinitrated derivative is formed, viz., chlorodinitrotoluene; this body crystallises in beautiful needles of a pale yellow colour; it is fusible at 91°. By partial reduction, by passing a current of sulphurous acid through its alcoholic solution treated with ammonia, a chloronitroamidotoluene is formed, $C_6H_2CH_3.Cl.NO_2.NH_2$, which crystallises in a mixture of ligroin and benzene in yellow flakes, fusible at 120°; by complete reduction, a chlorotoluylenediamine is formed, fusing at 123°.

NOTES AND QUERIES.

*** Our Notes and Queries column was opened for the purpose of giving and obtaining information likely to be of use to our readers generally. We cannot undertake to let this column be the means of transmitting merely private information, or such trade notices as should legitimately come in the advertisement columns.

Lime in Manuring.—Could any of your readers inform me if crushed limestone could be used as a substitute for lime in manuring. —X.

Arsenic in Coal.—(Reply to "Analyst").—As the arsenic in coal will exist as sulphide, it will be necessary to proceed as follows:—Mix the finely-powdered coal with strong nitric acid and evaporate to dryness on the water-bath; the residue is treated with water and evaporated to dryness; this is repeated. The residue should then be evaporated to dryness with dilute sulphurous acid, mixed with water, and again evaporated to dryness. The sample, after being prepared in the above manner, should be examined by Gutzeit's test (lead acetate modification). This is the best method for the quantitative determination of minute traces of arsenic —E. D.

MEETINGS FOR THE WEEK.

MONDAY, 18th.—Society of Arts, 8. (Cantor Lectures). "Electric Railways," by Major Philip Cardew, R.E., &c.

TUESDAY, 19th.—Royal Institution, 3. "The Cell as the Unit of Life," by Allan Macfadyen, M.D., B.Sc.

—— Mineralogical, 8. (This meeting will be held in the Apartments of the Geological Society, Burlington House). "Notes on an Occurrence of Minerals at Haddam Neck, Connecticut, U.S.A.," by H. L. Bowman, M.A., F.C.S. "On Calaverite from the Cripple Creek District," by G. F. Herbert Smith, B.A. (with Chemical Analysis by G. T. Prior, M.A., F.G.S.). "On the Arrangement of the Chemical Atoms in Boracite and Cassiterite," by W. Barlow, F.G.S.

WEDNESDAY, 20th.—Society of Arts, 8. "Evolution of Form in English Silver Plate," by Percy T. Macquoid.

—— Microscopical, 8. A Demonstration on the Metallography of Iron and Steel (with Lantern Illustrations), by Wm. H. Merrett, Assoc.R.S.M., F.C.S.

—— Institution of Mining and Metallurgy, 8. (Annual General Meeting). "The Electric Power Station at the Pierrefitte Mine," by E. H. Davies. "Note on Smelting Lead-copper Ore" and "Note on Lead Assaying," by P. R. Robert.

THURSDAY, 21st.—Chemical, 8. "Researches on Morphine" (Part II.), by S. B. Schryver and F. H. Lees. "The Constitution of Pilocarpine" (Part II.), by H. A. D. Jowett. "Note on the Latent Heats of Evaporation of Liquids," by Holland Crompton. "Action of Dry Silver Oxide and Ethyl Iodide on Benzoylacetic Ester, Desoxybenzoin, and Benzyl Cyanide," and "Alkylation of Acylarylamines," by G. D. Lander.

—— Royal Institution, 3. "Shakespeare in Relation to His Contemporaries in Art," by Sir Wyke Bayliss, F.S.A.

FRIDAY, 22nd.—Physical, 5. (This Meeting will be held in the Chemical Lecture Theatre of University College). "On the Expansion of Silica," by Prof. Callendar, F.R.S. "The Spectroscopic Apparatus at University College," by Dr. E. C. C. Baly.

—— Royal Institution, 9. "Some Recent Work on Diffusion," by Horace T. Brown, LL.D., F.R.S.

SATURDAY, 23rd.—Royal Institution, 3. "Sound and Vibrations," by the Rt. Hon. Lord Rayleigh, F.R.S., &c.

The Laboratory, Corporation St., Lancaster.

SPECIALITIES:—

COMBUSTIONS—C, H, and N (DUMAS).

FURFURAL DETERMINATIONS and the ANALYSIS AND DETERMINATIONS OF RADICALS IN CARBON COMPOUNDS, and other routine work necessary in Chemical Research.

Research work undertaken in Organic and Agricultural Chemistry, and other preliminary investigations for Chemical Experts, Scientific Investigators, College Professors, Manufacturers, &c. Work involving the use of large Experimental Digester and Vacuum Pans undertaken.

References, List of Charges, and other information on application.

THE

DAVY FARADAY RESEARCH LABORATORY

OF

THE ROYAL INSTITUTION.

Directors:

The Right Hon. LORD RAYLEIGH, M.A., D.C.L., LL.D., F.R.S.
Professor DEWAR, M.A., LL.D., F.R.S.

Superintendent of the Laboratory:

Dr. ALEXANDER SCOTT, M.A., D.Sc., F.R.S.

This Laboratory was founded by Dr. LUDWIG MOND, F.R.S., as a Memorial of Davy and Faraday for the purpose of promoting, by original research, the development and extension of Chemical and Physical Science.

The Laboratory is open free of charge to Workers of either sex, and any nationality, prosecuting individual investigations; and the extensive collection of Physico-Chemical Apparatus presented by the Founder is available for their use, together with such materials, chemicals, electricity, &c., as the Directors may authorise.

Assistants and a trained mechanician are attached to the Laboratory to aid Workers in the prosecution of their researches.

All persons desiring to be admitted as Workers must send evidence of scientific training, qualification, and previous experience in original research, along with a statement of the nature of the investigation they propose to undertake.

MICHAELMAS TERM.—Monday, October 1, to Saturday, December 15.
LENT TERM.—Monday, January 7, to Saturday, March 30.
EASTER TERM.—Monday, April 22, to Saturday, July 27.

Forms of application can be had from the Assistant Secretary, Royal Institution, Albemarle Street, W.

TECHNOLOGICAL EXAMINATIONS, 1901.

CITY AND GUILDS OF LONDON INSTITUTE.

The Institute's EXAMINATIONS in TECHNOLOGY will be held on April 29 and 30, May 1, 2, 4, 7, 8, 9, 10, 11, and 18, June 4, 8, and 15.

All applications from Local Secretaries for Examination in Technology must be forwarded to the Institute on or before March 25.

Only in exceptional cases and by payment of an additional fee can applications be received from Local Secretaries after that date.

Candidates in Technology, not attending any registered class, should apply at once to the Secretary of the nearest local centre.

Applications from any individual Candidates for Examination at the offices of the Institute should be made not later than April 1, addressed to the Examinations Department, City and Guilds of London Institute, Exhibition Road, London, S.W., and should be accompanied by a Postal Order for the amount of the Fee, the subject and grade of Examination being clearly stated.

Vol. LXXXIII., No. 2156

NOTES ON THE SPARK SPECTRUM OF SILICON AS RENDERED BY SILICATES.*

By W. N. HARTLEY, F.R.S.

The interesting account by Mr. Lunt (*Roy. Soc. Proc.*, vol. lxvi., p. 44), of his identification of three lines of silicon, corresponding with three unknown lines in the spectra of certain fixed stars, contains the following remarks :—

"It is a curious fact that Hartley and Adeney, and Eder and Valenta, who alone give us any extended list of lines due to silicon, appear not to have examined the spectrum of this element in the region of the three rays here considered. Their published wave-lengths show only lines in the extreme ultra-violet, and the majority of them are quite outside the region which can be examined by the McClean star spectroscope."

There is an inaccuracy here, and a similar mistake as to authorship occurs in the paper of Eder and Valenta. Silicon was not one of the sixteen elements whose spark spectra were investigated by Hartley and Adeney (*Phil. Trans.*, 1884, Part I., p. 63), because it was found to be practically a non-conductor, of electricity, and no uninterrupted stream of sparks could be obtained from it. A prior publication (*Roy. Soc. Proc.*, 1883, vol. xxxv., p. 301), "On Line Spectra of Boron and Silicon," by me, gives descriptions and wave-lengths of lines characteristic of these elements which were observed in solutions of borates and silicates. (For a list of these lines, see also Watts's "Index of Spectra," p. 127, 1899. In Appendix E., p. 21 of the Index, the same list of lines is headed H. and A., which is erroneous).

Having some of the spectra photographed in 1883, I find upon examination of the plates that they were closely investigated at that time. They show no trace of any line of silicon less refrangible than 2881·0 (Angström's unit).

There is a line at the less refrangible extremity of the spectrum which, to judge from its position, is yellow or yellowish-green in colour; but it certainly does not belong to silicon, because solutions of a silicate, and of hydrofluosilic acid containing 1 per cent, 0·1 per cent, 0·01 per cent, and 0·001 per cent of silicon, show this line to be stronger in the spectrum given by 0·01 per cent than in any other of the photographs. It has every appearance of, and no doubt is, the well-known pair of sodium lines with a mean wave-length of 5893. A concentrated solution of sodium silicate gave no stronger indication of this line, and only a feeble representation of the strongest sodium line 3301. This may be accounted for by the remarkable fact referred to in the original paper, that the lines of the metal in borates and silicates seem to be suppressed when the spectra of boron and silicon appear with greatest intensity, but if the quantity of the borate or silicate in the solution is diminished, the sodium lines gain in strength.

There is, however, a line near a very strong air line seen in the spectrum of a 1 per cent solution. It continues to increase in length and intensity in other spectra as the proportion of silica diminishes; otherwise it would not be noticeable because it is extremely short, feeble, and enveloped in air-lines when photographed from a 1 per cent solution. A solution equivalent to 0·001 per cent of silicon yields a spectrum in which this line is about one-fourth of the length of the air-lines, and of the seven carbon lines in other parts of the spectrum.

* A Paper read before the Royal Society, February 21, 1901.

It is in fact the least refrangible carbon line from the graphite electrodes 4266·3 (Hartley and Adeney), and is visible and of normal strength and length on photograph No. 10 in the *Journal of the Chemical Society*, 1882, vol. xli., p. 90. It is one of those lines which is occasionally absent from the carbon spectrum, and it is somewhat lengthened when the electrodes are wet (*Phil. Trans.*, 1884, Part I., p. 49). It is doubtless a carbon line, for Deslandres (*Comptes Rendus*, 1895, vol. cxx., p. 1259), gives its wave-length as 4267 (Rowland's unit), and he used carbon purified in Moissan's electric furnace. The least refrangible of the silicon lines on my plates is at wave-length 2881·0, and it corresponds with a line in the arc spectrum 2881·1 (Liveing and Dewar).

There is a group of air-lines* 4446·02, 4432·58, 4425·90, 4415·51, and 4413·60, then comes 4628·95 and 4674·2, but there is no trace of any silicon lines between 4573 and 4553 where Mr. Lunt found three.

Mr. Lunt used a powerfully disruptive discharge, and that apparently is sufficient to account for the difference in the spectrum which he obtained. I have always employed very simple apparatus, but it happens that when investigating the coefficient of extinction of the various rays of silicon a second series of experiments was made with a more powerful coil and jar. It was found that when all the lines had become very short, and the weaker lines had nearly disappeared, they could be reproduced to a great extent from the same solution by increasing the capacity of the Leyden jar or condenser; but as only extremely dilute solutions of silicates were used, the lines obtained by Mr. Lunt from the solid silicates did not appear.

I give here the normal length of the six lines in the characteristic group as they are seen when a 1 per cent solution and graphite electrodes are used, and of two isolated lines which are less refrangible; with them are compared the lines photographed from other more dilute solutions. The sodium line λ 3301 appears as a long line in the 1 per cent solution, and becomes shorter as the quantity of substance is reduced.

Silicon Lines.

A. Strength of solution, or per cent of silicon.
B. Length of the lines in hundredths of an inch.

Description of lines.	Wave-lengths. (Rowland's unit).	A, 1·0. B.	A, 0·1. B.	A, 0·01. B.	A, 0·001. B.
Strongest but one of the group	2506·8	20	10	10·0	9
A weaker line.. ..	2514·0	20	12	10·0	8
Strongest and longest	2515·9	20	15	10·0	10
The weakest lines of the group	2518·9	20	9	7·5	7
	2523·9	20	10	7·5	7
	2528·6	20	10	7·5	7
An isolated line weak and thin	2631·8	17	6	2·0	Barely visible
Very strong line ..	2881·5	22	14	10·0	9

Observations were carried as far as a solution containing 0·00001 per cent of silicon, the two strongest lines being still visible, but as the photographs of these more dilute solutions have been damaged by being kept so long a time in the atmosphere of the chemical laboratory they not now available for similar measurements.

As the sodium lines are suppressed when the silicon lines are strong, the two carbon lines are also reduced very much in length and strength. This is very easily observed on account of the close proximity of the silicon lines, the wave-lengths of the two carbon lines being 2508·7 and 2511·6 (Hartley and Adeney). In the more dilute solution,

* These wave-lengths are copied from the original numbers written upon the 36-inch enlargements of the spectra referred to as being published in the *Journal of the Chemical Society*. The values are according to Angström's unit, and are doubtless not so accurate as numbers more recently determined.

these lines are observed to be lengthened until they become of the normal dimensions of 20/100ths of an inch. It thus appears more than probable that the suppression of the sodium does not result from any chemical action within the spark discharge such as might be supposed to occur if the sodium were dissociated from the compound, and being in contact with a silicate were to liberate silicon, or to combine with silicon directly, and in presence of water give rise to the formation of silicon hydride.

The suppression of much of the sodium spectrum, and the shortening and weakening of the carbon lines, is more likely to be a purely physical phenomenon than the result of any chemical reaction in the spark.

ON SOME PROPERTIES OF LIQUID CHLORINE.

By A. LANGE.

Following on my researches on liquid ammonia and sulphurous acid (*Zeit. p. die ges. Kältenidus*, 1898, p. 39; *Journ. Soc. Chem. Ind.*, 1898, 191; *Zeit. f. Angewandte Chemie*, 1899), I have determined the specific gravity of liquid chlorine. These determinations are of special interest, as Knietsch (*Liebig's Annalen der Chemie*, cclix., 10) has also worked on this subject, and has given the specific gravity of chlorine between −80° and +80°; his figures may therefore serve as a check on the correctness of the method I have adopted.

At temperatures below 36°, Knietsch determined the densities in the usual manner, by estimating the volumes occupied at different temperatures by the same volume of liquid in a calibrated tube, taking into account the gaseous residue; at 40°, he placed a sensitive areometer in the liquid chlorine contained in a larger tube, and read the density directly. The first method enables the reading to be made correctly to the third place of decimals; the second method is less exact in spite of the compensation caused by the increase of volume of the areometer due to the elevation of temperature and the diminution of this volume due to the increase of pressure. With this second method, it is hardly possible to guarantee the correctness of the second decimal in the figure representing the density.

I will now describe briefly the principle of the method of determination I have adopted:—A vessel, of which the volume is exactly known, is filled with a given weight of a liquefied gas. By applying heat, the liquid dilates and finally fills the vessel. This point once reached, the rise of temperature, which has till now been slow, becomes notably quicker. Knowing the temperature produced by the sudden increase of pressure, we can deduce, with the help of other data, the density of the gas liquefied at this temperature. At low temperatures I used the following method, which, however, is a little less exact:—A vessel filled at a very low temperature was gently heated to the desired point, and the excess of liquid was allowed to pass into a second receiver, in which a higher pressure was maintained than in the first. For details of the operation I must refer my readers to my papers on ammonia and sulphurous acid; I would only remark here, that in the determinations of the specific gravity of liquid chlorine by the method giving the greatest variations of pressure, although care may be taken to drive all the air out of the tube of the manometer by introducing a little liquid chlorine, there is always an oscillation of the pointer of the manometer of about 0·5 atmosphere at about 1° before the temperature finally observed; this oscillation then gradually diminishes, the pointer becomes steady, and an exact reading can be obtained. I have given the results in Table I. in the same form as in my previous papers. The bomb used in Series 1, 2, and 4 had a capacity of 1·1764 litres at 15°; that used in Series 3, a capacity of 1·1801 litres. In Table I., the volume of the bomb will be found calculated for every temperature and pressure.

−44·8	—	1·8572	1·1738	1·5822
−45·8	—	1·8616	1·1738	1·5859

Starting from specific gravities observed directly, I have calculated the densities for every five degrees between −50° and +100°. For this purpose I took the density at 7·5° to be accurate, and corrected the other values according to the curve of the coefficient of dilatation. The mean error, calculated from the sum of the squares of the errors, is ±0·0012 for the first series, ±0·0008 for the second, 0·0009 for the third, and 0·0022 for the fourth. I have also calculated the volume at different temperatures; the volume at 0° being taken as unity. The coefficients of dilatation are applied to the volumes taken at the initial temperatures.

Table II. shows that the coefficient of dilatation of liquid chlorine increases constantly, but slowly; and that we do not observe a rapid increase at a certain temperature, as in the case of ammonia. At about 90° the coefficient of dilatation of liquid chlorine is as great as that of gases. But while carbonic anhydride and peroxide of nitrogen dilate at 0° more than their gases, this does not happen in the case of ammonia until about 65°, with chlorine at about 90°, and with sulphurous acid at about 95°.

I have also given in Table II. the results obtained by Knietsch for the purpose of showing that our results are concordant. The greatest differences are in the densities between 35° and 60°: but for these Knietsch's method, as he himself has pointed out, is less accurate.

If we heat the bomb filled with liquid chlorine to above the temperature at which the determination of the density is made—at temperature at which it is entirely filled with liquid—the pressure increases more rapidly than at below this point when we have only to deal with the variation of the tension of the saturated vapour; this increase of pressure is by no means so great as one would imagine, for it depends on the quotient of the coefficient of dilatation divided by the coefficient of compressibility. If, therefore, we know the coefficient of dilatation of chlorine at a given temperature, we can calculate the coefficient of compressibility by observing the increase of pressure caused by a slight—though not too feeble—variation of temperature, at the same time taking into account the increase of pressure of the gaseous chlorine due to the rise of temperature. Table III. contains the observations made for this purpose and the results obtained.

In Table IV. I have given the results obtained with sulphurous anhydride, ammonia, and chlorine.

In the observations of the variations of pressure no anomalies have been noticed as in the case of sulphurous acid. But at the highest temperatures, the variations of pressure were as great as could be obtained, considering what the pressure was. We may therefore conclude that the chlorine did not attack the iron. But at the end of a series of experiments carried up to 94°, after the tap of the bomb was opened and when the temperature had been kept for some time at 15°, we noticed that it weighed 3·3 grms. more than at the commencement—and that, even when taking into account the chlorine it still contained. On washing the bomb with water, we obtained a solution of chloride of iron containing a fair amount of oxide and which deposited a greenish yellow precipitate. The metal tap was not attacked, and no copper could be found in the solution obtained. The weight of the bomb when thoroughly cleaned was 30 grms. less than its original weight. The iron had thus been attacked, and it seemed important to determine the temperature at which this reaction commences. For this purpose the bomb was filled with chlorine, and, with the tap opened, was kept at 15° in a water-bath; the tap was then closed, and, after carefully drying the apparatus, it was again weighed. This operation was repeated after bringing the bomb, filled with liquid chlorine, to 40·2°, to 63·5°, to 83·4°, and to 96·2°. The bomb, whose capacity was 1·1801 litres, weighed 3·1966 kilogrms. when empty, and 3·2004 kilogrms. when full of chlorine gas at 15°. After having been brought to 40·2° and then weighed under the conditions described above, its weight was 3·2003 kilogrms.; there was thus no variation of weight, and therefore no attack of the iron.

—	—	36·8	0·000183	35·4°	0·000225
66·8	0·000271	65·7	0·000317	64·9	0·000366
90·0	0·000467	—	—	91·4	0·000673

The same was the case after raising the temperature of the bomb, filled with liquid chlorine, to 83·4°; it again weighed 3·2004 kilogrms. But when the temperature had been raised to 96·2°, it weighed 3·2035 kilogrms. under the same conditions; its weight had therefore increased 3·1 grms. From these observations we may conclude that chlorine acts on iron at above 90°, and it is probable that the attack is due to the presence of a small quantity of water.

We may here remark that Knietsch, at the commencement of his research (*Liebig's Annalen*, cclix., 111), made an analogous observation. He determined the vapour-tension of liquid chlorine at a temperature above 40° in an iron U-tube; one of the branches was connected to a manometer filled with toluene or petroleum, and contained concentrated sulphuric acid, the other branch contained the liquid chlorine.

"It is apparent," says Knietsch, "that above 100° the pressures are tinged with error; for, at this temperature, under the influence of iron there is formed hydrochloric acid, by reason of the presence of hydrogen and sulphuric acid, and thus the pressure observed is a little too high. We also observe, above all when the apparatus is left to itself, and particularly at the critical point, that the pressure increases, though very slowly. If we allow a little gas to escape, the presence of hydrochloric acid can be detected therein, and we again obtain correct values for the pressures at about 100°. Thus there is also chloride of iron produced in these experiments, and this is decomposed by the sulphuric acid, forming hydrochloric acid and sulphate.

Before closing, I would say a few words concerning the transport of liquid chlorine. According to Article 50 of the German Law, Chapter B, Par. xlvi., November 15, 1892, liquid chlorine, when carried by railway, must be contained in wrought- or cast-iron or cast-steel cylinders. These cylinders must not change form, but remain intact under a pressure of 50 atmospheres; such tests must be repeated every year. These cylinders may only contain a maximum charge of 1 kilogrm. of chlorine per 0·9 litre capacity. From this it results that liquid chlorine of 1/0·9 = 1·11 density would entirely fill the cylinders; now it does not reach this low specific gravity until above 100°. The testing pressure being 50 atmospheres, and the safe limit for ordinary usage being two-thirds of this, say 33 atmospheres, we can heat the cylinders up to 90° before reaching this limit; while my previous enquiries on the transport of liquid sulphurous anhydride and ammonia show a like security for both these bodies—the cylinders may be heated to 65° if they answer the tests—the rules are still more severe for liquid chlorine.—*Zeit. f. Angew. Chem.*, July 10, 1900.

LONDON WATER SUPPLY.

REPORT ON THE COMPOSITION AND QUALITY OF DAILY SAMPLES OF THE WATER SUPPLIED TO LONDON FOR THE MONTH ENDING FEBRUARY 28TH, 1901.

By SIR WILLIAM CROOKES, F.R.S.,
and
PROFESSOR DEWAR, F.R.S.

To CHARLES PERRIN, Esq., M.Inst.C.E.,
Water Examiner, Metropolis Water Act, 1871.

London, March 11th, 1901.

SIR,—We submit herewith, at the request of the Directors, the results of our analyses of the 184 samples of water collected by us during the past month, at the several places and on the several days indicated, from the mains of the London Water Companies taking their supply from the Thames and Lea.

In Table I. we have recorded the analyses in detail of samples, one taken daily, from Feb. 1st to Feb. 28th inclusive. The purity of the water, in respect to organic matter, has been determined by the Oxygen and Combustion processes; and the results of our analyses by these methods are stated in Columns XIV. to XVIII.

We have recorded in Table II. the tint of the several samples of water, as determined by the colour-meter described in previous reports.

In Table III. we have recorded the oxygen required to oxidise the organic matter in all the samples submitted to analysis.

Of the 184 samples examined by us during the month, all were found to be clear, bright, and well filtered.

The rainfall at Oxford during February has been 1·31 inches; the average fall for the last thirty-five years is 1·80 inches; this leaves a deficit of 0·49 inch, and, added to the serious deficit of last month, makes a total deficit of 1·53 inches, or 39·4 per cent on the thirty-five years' average.

Our bacteriological examinations of 481 samples have given the results recorded in the following table; we have also examined 34 other samples, from special standpipes, &c., making a total of 515 samples in all:—

	Microbes per c.c.
New River, unfiltered (mean of 23 samples) ..	800
New River, filtered (mean of 118 samples) ..	5
Thames, unfiltered (mean of 23 samples) ..	5310
Thames-derived water, from the clear-water wells of eight Thames-derived supplies (mean of 262 samples)	26
Ditto ditto .. .. highest	273
Ditto ditto .. .. lowest	0
River Lea, unfiltered (mean of 23 samples) ..	172
River Lea, from the East London Company's clear-water wells (mean of 32 samples) ..	18

Of the 412 samples of the impounded and filtered water supplied to London, examined bacteriologically during the past month, eighteen samples, or 4·3 per cent, were sterile. Only two samples out of the total number examined contained more than 150 microbes, and only nine samples, or 2·1 per cent of the whole number of samples examined, contained more than 100 microbes per c.c.; the mean of the excess samples being 151. Last month the excess samples amounted to 12·5 per cent of the whole number examined.

It is thus seen that the samples containing more than 100 microbes per c.c. this month are only one-sixth of the number found during the month of January, when the water supply of the metropolis was undoubtedly, as a whole, at one of its worst yearly periods.

We are, Sir,
Your obedient Servants,
WILLIAM CROOKES.
JAMES DEWAR.

SOME PRINCIPLES AND METHODS OF ROCK ANALYSIS.*

By W. F. HILLEBRAND.

(Continued from p. 128).

The Sodium-Carbonate Method.

Purity of the Sodium Carbonate used as a Flux.—Notwithstanding the most earnest efforts for years, it has been impossible to procure, either in the open market or by special arrangement with manufacturers, an article of sodium carbonate which can be called chemically pure. With special precautions small lots can be prepared in the laboratory that will contain less than 1 m.grm. total impurity in 10 grms.; but such an article can not be purchased in the market, and rarely will the so-called chemically pure dry sodium carbonate contain as little as 1 m.grm. in 10 grms. The invariable contaminating substances, aside from sand and straw, which have sometimes been found in large amount, are silica, alumina, iron, lime, and magnesia, all of these going into aqueous solution with the carbonate. The chief of these impurities are usually silica, alumina, and lime. An article of the above degree of purity is satisfactory in almost all imaginable cases, since the use of the usually extravagant amount of 10 grms. for a fusion would introduce an error of but 0·1 per cent in the analysis, supposing 1 grm. of mineral to be operated on, and it would, moreover, be distributed over several constituents. This error is undoubtedly fully equalled by the introduction of dust from the air in the various long evaporations.

* *Bulletin of the United States Geological Survey*, No. 176.

Precautions in Fusing.—Special directions with regard to the fusion and its first treatment are unnecessary, except to say that ordinarily from 4 to 6 parts of flux should be used to 1 of rock, and that the flame should not be directed vertically against the bottom of the crucible, but at an angle against the side and bottom, nor should the flame be allowed to envelope the whole crucible. These precautions apply in all ignitions of reducible substances, and yet they are rarely observed. In neither case, if neglected, will there be the necessary oxidising atmosphere within the crucible; on the contrary, reduction may occur fraught with serious consequences. This is especially true if the rock contains more than traces of pyrite or other sulphide, when, after cleansing and igniting the crucible, there may appear on its interior a darkening due to oxidation of reduced iron which had alloyed with the platinum. This may in exceptional cases amount to several m.grms. in weight, and can be removed only by repeated ignitions, followed each time by scouring or treatment with hydrochloric acid or acid potassium sulphate. In order to avoid the use of nitre in case of pyritiferous rocks, it is well to first roast the weighed powder in the crucible in which the fusion is to be made.

Treatment after Fusion.—When fusion is complete, the crucible is seized with the tongs (Fig. 1, p. 69), and the contents are caused to solidify in a thin sheet over the sides and bottom by imparting an appropriate rotating motion with the arm during the cooling process. This is far preferable to allowing the melt to form a thick cake at the bottom, since much less time is required for disintegration, and separation from the crucible is usually much easier.

It sometimes happens that the cooled flux, and even its solution, will indicate absence of manganese when it is really present in quantity to give normally a strong colouration. Two fusions made side by side or successively, under apparently similar conditions, may in one case show little or no manganese, in the other considerable. This observation has been frequently made, and therefore the absence of a bluish-green colour in the fusion is not to be taken as proof of the absence of manganese. This difference of behaviour I can ascribe to no other cause than that of a reducing atmosphere in one of the crucibles, and an oxidising one in the other, even though the conditions were apparently alike.

The contents of the crucible are placed in a rather tall covered beaker with some water, and hydrochloric acid of 1·1 specific gravity is added in excess. The depth of the pink colour usually produced on addition of the acid allows of judging approximately as to the amount of manganese present. The beaker is placed on the water-bath, and when disintegration is complete, having been assisted by gentle pressure with a blunt glass rod, the contents are transferred to a large platinum dish and evaporated on the bath.

Subsequent Treatment.

From this point the treatment will ordinarily be the same whether the boric-oxide or the sodium-carbonate method of decomposition has been employed.

Drying and Testing of Silica.—As to the best way of rendering silica insoluble by evaporation, the writer's predilection is for a double evaporation instead of a single one on the water-bath. By fusing with sodium carbonate in the forenoon, the silica is ready for the first filtration in the afternoon. It is quite unnecessary to carry the evaporation beyond approximate dryness. The filtrate is again evaporated, always in platinum, and is ready for final filtration the following morning, when approximately 1 per cent of silica is recovered and added to the main portion. The writer's experience is that a better separation of silica is effected hereby, and in no more time than by a single long evaporation. That which is subsequently recovered from the precipitate of alumina, &c. (see *prox.*, "Recovery of Silica," &c.), rarely exceeds a half or, at the most, 1 m.grm.

Drying in an air-bath at 110° C. or higher, or on a hot plate or sand-bath, or even over a free flame, in order to render silica insoluble, offers no advantage unless much magnesium is present, and then the most favourable temperature, according to Gilbert (*Technology Quarterly*, 1890, vol. iii., p. 61; Abstract in Fresenius's *Zeit. fur Anal. Chemie.*, 1890, vol. xxix., p. 688), is 120° C. The presence of much calcium chloride seems to facilitate dehydration of the silica, while magnesium chloride above 120° C., on the other hand, by decomposing, forms a silicate which dissolves in hydrochloric acid, and increases the amount of silica carried into the filtrate. It does not appear from Gilbert's paper that the blast-furnace slags, on which he experimented, contained titanium, phosphorus, or iron in appreciable amounts. Basic magnesian rocks usually do, and in such cases it is probable that the employment of a drying temperature of 120° would materially add to the large impurity always to be expected with the silica. In other cases he confirms the earlier belief that drying temperatures higher than that of the water-bath increase the amount of insoluble impurity, chiefly alumina, in the silica, and that this amount can not be reduced by long digestion with hydrochloric acid. Further, he confirms Lindo's statement that evaporation with sulphuric acid till the appearance of white fumes gives a higher result in silica than with hydrochloric acid. But for general rock analysis the use of sulphuric acid at this stage must be rejected utterly.

Blasting for twenty to thirty minutes* is necessary to expel all moisture from the silica, and it is then not hygroscopic. Its weight should always be corrected for impurities, which are never absent, by evaporating with hydrofluoric and sulphuric acids, and again blasting. If toward the end of evaporation with these acids, when the hydrofluoric acid has been driven off and the sulphates begin to appear in solid form, the residue has a peculiar milky or enamel-like appearance, it may be taken as evidence of much phosphorus and titanium. This appearance is possibly due to zirconium with the phosphorus and titanium (see footnote, *prox.*), and is so unusual and striking that it is worth while calling attention to it. With basic rocks very rich in titanium and phosphorus the residue may amount to 2 or even 3 per cent of the rock.

The subsequente precipitate of alumina, &c., is usually ignited in the crucible containing the residue from the silica.

It might be supposed that this residue would contain most of the barium of those rocks carrying that element, together with sulphur or sulphates, but the reverse is true as a rule. Only when there is a considerable excess of SO_3 over the BaO will much of the latter be found there, and in the vast majority of cases there is none at all. Should some be present, its removal and estimation at this stage is not necessary, as it can be more conveniently recovered later, together with the silica accompanying the alumina, &c., precipitate (see *prox.*).

The separation of silica in rocks containing fluorine has been touched upon in commenting on the boric-oxide and sodium-carbonate methods of fusion (see p. 127, and footnote, p. 128), and will be considered further under the head of "Fluorine."

Platinum in Filtrates.—The filtrates from the silica always contain notable amounts of platinum. This arises in very small degree from the crucible fusion, in a larger one indirectly from the action of hydrochloric acid on manganate, vanadate, and sometimes chromate of sodium, and, if much iron is present, in no small degree from the reduction of ferric chloride to ferrous by the platinum of the dish. This last reaction is little known, apparently,

* It must be borne well in mind that some platinum crucibles lose weight steadily and very appreciably on long blasting, not only when new, but even after long use. When a crucible suffers from this defect the rate of loss should be ascertained from time to time, and allowance made accordingly, or else the weight of the crucible should be taken after and not before ignition of the precipitate. (See on this subject Hall, *Journ. Amer. Chem. Soc.*, 1900, vol. xxii., p. 494).

but is mentioned in Gmelin-Kraut (*Anorg. Chem.*, vol. iii., p. 359, Sixth revised edition), and can be readily demonstrated by evaporation of ferric chloride in platinum.

The removal of this platinum before precipitating alumina and iron is not necessary (but see footnote, *prox.*), and to do so involves the re-oxidation of all iron and subsequent boiling to remove or destroy the excess of oxidising agent, together with the expenditure of much valuable time. The iron is already oxidised by the fusion, and needs no further help in that direction. Nevertheless, if time is not a prime object, its removal by hydrogen sulphide is to be recommended. In the following descriptions, however, it is assumed that the platinum has not been gotten rid of at this stage.

VII.—*Metals Precipitable by Hydrogen Sulphide.*

The preaence in appreciable amounts of metals precipitable by hydrogen sulphide, except perhaps copper, is of such infrequent occurrence in most rocks that discussion is unnecessary in their connection. In case it is necessary to precipitate them at this stage, however, it is always well to bear in mind that a little titanium may be thrown down along with them. Separations of the silica should be made in porcelain, to eliminate platinum, or, better still, the quantitative estimation of these metals should be made in a separate portion of the rock broken up by the action of hydrofluoric and sulphuric acids.

(To be continued).

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Ordinary Meeting, March 7th, 1901.

Dr. PERKIN, F.R.S., Vice-President, in the Chair.

MESSRS. T. H. Page and James Moir were formally admitted Fellows of the Society.

The following certificates were read for the first time:—Ernest Clarke, 9, Polygon Avenue, Stockport Road, Manchester; Thomas Kennedy Cockburn, 26, Elm Street, Whiteinch, Glasgow; Eustace Coddington, 131, St. James' Road, Upper Tooting, London, S.W.; Hugh Edward Ellis, 18, Belmont Road, Aberdeen; John Vargas Eyre, 26, Bridge Road West, Battersea Park, S.W.; Francis Robert Henley, Watford, Rugby; Charles Edward Kenneth Mees, 33, St. Saviour's Road, Croydon; Arthur Peacock, Smithies Bridge House, Heckmondwike, Yorks.; William Hammond Robinson, The Limes, Painswick Road, Cheltenham; Henry Ewing Smith, 22, City Road, London, E.C.; William Henry Taylor, 19, Shafton Road, Victoria Park Road, N.E.

Of the following papers, those marked * were read:—

*29 "*Nomenclature of the Acid Esters of Unsymmetrical Dicarboxylic Acids.*" By J. J. SUDBOROUGH.

After mentioning the systems adopted by Brühl, Wegscheider, and Anschütz, the author suggested the following nomenclature.

Of the two isomeric monoalkyl esters of an unsymmetrical dibasic acid, that ester be termed the α-compound which has the higher esterification constant, and the other with the lower constant the β-compound.

The advantages of this system are:—(1). Similarly constituted esters receive similar names; (2) in the case of many of the simpler acids, the substituent which produces the want of symmetry is in the α-position to the alkylated carboxylic group; (3) ease with which the two esters may be identified.

*30. "*Additive Compounds of α- and β-naphthylamine with Trinitrobenzene Derivatives.*" By J. J. SUDBOROUGH.

The red needles which were obtained when α-naphthylamine trinitrobenzoate was boiled with alcohol (*Trans.*, 1899, lxxv., 588), are an additive compound of trinitrobenzene with α-naphthylamine. A number of other similar compounds have been obtained; all are red or reddish-purple in colour, are remarkably stable, may be crystallised from glacial acetic acid, and are only slowly decomposed by cold dilute hydrochloric acid; they are also stable when exposed to the air, and in these properties differ from the additive compounds of trinitrobenzene, with aniline, toluidine, &c., described by Hepp (*Annalen*, 1882, ccxv., 344).

The following are the compounds which have been prepared:—*α-Naphthylamine trinitrobenzene*, m. p. 214°; *β naphthylamine trinitrobenzene*, m. p. 162°; *α-naphthylamine trinitrotoluene*, m. p. 141·5°, the *β-isomeride*, m. p. 113·5°; *α-naphthylamine picramide*, m. p. 203°, and the *β-isomeride*, m. p. 161·5°; *α-naphthylamine ethyltrinitrobenzoate*, m. p. 135°, and the *β-isomeride*, m. p. 126°; *α-naphthylamine ethylpicrate*, m. p. 79·5°; and *α-naphthylamine methylpicrate*, m. p. 75°.

With the object of determining the constitution of these compounds, the action of acetic anhydride and of alcoholic potash on them has been studied; it was thought probable that these reagents might indicate the presence of a hydroxyl group.

α-Naphthylamine trinitrobenzene and acetic anhydride warmed for a few minutes yield a monoacetyl derivative, which crystallises from benzene in sulphur-yellow needles melting at 140·5°. The compound has the acetyl group attached to nitrogen, as the same substance may be obtained by the direct union of trinitrobenzene and α-acetnaphthalide, and as it yields α-acetnaphthalide on treatment with methyl alcoholic potash. Several similar acetyl derivatives have been prepared.

A methyl alcoholic solution of potassium hydroxide decomposes the red compounds, yielding the potassium derivative of trinitrobenzene described by Lobry de Bruyn.

*31 "*Acetylation of Arylamines.*" By J. J. SUDBOROUGH

According to Ulffers and von Janson (*Ber.*, 1894, xxvii., 93), acid ortho-substituents retard the introduction of an acetyl group into a primary arylamine, but at the same time facilitate the introduction of a second acetyl group. Quantitative experiments have been made by boiling aniline, *o*-toluidine, *p*-toluidine, pseudocumidine, α- and β-naphthylamines with acetic anhydride for an hour, and determining the percentage of the arylamine converted into mono- or di-acetyl compounds. The results indicate that a methyl or phenylene group in an ortho-position facilitates diacetylation. All *o*-substituents, whether of a positive or negative character, thus appear to have the property of accelerating the formation of diacetyl derivatives of primary arylamines.

The following new compounds were described: *Diacetylpseudocumidine*, $C_6H_2Me_3{\cdot}NAc_2[Me_3:N=1:2:4:5]$, well developed, transparent prisms melting at 69·5°; *diacetyl-α-naphthylamine*, $C_{10}H_7NAc_2$, colourless, hard prisms melting at 130°; *diacetyl-β-naphthylamine*, colourless plates melting at 66·5°; and *diacetyl-2:6-dibromaniline*, large prisms melting at 100°. Most of these diacetyl derivatives crystallise remarkably well, and are readily soluble in the ordinary organic solvents.

*32 "*Formation of Amides from Aldehydes.*" By R. H. PICKARD and W. CARTER.

When an aldehyde is oxidised with ammonium persulphate in the presence of lime, a 30—40 per cent yield of the amide of the corresponding acid is obtained. The greater portion of the remainder of the aldehyde can be recovered unchanged, and by further oxidation the yield of amide can be increased to 70 per cent of the weight of aldehyde taken. Substituted amides can be obtained by using potassium persulphate and an amine.

*33. "*A Method of Isolating Maltose when Mixed with Glucose.*" By A. C. HILL, M.A.

This method is, essentially, one of removal of the glucose by fermentation with *Saccharomyces Marxianus*, a yeast observed by Hansen in 1888 as not fermenting

maltose. It includes also certain details of procedure, which have been found to facilitate, even if they are not necessary to, an easy crystallisation of the maltose after the fermentation is over, and reduce to a minimum such adventitious impurities as the by-products of fermentation and the oxidation products of the sugars.

A pure culture of the yeast, which has been grown in a glucose broth, is washed repeatedly with sterilised tap water, making use of a centrifuge, and is then added to a sterilised solution of the sugars which it is desired to ferment. The solution, which may be in an ordinary flask closed by a cotton-wool plug, should not contain much more than 10 per cent of sugar, and should be made up in part with sterilised tap water.

The fermentation is conducted at 25—29°, and proceeds slowly in the absence of proteid, and without any notable multiplication of the yeast cells. When the evolution of carbon dioxide has nearly ceased, the flask is heated for a minute or so at 100° in the autoclave, and then its contents are freed from cells by filtration through a porous funnel. Alcohol is added to the solution to one-third of its volume, and the whole evaporated down in a current of carbon dioxide to a thick syrup under diminished pressure; if necessary, more alcohol is added during the evaporation, so that the temperature does not rise above 60°. The rest of the process resembles that usually employed in the re-crystallisation of maltose from 80 to 85 per cent ethyl alcohol, and results in the separation of the maltose quite white at the first crystallisation.

34. "*The Vapour Pressure of Aqueous Ammonia Solution.*" By E. P. Perman, D.Sc.

The vapour pressure of aqueous ammonia solutions of concentrations varying from nothing to 35 per cent has been found by a statical method; the temperatures ranged from 0° to 60°. The curves showing the variation of pressure with concentration at various temperatures are found to be approximately represented by the equation $p(100-c)=ac+bc^2$; a and b are constants, c is the concentration of the ammonia in the solution.

The equation may be put in the form $p(100-c)=c.k$, when $k=a+bc$, and is the reciprocal of the solubility coefficient. The variation of pressure with temperature (the concentration remaining constant) is expressed with fair accuracy by the equation $\log.p=\alpha+\beta t+\gamma t^2$, α, β, and γ being constants, of which γ is always negative.

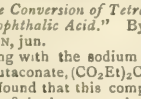
The constant β is found to have the same value as the corresponding constant found in the expression $\log.b=\alpha'+\beta' t$ for the *rate of escape* of ammonia from aqueous solution (*Trans.*, 1898, lxxiii., 511).

35. "*The Influence of Sodium Sulphate on the Vapour Pressure of Aqueous Ammonia Solution.*" By E. P. Perman, D.Sc.

The author has determined the vapour pressures of ammonia solutions containing sodium sulphate in solution at temperatures varying from 26° to 47°, and has compared them with corresponding solutions of ammonia without sodium sulphate. The curves show no break at 33°, nor do they diverge more than those for ammonia solution. Hence it seems probable that the sodium sulphate does not exist as a hydrate in solution.

36. "*Formation of Aromatic Compounds from Ethyl Glutaconate and its Derivatives. The Reduction of Trimesic Acid and the Conversion of Tetrahydrotrimesic Acid into Tetrahydroisophthalic Acid.*" By W. T. Lawrence and W. H. Perkin, jun.

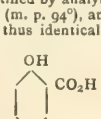
In experimenting with the sodium compound of ethyl sodio-dicarboxyglutaconate, $(CO_2Et)_2CNa{\cdot}CH{:}C(CO_2Et)_2$, the authors have found that this compound, when heated with alcohol at 150°, is decomposed with formation of a large yield of *ethyl trimesate*,—



and further, that methyl sodiodicarboxyglutaconate under the same conditions is converted into *methyl trimesate*.

When the sodium compound of ethyl glutaconate, $CO_2Et{\cdot}CHNa{\cdot}CH{:}CH{\cdot}CO_2Et$, is heated with alcohol at 150°, it is also decomposed, but in a different manner, and the product on hydrolysis yields *hydroxyisophthalic acid*.

This acid was identified by analysis, and by conversion into the methyl ester (m. p. 94°), and into the ethyl ester (m. p. 52°), and it is thus identical with the hydroxyisophthalic acid,—



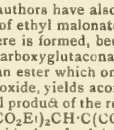
which Kupferberg (*Journ. Prakt. Chem.*, 1877, [2], xvi., 428), obtained by heating sodium salicylate in a current of carbon dioxide.

When ethyl methylglutaconate,—

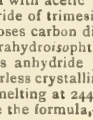
$$CO_2Et{\cdot}CHMe{\cdot}CH{:}CH{\cdot}CO_2Et,$$

is heated with sodium ethylate and alcohol at 140°, it yields a solid ester melting at 96° which, on hydrolysis, is converted into an acid very sparingly soluble in water, and melting at 216°; these substances are at present under investigation. The authors have also found that when the sodium compound of ethyl malonate is digested with ethyl trichloroacetate there is formed, besides the sodium compound of ethyl dicarboxyglutaconate (Ruhemann, *Ber.*, 1896, xxix., 1017), an ester which on hydrolysis and elimination of carbon dioxide, yields aconitic acid. This ester, which is the normal product of the reaction, therefore must have the formula $(CO_2Et)_2CH{\cdot}C(CO_2Et){:}C(CO_2Et)_2$.

When trimesic acid, dissolved in sodium carbonate, is treated with sodium amalgam, it is readily reduced with formation of a mixture of acids, which are evidently stereoisomeric modifications of tetrahydrotrimesic acid,—



One of these acids has been isolated in a pure condition; it melts at about 210°, and is very sparingly soluble in dry ether. When digested with acetic anhydride it yields a resinous double anhydride of trimesic acid and acetic acid, which on distillation loses carbon dioxide, with formation of the anhydride of tetrahydroisophthalic acid. On treatment with potash this anhydride yields tetrahydroisophthalic acid as a colourless crystalline substance sparingly soluble in water, and melting at 244°; from its method of formation it must have the formula,—



and is the first tetrahydroisophthalic acid which has so far been prepared. The authors are continuing their investigation on the action of sodium ethylate on the derivatives of glutaconic acid, and other similarly constituted acids.

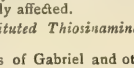
37. "*Optical Activity of certain Ethers and Esters.*" By P. A. Guye.

The author has confirmed the results of Tschugaeff's observations, quoted by McCrae and Patterson (*Trans.*, 1900, lxxvii., 1096), that the optical rotation of compounds containing the phenacetyl group resembles more closely that of compounds containing the acetyl or the chloroacetyl group, than that of compounds containing the toluyl group, although the mass of the phenacetyl group is more nearly that of the toluyl group than of either of the other groups named. The examination of a number of compounds of amyl (phenyl-amyl oxide, benzyl-amyl oxide,

and various amyl esters) has led the author to an analogous conclusion. It is, however, only one case of a more general conclusion already drawn by him, namely, that when substitutions of chains or groups of elements are effected in an asymmetric carbon compound, sufficiently far from the asymmetric carbon atom, the optical rotation is only slightly affected.

38. "*Halogen-substituted Thiosinamines.*" By A. E. DIXON, M.D.

From the researches of Gabriel and others, as well as from his own previous work, the author thought it not unlikely that the "chlorallylthiourea" of Henry (*Ber.*, v., 188), obtained from β-chloroallylthiocarbimide and ammonia, might really be the hydrochloride of a ring-compound,—

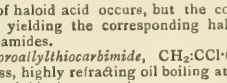


to test this, he has prepared the thiocarbimide, and examined a number of its compounds with bases.

Contrary to anticipation, the addition products so obtained are not closed chain saline derivatives; no formation of haloid acid occurs, but the constituents unite directly, yielding the corresponding halogen-substituted thiocarbamides.

β-Chloroallylthiocarbimide, $CH_2{:}CCl{\cdot}CH_2{\cdot}NCS$, is a colourless, highly refracting oil boiling at about 182°; it is slightly soluble in water, has a very pungent odour, and readily blisters the skin.

With ammonia it yields Henry's β-chloroallylthiourea; prisms, melting at 93·5—94·5° (corr.); Henry gives 90—91°. This substance is moderately soluble in water, and easily so in alcohol; the latter solution, if moderately dilute, gives no precipitate with silver nitrate, but is freely desulphurised by warming with alkaline lead tartrate. Chloroallylthiourea undergoes no isomeric change if boiled in aqueous solution; when fused with monochloracetic acid, it yields the hydrochloride of *β-chloroallylthiohydantoin*,—



white prisms, which begin to decompose at about 170°, and lose the combined acid on re-crystallisation from water. The free thiobydantoin is deposited from water in leaves, and from alcohol in prisms, both forms melting at 149°; when hydrolysed by boiling with dilute alkali, thioglycollic acid is produced.

ab-*Chloroallylphenylthiocarbamide*,—

$$CH_2{:}CCl{\cdot}CH_2{\cdot}NH{\cdot}CS{\cdot}NH{\cdot}C_6H_5,$$

prepared from the thiocarbimide and aniline, is deposited from benzene in plates, m. p. 91—92°. When desulphurised by silver nitrate it gives rise to the corresponding ab-*chloroallylphenylcarbamide*, as slender prisms, m. p. 151—152°.

ab-*Chloroallylorthotolylthiocarbamide* separates from weak alcohol in prisms, m. p. 84—85°.

ab-*Chloroallylbenzylthiocarbamide* crystallises from a mixture of benzene and light petroleum in very brilliant prisms, m. p. 69°. Unlike the preceding thiocarbamides, it is not desulphurised when boiled with alkaline lead tartrate.

Piperdine yields *chloroallylpiperidylthiourea* in transparent quadrangular plates, m. p. 146·5—147·5°.

n-*Chloroallyl-ν-benzylphenylthiourea*,—

$$C_3H_4Cl{\cdot}N{:}C(SH){\cdot}NBzPh,$$

is deposited from light petroleum in needles, m. p. 77—78°.

β-Chloroallylthiocarbimide, dissolved in chloroform, absorbs bromine, yielding *β-chloro-βγ-dibromopropylthiocarbimide*, $CH_2Br{\cdot}CClBr{\cdot}CH_2{\cdot}NCS$, a dense, yellowish liquid, volatile in a current of steam; it unites spontaneously with aniline, forming the hydrobromide of a ring compound,—

The hydrobromide occurred as a sandy powder, m. p. 112—113°; when treated with cold alkali, hydrogen bromide was removed, but the base could not be obtained in a state fit for analysis.

With benzylamine an oily hydrobromide was produced; from this potash withdraws a molecule of hydrogen bromide, leaving the free base,—

which crystallises in prisms, m. p. 107—108°, and dissolves in hydrobromic acid to re-form the oily hydrobromide.

39. "*A Form of Tautomerism Occurring amongst the Thiocyanates of Electro-negative Radicles.*" By A. E. DIXON, M.D.

Some years ago (*Trans.*, 1897, lxxi., 640; see also 1899, lxxv., 389), the author remarked that the so-called "phosphorus trithiocyanate," $P(SCN)_3$, appeared to possess thiocarbimidic as well as thiocyanic properties, and subsequent investigation tends to show that this power to function in both capacities is also manifested by the products obtainable from metallic thiocyanates and the chlorides of a number of electro-negative mineral elements and compound-radicles.

The chlorides, dissolved in suitable anhydrous solvents, were caused to interact with excess of lead or other metallic thiocyanate, if possible, until the chlorine was completely eliminated as metallic chloride; the solid residue was then filtered off, and the filtrate treated with a base such as aniline. Precipitates were thus obtained, which gave the desulphurisation tests with lead and silver salts, characteristic of thiocarbamides, and were usually hydrolysed by contact with water so as to afford the substituted thiourea corresponding to the base used. Unfortunately, no efficient method has yet been found for purifying these precipitates, which are rarely free from more or less contamination with basic thiocyanate.

"Phosphorus trithiocyanate," $P(SCN)_3$, gave with aniline a yellow solid insoluble in cold water, but decomposed when boiled with water into phenylthiourea and an acid of phosphorus; this substance is probably phosphorus triphenyltrithiourea, $P(NH{\cdot}CS{\cdot}NH{\cdot}C_6H_5)_3$. With *o*-toluidine a yellow powder, melting between 81° and 83° was obtained; it appears to be the corresponding tolyl derivative nearly pure. Both these compounds are very freely soluble in alcohol and acetone, but nearly insoluble in benzene, chloroform, and light petroleum.

"Phosphoryl trithiocyanate," $PO(SCN)_3$, obtained in solution by boiling phosphorus oxychloride in dry cumene with lead thiocyanate, gave with silver and lead salts the usual thiocarbimidic reactions, and united spontaneously with aniline, *o*-toluidine, and dry ammonia.

The *aniline* compound was a pale yellow powder melting at about 111—112°, freely soluble in alcohol, ethyl acetate, acetone, glacial acetic acid, and nitrobenzene; insoluble, or nearly so, in chloroform, ether, carbon disulphide, benzene, and light petroleum. It was nearly insoluble in cold water, but dissolved gradually on boiling; the solution contained phosphoric and thiocyanic acids, and on cooling, gave a crystalline deposit of phenylthiourea. The latter appears to be formed by hydrolysis of phosphoryltriphenyltrithiocarbamide:—

$$PO(NH{\cdot}CS{\cdot}NH{\cdot}C_6H_5)_3+3H_2O=H_3PO_4+3CSN_2H_3{\cdot}C_6H_5.$$

Orthotoluidine gave a tenacious oil, hardening presently to a resin-like solid; its properties resembled those of the phenylic homologue, but the substance could not be obtained in a pure condition.

Dry *ammonia* gas yielded a pale yellow granular solid, melting, imperfectly, below 60°, readily soluble in water, and containing a very appreciable quantity of ammonium thiocyanate. The solution in cold water gave with excess of ammonia, followed by magnesia mixture, scarcely any precipitate. But this solution, if previously boiled and allowed to cool, then reacted freely with the above test;

consequently, it is inferred that the phosphoric acid does not exist ready formed in the solution, but originates through the hydrolysis of the phosphoryltrithiourea, $PO(CSN_2H_3)_3$.

The "thionyl thiocyanate" of McMurtry (*Trans.*, 1889, lv., 48), differs in physical and chemical characters from all the known electro-negative thiocyanates; it is suggested that this compound, of which the thiocyanic properties are very feebly marked, whilst it gives decided thiocarbimidic reactions, is probably a polymeric form, $[SO(NCS)_2]_n$.

Carbonyl chloride, in toluene, reacted with lead thiocyanate on standing; the dissolved sulphuretted product (which was freely desulphurised by lead and silver salts) combined at once with aniline, yielding in small quantity a substance melting at about 174° and possessing the characters of a thiocarbamide.

Annual General Meeting.

The Annual General Meeting of the Society for the Election of Officers and other business will be held on Thursday, March 28th, at three o'clock in the afternoon.

CORRESPONDENCE.

AMERICAN SPELLING OF CHEMICAL WORDS.

To the Editor of the Chemical News.

Sir,—In your issue of February 8th, 1901 (vol. lxxxiii., p. 71), the reviewer of a book published in the United States speaks favourably of it, but says:—"It is a pity that this useful manual has not been translated into English," and he objects to the spelling of certain words, "sulfur," "oxid," &c. Similar criticisms on American books have appeared in the Chemical News at intervals during recent years, and readers of these reviews might infer that the unfamiliar spelling was merely an idiosyncracy of the author. Such criticisms, however, show that the reviewers fail to recognise that the American authors use a definite system, endorsed by high authorities in the United States, and have not devised novel forms simply to be thought eccentric.

At the meeting of the American Association for the Advancement of Science, held at Cleveland, Ohio, in 1888, the Chemical Section appointed a Committee consisting of Professors T. H. Norton, Edward Hart, H. Carrington Bolton, and Jas. Lewis Howe, to secure by correspondence and by personal contact the consensus of opinion held by American chemists on the "Spelling and Pronunciation of Chemical Terms." This Committee formulated a body of rules, and during three succeeding years they were discussed in extended correspondence, and orally at the intervening meetings of the Chemical Section held at Toronto and at Indianapolis; finally, at the Washington meeting, held in 1891, the report was formally adopted. Almost immediately thereafter, the United States Bureau of Education gave its sanction to the reformed spelling, and greatly promoted its use by printing the Rules in chart form, and sending thousands of copies to educational institutions throughout the country. Since then the improved method has gradually come into vogue; many writers of text-books use it, one widely circulated English dictionary has adopted it, and many chemists prepare their manuscripts with the reformed spelling, though some editors change the style before printing the communications. The new system has the merit of simplicity, lucidity, and uniformity, and it is founded on a logical basis, so it is rapidly becoming the standard system in the United States.

I do not propose to enter upon details at this time, but I wish to point out that the word "sulphur," spelled as if derived from Greek, is etymologically incorrect, and being replaced by "sulfur" on this side of the Atlantic. Those seeking full details will find the rules for spelling in the *Proceedings of the American Association for the Advancement of Science*, vol. xl.; *Journ. Analyt. Applied Chem.*, March, 1892, vol. vi.; Witthaus' "Medical Students' Manual of Chemistry"; and in the *Annual Report U.S. Bureau of Education*, 1893-94, pages 873-876.

The disfavour with which such reform is received in Great Britain has its counterpart in the United States, where objection is made to the ultra conservatism that causes British writers to retain the old-fashioned and erroneous forms, and thus hamper progress in the right direction. Americans in reviewing books from across the Atlantic do not make unfavourable comments every time that they notice archaic spellings; pray "let us have peace," and a discontinuance of even gentle reminders of the error of our ways (?) in the matter under discussion, for the reformed spelling has come to stay, and criticisms of those we honour and esteem in the mother country will not dissuade our writers from the upward movement.

Allow me to add that I am not acquainted with the American author whose book has been reviewed, and this letter has been written not in defence of his action but rather in hopes of enlightening others.—I am, &c.,

H. Carrington Bolton.

Washington, D.C.

PROUT'S HYPOTHESIS AND RADIO-ACTIVE ELEMENTS.

To the Editor of the Chemical News.

Sir,—Many chemists believe that the fact that most of the seventy odd elements have atomic weights differing by only a small amount from whole numbers is something more than a mere accident. The recent discovery of a number of heavy radio-active elements raises the question how far the presence of minute quantities of unknown elements may have affected the accuracy of atomic weight determinations.—I am, &c.,

Geoffrey Martin.

Bristol, March 13, 1901.

ANALYSIS OF HEN-DUNG.

To the Editor of the Chemical News.

Sir,—In January last I collected a clean fresh sample of hen-dung, which, after removing pebbles (grit supplied to the fowls), I found to contain:—

Water	64·25
*Organic matter	24·28
Alumina	0·42
Ferric oxide	0·54
Lime	1·72
Magnesia	0·40
Phosphoric anhydride	0·79
Sulphuric anhydride	0·70
Chlorine	0·05
Sand and insoluble matter	5·79
Potash	0·36
Soda	0·03
	99·33

* Containing—Ammonia, 0·77 p.c.; Total Nitrogen, 1·05 p.c.

Of course different food must cause considerable variations, but the above numbers for the three chief manurial ingredients are strikingly lower than the average values quoted by Storer (N 1·60, P_2O_5 1·7, K_2O 0·8) and Ulrich (N 1·2—2·4, P_2O_5 3·0—4·2, Alkalis 2·0—2·2), especially the phosphoric acid and potash. It would appear, therefore, that fowl-dung may sometimes be by no means a highly concentrated manure. The above percentage of

K_2O is less than Wolff's average (0·5) for farmyard manure.

It will be noticed that there is a considerable percentage of sulphur; as the fowls were doing very little laying possibly this might be larger than usual, as less would be required for the formation of albumen. The manurial ingredients, however, might also be expected to be larger on this account; but as the birds had not completely recovered from moulting a special drain might result. Can anyone inform me if large variations occur in different seasons with birds fed throughout with similar food?—I am, &c.,

L. V. Wright.

Pocklington, March 16, 1901.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Note.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. cxxxii., No. 8, February 25, 1901.

Certain Conditions of Reversibility.—Albert Colson.—The author performed various experiments on the dissociation of silver carbonate in order to find whether carbonic oxide behaves in the same way as hydrogen with regard to silver oxide. Towards 10°, the reduction of the metallic oxide by CO is extremely rapid, white silver being deposited. At −21° the reduction is very slight; however, the gaseous CO is totally absorbed, but in most cases it is in a great measure replaced by a corresponding quantity of carbonic anhydride.

Compressibility of Solutions.—M. Guinchant.—The author investigates the relation between the volume of a dissolved substance and the pressure. His experiments show that the volume of the dissolved body is independent of the pressure; at least, up to the pressure of four atmospheres. It is therefore probable that the variation in volume which accompanies the simple solution of a body in water is due to a variation in the state of aggregation of the solvent rather than to the volume occupied by the dissolved molecules. By this last hypothesis, the variation in volume, independent of the pressure, must be regarded as representing the co-volume of the dissolved body.

Indium.—C. Chabrié and E. Rengade.—The authors' researches were made on the alums of indium and the alkaline metals, cæsium, and rubidium. These were decomposed by heat into oxide of indium, barium sulphate, and cæsium or rubidium sulphate, all three substances being accurately estimated. The numbers obtained agree very well with the formula $SO_4Rb_2+(SO_4)_3In_2+24H_2O$. Indium acetylacetonate is not volatile without decomposition, and so, to determine the atomicity of indium, the rise in boiling-point of a solution of indium acetylacetonate in ethylene bromide has to be determined; this gives a molecular weight of 405, and is a further proof that indium is trivalent.

A New Crystalline Sulphate of Molybdenum.—M. Bailhache.—Sulphuric acid dissolves molybdic acid when heated, and forms with it a molybdic sulphate, MoO_3SO_3, which has been known for some time. This compound consists of colourless crystals, which are very soluble in water and are deliquescent. If the sulphuric solution is now reduced, it becomes blue, but no further crystalline body can be obtained. However, under certain conditions, it is possible to obtain with great facility a new compound derived by the reduction of the double anhydride MoO_3SO_3, and perfectly crystalline. A rapid current of hydrogen sulphide is used for the reduction. The substance is produced in the form of a crystalline sand, very dark olive-green in colour, and analysis shows it to have the formula $Mo_2O_5.2SO_3$.

New Reactions of Organo-metallic Derivatives. α-Alcoyl-β-ketonic Ethers.—E. E. Blaise.—In a previous paper, the author showed that organo-metallic derivatives react on bodies containing the nitrile function, giving compounds which, when decomposed by water, give rise to ketone derivatives. The present paper contains an account of the α-alcoyl-β-ketonic ethers which can be obtained by this method. These ethers are produced when nitriles are condensed with α-bromated ethers of the homologous acids of acetic acid in presence of zinc.

Action of Organo-metallic Derivatives on Ether Salts.—A. Béhal.—The alcoylo-halogen derivatives of magnesium react on the ether-salts of the cyclic series, and their action can be considered as taking place in three phases. In the first, a molecule of the organo-metallic derivative is fixed on to the ether salt; in the second, a second molecule of the organo-metallic derivative is fixed, and a molecule of magnesium iodoalcoylate is eliminated; finally, in the last phase, a carbide of the ethylenic function is formed.

Synthesis of Tertiary Alcohols of the Fatty Series.—Henri Masson.—The author examined the action of the organo-metallic derivatives on the derived ethers of the monobasic acids of the fatty series. At first he used organo-metallic derivatives of zinc, but finally utilised the organo-metallic derivatives of magnesium, which are more tractable than those of zinc, and with which the reactions are sharper. In all cases he obtained the tertiary alcohols.

Absorption-spectra of the Indophenols, and Colouring-matters of Triphenylmethane.—C. Camichel and P. Bayrac.—The authors conclude from their experiments that the law of auxochromes no more exists for the compounds of triphenylmethane than for the indophenols. The replacing of a tertiary nitrogen by a primary nitrogen, and the number of tertiary nitrogens, are the factors having a great influence on the absorption of light; but the law applying to this phenomenon has yet to be found. The authors have examined the influence of concentration on the alcoholic solutions of the indophenols, and on the aqueous solutions of the colouring-matters of triphenylmethane, but up to now they have always found that the coefficient of absorption is proportional to the concentration.

Constitution of Glucose.—L. J. Simon.—The aldehydic properties of glucose are represented by the linear formula of Berthelot, Fittig, and Kiliani, $CH_2OH-CHOH-CHOH-CHOH-CHOH-CHO$. This formula agrees with the processes of reduction and oxidation, with the fixation of hydrocyanic acid realised by Kiliani, and it agrees well with the stereo-chemical researches of Fischer, but it leaves unexplained certain interesting points which are discussed by the author in this paper.

Journal de Pharmacie et de Chimie, Series 6, Vol. xii., No. 7.

Estimation of Glycerophosphate of Quinine.—M. Prunier.—Two grms. of the glycerophosphate are dissolved by means of 10 or 15 c.c. of $\frac{1}{10}$th N nitric acid, and precipitated by a sodic solution containing about 6 grms. of alkali. Filter, and wash the quinine on the filter, dry at 110°, and weigh. The total filtrate, carefully measured, is divided into two equal parts. The first, used for the estimation of the acid, is supersaturated with nitric acid after the addition of 2 or 3 grms. of saltpetre, then evaporated to dryness under a funnel. Then proceed as above, by repeated additions of nitric acid, to obtain first a white ash, and then the melted mass which contains the whole of the phosphoric acid. The other half of the solution serves to complete the estimation of the quinine. For this purpose more alkali is added; then boil so long as a white pearly material separates out; this is collected on a filter. The filtrate is again boiled, and when no more

than a slight cloudiness is formed, shake up with about 50 c.c. of ether and chloroform to remove the last traces of saponified quinine. Wash, dry, and weigh, and in this manner a second quantity of quinine is obtained, which, added to the portion of quinine precipitated in the cold, gives the percentage of the alkaloid present.

Practical Apparatus for the Preparation of Tribromide of Arsenic.—E. Jory.—The author has obtained tribromide of arsenic in a state of purity by the direct action of bromine fumes on arsenic. A matras containing bromine is placed on a water-bath fitted with a cork with two holes and connected through a Welter S-tube with an escape-tube bent in such a manner that the condensed bromine will fall back again into the matras; this tube is connected to a combustion-tube, 2 c.m. in diameter and 15 to 18 c.m. long, containing the arsenic; the other end of this tube is contracted and connected with a flask to receive the tribromide; the second hole is fitted with a glass tube for making communication between the interior of the matras and the air. The matras is gently heated, and when the bromine fumes reach the arsenic, the attack takes place energetically, and owing to the heat generated the tribromide of arsenic is melted and runs into the flask. When cooled it is perfectly white and well crystallised.

No. 8.

On the Filtering Value of old Alluvial Deposits.—F. Malméjac.—Already inserted in full.

Detection of Copper.—A. Bellocq.—If a drop of a solution of sulphate of copper at 1 or 0·5 per cent is allowed to fall into a litre of potable water, and a zincic reagent is added drop by drop until the reaction is strongly alkaline, and the whole is then allowed to stand for four or five hours until it is perfectly limpid, a flocculent precipitate will be formed, varying in appearance from pure white to dirty grey, yellow, or brown, according to the purity of the water. On adding to this precipitate, collected in a small porcelain crucible and dried, a small excess of HCl and then ammonia, the characteristic blue colour of copper is obtained. The sensitiveness of the reaction exceeds the above limits.

MISCELLANEOUS.

Merck's Digest, No. 10.—Cacodylic Acid and Cacodylates.—Cacodylic acid is di-methyl arsenic acid, represented by the formula $As(CH_3)_2O(OH)$. It occurs as oblique rhombic crystals, which dissolve very readily in water and in alcohol, and melt at 200°. Recent investigations have shown that in the form of its salts the toxicity of cacodylic acid is comparatively slight, and hence it is an excellent medium for introducing, without danger, large quantities of arsenic into the human organism. At the same time, ways have been found to avoid the communication of the unpleasant garlic odour to the breath. Cacodylic acid is rarely prescribed as such, but preference is given to the sodium salt; further, the cacodylates of iron, mercury, guaiacol, potassium, calcium, magnesium, lithium, and quinine are contemplated for clinical use. Whether administered internally or injected subcutaneously, cacodylic acid acts as a tonic, and causes no digestive disturbance even when taken in large doses. Its dissociation in the organism is extremely rapid, and the excretion of the ultimate products takes place mainly through the lungs and kidneys.

Preparation of Tetrachloromethane, CCl_4.—E. Serra.—This substance can be obtained absolutely free from CS_2, $CHCl_3$, or S_2Cl_2. Sulphide of carbon is saturated with chlorine in the presence of a little iodine and iron filings; it is then distilled, and the distillate treated with milk of lime in a retort. A brisk reaction takes place, part of the nearly pure product passes over, and the rest is driven over by the help of steam. The dried product is dissolved in a little ICl_3, and heated in a flask fitted with a vertical condenser; hydrochloric acid is given off, and we find free iodine, which is saturated with chlorine until, at the boiling-point, the ICl_3 remains unchanged. The operation is finished by treating with Na_2CO_3 and milk of lime, drying and distilling.—*Gazz. Chim. Ital.*, [II.], vol. xxix., p. 353.

The Chlorisation of *m*-Acet-toluide.—F. Reverdin and P. Crépieux.—By chlorising *m*-acet-toluide by means of chlorate of soda and hydrochloric acid, the authors have obtained a monochlorised, dichlorised, or trichlorised derivative, according to the proportions used; these bodies are fully described.—*Bull. Soc. Chim. de Paris*, Series 3, xxiii., Nos. 20 and 21.

Preparation of Pentachlorophenol.—Et. Barral and L. Jambon.—Pentachlorophenol is very difficult to obtain in a state of purity. It has been prepared by a large number of methods, of which only three are of any value, and they consist in chloridising phenol in the presence of one of the three following bodies:—(1) Chloride of antimony, (2) iodine, (3) anhydrous perchloride of iron. The best conditions are the following:—The chloridising agent must be employed in small quantity, to prevent the formation of tarry matters; it must not be added directly to the phenol at the commencement of the operation, but only when the latter has been converted into trichlorophenol. In spite of the high fusing-point (186°) of pentachlorophenol, it should not be heated above 135—140°, or it may decompose into perchlorodioxydiphenylene and hydrochloric acid, $2C_6Cl_5{\cdot}OH = C_{12}Cl_8O_2 + 2HCl$. The chlorine must be perfectly dry, or tetrachlorised quinone will be formed, $C_6Cl_5.OH + H_2O + Cl_2 = C_6Cl_4O_2 + 3HCl$. By using binoxide of lead, the purification of pentachlorophenol has been made as rapid and perfect as possible. The return, however, is very variable; for, in some cases, with $SbCl_5$ it has been as low as 10 per cent, while with chlorisation in the presence of anhydrous perchloride of iron under the most favourable conditions, as much as 95 per cent of the theoretical return has been obtained.—*Bull. Soc. Chim. de Paris*, Series 3, xxiii., Nos. 20 and 21.

Salts of Thorium.—A. Rosenheim and J. Schilling.—*Chlorides of Thorium.*—On adding aqueous ammonia to a solution of thorium a hydrate is precipitated; this is filtered, washed, and treated with alcoholic HCl. After suitably concentrating the solution small white needles are obtained, which consist of a hitherto unknown oxychloride of thorium corresponding to the formula $Th\begin{matrix}(OH)_2\\Cl_2\end{matrix} + 8H_2O$. The mother-liquor afterwards deposits brilliant crystals, fairly stable in the air. These are shown by analysis to be a chloride of thorium $ThCl_4 + 9H_2O$. If, instead of concentrating the alcoholic solution, the solvent is almost entirely driven off, a syrupy mass remains, which, under the influence of dilute HCl, deposits a fresh oxychloride of thorium in the form of a crystalline powder. This new salt has the formula $Th\begin{matrix}OH\\Cl_3\end{matrix} + 11H_2O$. By mixing alcoholic solutions of chloride of thorium and hydrochlorate of pyridine, the authors have obtained a well-crystallised double salt $(C_5H_5N)_2H_2ThCl_6$. *Bromides of Thorium.*—The hydrate of thorium is treated with HBr, and the alcoholic solution slowly evaporated. This latter then deposits, in the form of small quadratic crystals, an oxybromide $Th\begin{matrix}(OH)_2\\Br_2\end{matrix} + 11H_2$, analogous to the preceding oxychloride. In this case there is also formed a tetrabromide of thorium, $ThBr_4 + 7H_2O$, which crystallises in well formed colourless needles. These latter are not very stable, but decompose rapidly in the air, losing HBr. By reacting with bromide of thorium and hydrobromate of pyridine in alcoholic solution a double salt is also formed of the composition $(C_5H_5N)_2H_2ThBr_6$. This compound, easily soluble in water and in absolute alcohol, changes rapidly when exposed to the air, taking an intense yellow colour. The authors propose to continue this research, and will examine the preparation and properties of the oxides and sulphates of thorium.—*Berichte*, xxxiii., p. 977.

Some Chlorarates of Organic Bases with Abnormal Compositions.—G. Fenner and J. Tafel.—Piperidine gives two chlorarates; the normal salt $C_5H_{12}NAuCl_4$ always forms in aqueous solution; it is stable, and may be re-crystallised in alcohol and water. The abnormal salt, $(C_5H_{12}N)_2AuCl_5$, forms exclusively in alcoholic solution, or when the normal solution is treated with an alcoholic solution of hydrochlorate of piperidine or simply hydrochloric gas. On the other hand, the normal salt is regenerated when it is treated with water, in the cold, or when its alcoholic solution is heated, $(C_5H_{12}N_2)AuCl_5 = C_5H_{12}N.AuCl_4 + C_5H_{12}NCl$. Other bases form abnormal chlorarates which have practically the same properties, while methylamine, aniline, pyridine, and conicine give none. *Piperidine.*—The normal salt crystallises in water in flakes, fusible at 218—229° with decomposition; it is soluble in alcohol and water. It is dissociated in warm alcoholic solution. The abnormal salt, prepared in alcoholic solution with chloride of gold, is slightly soluble in alcohol; it is a yellow, crystalline powder, fusible at about 197°, giving off hydrochloric gas. The reciprocal transformation of the two salts takes place as has been shown above. *Isopropylamine.*—The abnormal salt consists of a microcrystalline yellow powder, fusible at about 159°, soluble in alcohol. The normal salt is in yellow tables, fusible at 131—135°. *Au-methylpiperidine.* The normal salt melts at about 96—100°, and the abnormal salt at about 102—104°. It occurs in yellow flakes. *Quinolein.*—The abnormal salt melts at 180°, and decomposes about 260°. The normal salt melts at 235—238°, and decomposes likewise at 260°. The *Chlorauvate of Pyridine*, $C_5H_6NAuCl_4$, is slightly soluble in boiling alcohol (1 in 60). That of methylamine is decomposed into hydrochlorate by ether in the presence of hydrochloric gas.—*Berichte*, vol. xxxii., p. 3220.

MEETINGS FOR THE WEEK.

MONDAY, 25th.—Society of Arts, 8. (Cantor Lectures). "Electric Railways," by Major Philip Cardew, R.E., &c.

TUESDAY, 26th.—Royal Institution, 3. "The Cell as the Unit of Life," by Allan Macfadyen, M.D., B.Sc.

—— Society of Arts, 8. "The Commonwealth of Australia," by The Hon. Sir John Alexander Cockburn, K.C.M.G.

WEDNESDAY, 27th.—Society of Arts, 8. "Clocks, Carillons, and Bells," by A. A. Johnston.

THURSDAY, 28th.—Royal Institution, 3. "Shakespeare in Relation to His Contemporaries in Art," by Sir Wyke Bayliss, F.S.A.

—— Society of Arts, 4.30 (at the Imperial Institute, South Kensington). "The Greek Retreat from India," by Colonel Sir Thomas Hungerford Holdich, R.E., K.C.I.E., C.B.

—— Chemical, 3. (Annual General Meeting).

FRIDAY, 29th.—Royal Institution, 9. "Polish," by Lord Rayleigh, F.R.S., &c.

SATURDAY, 30th.—Royal Institution, 3. "Sound and Vibrations," by the Rt. Hon. Lord Rayleigh, F.R.S., &c.

ON THE PREPARATION OF LARGE QUANTITIES OF TELLURIUM.*

By EDWARD MATTHEY, A.R.S.M.

FOR several years I have worked upon bismuth ores of varying richness for the extraction of the bismuth they contain, and I have already communicated the results to the Royal Society (*Roy. Soc. Proc.*, 1887, vol. xlii., p. 89; 1890, vol. xlix., p. 78; and 1893, vol. lii., p. 467). Many, if not most of these ores, contain traces of tellurium.

Tellurium has a marked tendency to associate itself with bismuth, as silver may be said to do with lead, or phosphorus with iron, and accordingly the crude bismuth extracted from these ores invariably contained small quantities of tellurium, which was reduced together with the bismuth, and was found to exist in it in a greater proportion than in the ores.

The presence of even minute traces of tellurium in bismuth being sufficient to render this metal unsaleable, it is necessary to remove every portion of the tellurium whilst refining the crude bismuth. The alkalis containing the tellurium resulting from the refining of the crude bismuth were thrown aside, and were left for future investigation.

I have now been able to treat these alkaline residues, and have extracted from them a substantial amount of metallic tellurium, weighing 26 kilos. This amount of tellurium was produced from 321 tons of mineral containing an average amount of 22·50 per cent of bismuth.

The amount of metallic tellurium obtained corresponds to an average of 0·007 per cent of the original mineral.

The 26 kilos. of metallic tellurium was obtained by soaking the telluride alkalis, resulting from refining the telluric bismuth in hot water—acidifying these solutions with hydrochloric acid, and precipitating the tellurium with sodium sulphite. A crude mixture of bismuth and tellurium was thus obtained, the tellurium forming about 47·5 per cent of the crude metal.

This was dissolved in nitric acid, and again treated in the same way, and yielded the amount of tellurium represented by the 26 kilos. This shows on analysis:—

Tellurium	97·00
Bismuth	2·15
Copper	0·65
Iron	0·10
Loss	0·10
	100·00

The appearance of the metal when broken shows a crystalline fracture, of needle-like structure, and of bright metallic lustre. It does not readily tarnish in the air at the ordinary temperature. If slowly cooled, a crystalline form very much resembling that of bismuth is obtained.

Its specific gravity is 6·27, as against 6·23, the density of uncompressed tellurium found by Spring.

The temperature of solidification was determined by means of the Le Chatelier pyrometer, and proved to be 450° C., or 5° lower than that given by Carnelley and Williams (*Chem. Soc. Journ.*, vol. xxxvii., p. 125).

Some tellurium prepared from this 26 kilos. to chemical purity also gave 450° C. as the solidifying point.

Commercial tellurium obtained from Germany proved to have the same melting-point and specific gravity as my own tellurium.

I found the electrical resistance to be about 800 times that of copper. The resistance, however, appears to be very greatly dependent on the crystalline conditions.

A rod cast and cooled quickly has a lower resistance than one that has been cooled slowly. A current of a few ampères will quickly raise the temperature of a rod 0·2 inch in diameter. In casting small rods of tellurium, of, say, ⅜ inch diameter, there is much contraction, and partial separation takes place even after some hours.

The thermo-electric power of tellurium appears to be great.

It has been a source of great satisfaction to me, as a metallurgist, to produce so large an amount of tellurium from a mineral in which it existed only in minute traces. The amount of 57½ lbs. (26 kilos.) of tellurium was derived from 187,019 lbs. of crude bismuth, which resulted from the treatment of 831,168 lbs. of mineral.

* A Paper read before the Royal Society, March 14, 1901.

SOME PHYSICAL PROPERTIES OF NITRIC ACID SOLUTIONS.*

By V. H. VELEY, F.R.S., and J. J. MANLEY,
Daubeney Curator, Magdalen College, Oxford.

THE results obtained by the authors on the electric conductivity of solutions of nitric acid have led them to continue their investigations on other physical properties of the same substance with a view of confirming the conclusions drawn therefrom.

In the present paper the properties examined are the densities, with especial reference to the contractions, and the refractive indices.

The various sources of error and their possible magnitude are discussed in full; for the densities, those of analysis, unavoidable in this case, temperature, errors of filling pyknometers both with acid and water; for the refractive indices, those of micrometer screws, divided circle, parallelism of quartz plates are more especially alluded to, as also the several effects likely to be produced by the various substances with which the acid solutions of necessity came into contact. The results obtained by both methods are given in a series of tables, and compared with those calculated from various equations for straight lines. These show that the physical properties are discontinuous at points corresponding very approximately to the concentrations required for simple molecular combinations *only* of nitric acid and water. In the case of the densities and contractions, the best defined points of discontinuity correspond to the composition of the hydrates with 14, 7, 4, 3, 1·5, and 1 molecular proportions of water; in the case of the refractive indices, the most marked points correspond to the 14, 7, and 1·5 hydrates.

The results for the contractions further confirm those for the electric conductivities as to a remarkable discontinuity at concentrations 95 per cent to 100 per cent, which can possibly be explained by some cause other than the combination of acid with water.

The contractions show that these points of discontinuity, though to some degree real, yet to another degree are ideal in that there is within the limits of 1 to 2 per cent in the vicinity of such points a transition stage.

The values for μ are further expressed in terms both of Gladstone and Dale's and of Lorentz's formula, and it is shown that the values in neither case are constant, but decrease with increase of concentration, and also that Pulfrich's formula which expresses the relation between the refractive index and the contraction in terms of a constant is only approximately applicable for results differing by small percentage concentrations, but not so in the case of considerable differences.

The results are illustrated by a selection of curves, with especial reference to the points of discontinuity.

* Abstract of a Paper read before the Royal Society, March 7th, 1901.

QUANTITATIVE DETERMINATION OF SCAMMONY FOR COMMERCIAL PURPOSES.

By P. L. ASLANOGLOU.

To a weighed quantity of scammony add some ether and gently warm, to dissolve quicker; let it stand to settle, and filter through some cotton-wool; to the residue add some more ether, and repeat as above three times. All earthy and insoluble matter will remain in the filter. Wash well the cotton-wool with warm ether, and to the filtrate add enough turpentine, and let it stand for some hours, when a globular oily-looking precipitate will be found to settle down in the ether-turpentine mixture, consisting solely of scammony; any admixture of other gum-resins will be kept in solution by the ether-turpentine mixture; the scammony, being insoluble in turpentine, precipitates. Decant the ether-turpentine mixture, wash precipitated scammony with fresh turpentine only, evaporate gently on a water-bath, and weigh; thus one has the commercial value of scammony in samples. To estimate the earthy insoluble matters, the cotton-wool filter should be dried with its contents in a water-oven, burned, and weighed; of course, the ash of cotton-wool per grm. used should be known. The ether-turpentine mixture, evaporated and weighed, will give the amount of foreign gum-resins.

ON OXIDE OF BISMUTH.

By M. PAUL THIBAULT.

Commercial oxide of bismuth always contains a certain proportion of nitric acid; it therefore appeared to be of interest to examine its precipitation with a view to obtaining the hydrate of oxide of bismuth free from acid.

The methods given by Carnelley and Walker, Muir and Carnegie, and Arpe were tried, and all gave oxides containing nitric acid, as also did that of M. Baudran. However, the oxide obtained by this latter method contained a little less nitric acid (about 0·5 per cent less in HNO_3) than those obtained by the previous methods.

We therefore made use of this method, working at different temperatures, the temperature varying by 10° at a time, from 0° to 100°. The quantities of nitric acid found varied from 2 to 5 per cent; the smallest amount being found at 0°, and the greatest at 100°.

By using the halogen salts of bismuth instead of the nitrate our results were of a similar character.

By using potash instead of ammonia in these last experiments the proportion of hydrochloric acid was diminished.

M. Baudran has stated that contact with the alkali, far from destroying the sub-salt, increased its proportion. We verified this fact and found that a precipitate of oxide of bismuth, giving 3·45 per cent of acid when washed immediately, contained 6·20 per cent after three days, and 9·40 per cent after twenty days, or an increase of about 5 per cent of acid in twenty days.

The idea then occurred to us to precipitate the oxide of bismuth from an alkaline solution by means of an acid, instead of precipitating the acid solution by an alkali, profiting by the known property of oxide of bismuth of dissolving in potash in the presence of glycerin. This solution is precipitated by sulphuric acid.

The oxide obtained in this manner contains neither nitric nor sulphuric acids.

We commence by dissolving crystallised nitrate of bismuth in water in the presence of glycerin; we then add a solution of potash containing enough alkali to form an excess; we then saturate with dilute sulphuric acid, taking care not to add too much acid; for this purpose it is perhaps better to leave the solution with a slight alkaline reaction.

In this manner we obtain a white gelatinous product, which can be preserved in this state provided it is kept in water; it does not change on exposure to light. Even after prolonged washing with cold water it still retains small quantities of potash; when submitted to desiccation it becomes transformed into a greyish-white powder of a composition answering to the formula $Bi_2O_3.H_2O$.

To determine its composition we analysed three samples, each dried in a different manner:—

1. *In Dry Air.*

	Found. I.	Found. II.	Calculated for $Bi_2O_3.H_2O$.
Bi_2O_3	95·47	95·08	96·30
H_2O..	4·53	4·92	3·70

2. *In Sulphuric Vacuo.*

	Found. I.	Found. II.	Calculated for $Bi_2O_3.H_2O$.
Bi_2O_3	95·95	95·98	96·30
H_2O..	4·05	4·02	3·70

3. *In the Oven at* 100—105°.

	Found. I.	Found. II.	Calculated for $Bi_2O_3.H_2O$.
Bi_2O_3	96·36	96·04	96·30
H_2O..	3·64	3·96	3·70

Thus, by our method, we are able to obtain a hydrate of oxide of bismuth free from acid, and capable of preserving its gelatinous state, by precipitating the oxide from its alkaline solution by an acid, instead of precipitating it from its acid solution by an alkali.—*Bull. Soc. Chim.*, Series 3, vol. xxv., No. 3.

ALCOHOLATES OF ALUMINIUM. THEIR PROPERTIES AND THEIR REACTIONS.

By V. TISTCHENKO.

A current of dry hydrochloric acid decomposes the ethylate of aluminium with evolution of heat; this body changes into a brown liquid which solidifies on cooling. The reaction is fairly complex; there is not only alcohol and chloride of aluminium formed, the proportion of chlorine in the solid residue is lower than that corresponding with $AlCl_3$. The isobutylate and the isopropylate in solution in perchloride of carbon, treated with dry HCl, and kept either at the temperature of the laboratory or at 0° C., gave the reaction $Al(OR)_3+3HCl=AlCl_3.3ROH$. These solid compounds of $AlCl_3$ with the isopropylic and isobutylic alcohols are very hygroscopic; water decomposes them, forming alcohols.

With the halogen derivatives of the saturated carbides ethylate of aluminium does not form simple or mixed ether oxides, even when heated in sealed tubes; the experiment was tried with iodide of ethyl, bromide of ethyl, and chloroform. Neither does the isopropylate react with C_2H_5I at 100°; there is a certain reaction at 170—180°, but ether oxide is not formed.

Under the direction of the author, M. Gabounia treated the isopropylate of aluminium with dibromopropylic alcohol produced by the union of Br_2 with allylic alcohol; he obtained the following reaction:—

$$Al(C_3H_7O)_3+3CH_2Br\,CHBr.CH_2OH = Al(CH_2Br.CHBr.CH_2O)_3+3C_3H_7OH.$$

Dibromopropylate of aluminium forms a viscous colourless mass, absorbing moisture with rapidity, and decomposed by water into Al_2O_3 and dibromopropylic alcohol. Ethylate of aluminium reacts slowly in the cold on chloride of acetyl, but more rapidly on the water-bath, giving $AlCl_3$ and acetate of ethyl, but the return is far from the theoretical amount.

The author and his pupils have examined the action of some anhydrides on the alcoholates of aluminium; this action is of interest as it enables us to obtain salts of weak acids and aluminium.

Ethylate of aluminium with acetic anhydride gives acetate of ethyl and neutral acetate of aluminium; this body occurs as a white powder soluble in water; the solution does not become cloudy on boiling, but the addition of acetate of soda gives an abundant precipitate.

$Al(C_2H_3O_2)_3$ decomposes above 200° C., giving off CO_2, acetone, and acetic acid. A prolonged current of CO_2 over ethylate of aluminium moistened with benzene gives a colourless, semi-transparent mass, which is the salt $Al(CO_3C_2H_5)(OC_2H_5)_2$. In an analogous manner SO_2 gives the compound $Al(OSO.C_2H_5)_2(OC_2H_5)$.

The author and his pupils have also examined the decomposition of the alcoholates of aluminium by heat, besides examining the decomposition by heat of a number of alcohols, ether oxides, and aldehydes.—*Journ. Soc. Phys. Chim. R.*, vol. xxxi., p. 784.

ON THE COMPLEX SALTS OF PLATINUM. ALKALINE-EARTHY OXALONITRITES.

By M. VÈZES.

The platino-oxalonitrite of potassium,

$$Pt(C_2O_4)(NO_2)_2K_2+H_2O,$$

of which the preparation and principal properties have already been described (*Bull. Soc. Chim.*, Series 3, vol. xxi., p. 481; Chemical News, vol. lxxx., p. 63), serves as the starting point in the preparation of these new salts, also derived from a platino-oxalonitrous acid, which can be formulated thus:—$Pt(C_2O_4)(NO_2)_2H_2$.

I propose in this paper to examine the reactions by which alkaline-earthy platino-oxalonitrites can be formed in a similar manner.

1. *Action of Chloride of Barium on Platino-oxalonitrite of Potassium.*—When we make a solution of chloride of barium react on a solution of platino-oxalonitrite of potassium, we obtain reactions which are very different according to the conditions under which the operation is performed.

If we operate in the cold, using 1 molecule of chloride of barium for each molecule of platino-oxalonitrite, each salt being dissolved in the smallest possible amount of water, we obtain an abundant golden-yellow crystalline deposit in a few moments. The analysis of these crystals, of which the results are given below, leads to the formula $Pt(C_2O_4)(NO_2)_2Ba+5H_2O$, or a platino-oxalonitrite of barium. The double decomposition in cold solution, which has given rise to this new salt, has thus consisted of a change of metals between the two reacting salts; it can be represented by the equation:

I. $Pt(C_2O_4)(NO_2)_2K_2+BaCl_2=Pt(C_2O_4)(NO_2)_2Ba+2KCl.$

If we mix the same solutions boiling, containing the same relative quantities of the two reacting salts, we observe that the mixture rapidly becomes cloudy, giving a white crystalline precipitate. The analysis of this precipitate shows that it is free from platinum; it is the hydrated oxalate of barium, C_2O_4Ba,H_2O, containing 56·98 per cent Ba; calculated, 56·45. The whole of the barium used in the state of chloride being thus precipitated in the form of oxalate, the supernatant liquid is a solution of platinodichloronitrite of potassium, $PtCl_2(NO_2)_2K_2$, which can be obtained in the crystalline state after sufficient concentration. The double decomposition, effected in boiling solution, has thus consisted of a change between the groups CO_2 of the oxalonitrite and the atoms of chlorine of the chloride of barium; it can be represented by the equation:—

II. $Pt(C_2O_4)(NO_2)_2K_2+BaCl_2=PtCl_2(NO_2)_2K_2+C_2O_4Ba.$

Finally, we can get a third reaction, different to both the preceding ones, if we modify the proportions in which the two salts are made to react; by using only a demi-molecule of chloride of barium for each molecule of platino-oxalonitrite of potassium, and by operating in the cold, we observe the production of a yellow solution, which first remains perfectly limpid, and then after a few hours forms small yellowish-brown prisms, of a deeper colour than the platino-oxalonitrite of barium or the platino-oxalonitrite or platinodichloronitrite of potassium. The analysis of these crystals (see below), leads us to look upon them as a mixed platino-oxalonitrite of barium and potassium; they correspond in fact to the formula:—

$$Pt_2(C_2O_4)_2(NO_2)_4BaK_2,4H_2O=$$
$$=Pt(C_2O_4)(NO_2)_2Ba,Pt(C_2O_4)(NO_2)_2K_2,4H_2O,$$

and result from a reaction analogous to No. I., but in which the change of metals has only been partial:—

III. $2Pt(C_2O_4)(NO_2)_2K_2+BaCl_2=$
$$=Pt_2(C_2O_4)_2(NO_2)_4BaK_2+2KCl.$$

This reaction is also produced without the precipitation of barytic oxalate, if we mix warm solutions (80°) of the two salts in the proportions given above. The precipitate of barytic oxalate only appears if we operate at a boiling temperature, and even then it only occurs with a small portion of the barium present, so that the filtrate will still give a good return of barytopotassic-platino-oxalonitrite. In this case the mother-liquor, concentrated in its turn, gives a deposit of platinodichloronitrite of potassium, resulting, like the barium oxalate first obtained, from the reaction (II.) effected on a part of the reacting mixture.

The two new salts which have just been described, platino-oxalonitrite of barium and platino-oxalonitrite of barium and potassium, form a series with platino-oxalonitrite of potassium,

$$Pt(C_2O_4)(NO_2)_2Ba+5H_2O,$$
$$Pt_2(C_2O_4)_2(NO_2)_4BaK+4H_2O,$$
$$Pt(C_2O_4)(NO_2)_2K_2+H_2O,$$

which does not admit of any other term.

If, in fact, we cause chloride of barium and platino-oxalonitrite of potassium to react in any other proportions than those given above, we do not obtain new salts, but mixtures of the preceding ones; for example, the action of 1 molecule of platino-oxalonitrite of potassium on less than half a molecule of chloride of barium gives very plainly a deposit of the barytopotassic salt, quickly followed by a second crystalline deposit of a much lighter colour, and which is nothing else than the excess of the potassium salt used.

These results collectively should apparently be interpreted as follows:—The platino-oxalonitrite of barium, formed by the reaction I., is the normal product of the action of chloride of barium on platino-oxalonitrite of potassium. But it decomposes in aqueous solution, slowly in the cold and rapidly on boiling, with a deposit of hydrated oxalate of barium; in the presence of a chloride this deposit is accompanied by the formation of a platinodichloronitrite (reaction II.). This decomposition is facilitated by the presence of an excess of chloride of barium or potassium; on the other hand, it is retarded by the presence of an excess of platino-oxalonitrite of potassium; but, in the latter case, the barium salt, thus rendered more stable, becomes united to the excess of the potassium salt, and forms a mixed baryto-potassic salt (reaction III.).

2. *Platino-oxalonitrite of Barium.*—The examination which has just been described of the possible reactions between platino-oxalonitrite of potassium and chloride of barium leads, as far as it concerns the platino-oxalonitrite of barium, to the following method of preparation, which has been used for obtaining considerable quantities of this salt (about 200 grms.), which were necessary for the preparation of other oxalonitrites.

The platino-oxalonitrite, which is the starting-point of

this preparation, is obtained by the method already described (*loc. cit.*), with one single modification. With a view to increasing the yield of the operation, the yellow liquor containing the salt is evaporated down before cooling, so as to reduce its volume from 2 litres to about half a litre. Thus we immediately obtain 180 grms. of the salt instead of 160 grms. without interfering with its purity, while still starting with 200 grms. of the hydrated platinonitrite; the theoretical return is 190 grms., and not 210 grms. as was previously stated by mistake (*loc. cit.*).

The reaction it is desired to produce between the two solutions should take place in the cold, and as the platino-oxalonitrite of potassium is only slightly soluble in cold water the amount of material employed is limited by the volume of the solution in use. For each operation I used 70 grms. of the pure salt; this was dissolved in boiling water (about a litre), and then diluted with cold water, bringing the total volume to 5 litres. After completely cooling, 150 c.c. of a cold solution of chloride of barium, containing 1 molecule of the salt per litre, was poured slowly in with constant stirring. The solution, which is first of a pale yellow colour, becomes darker, and a crystalline deposit of platino-oxalate of barium is slowly formed. This deposit is complete in a few hours: if we wait too long we observe white patches of oxalate of barium appear on the golden-yellow crystals of the salt; this is caused by the decomposition of the portion still remaining in solution.

After decanting and draining the crystals left, they are re-dissolved as rapidly as possible in about a litre of boiling water. There is still a slight deposit of oxalate of barium formed in this operation; it is separated by filtration, and the filtrate left to cool. The platino-oxalonitrite of barium crystallises immediately, and this time is perfectly pure; it is collected rapidly and dried between filter-paper. In this way, starting with the above mentioned weight of material, 62 grms. of the pure crystallised salt are obtained; theory requires 90 grms. The missing 28 grms. exist partly in the 5 litres of the mother-liquor from the double decomposition, and partly in the litre of mother-liquor from the re-crystallisation; but their extraction in the form of the barium salt is impossible, the prolonged evaporation it has been necessary to submit these 6 litres of liquid to, having had the effect of precipitating all the barium in the form of oxalate, while the platinum has passed into the state of platinodichloronitrite of potassium (reaction II.). We might therefore make use of this transformation to prepare this platinodichloronitrite from residues. It is, however, better to add an excess of oxalate of potassium to the boiling mother-liquors. This transforms the platinodichloronitrite into platino-oxalonitrite of potassium, which is much less soluble, and therefore much easier to collect by cooling. We also recover practically all the potassium salt which has not been used in the reaction.

Platino-oxalonitrite of barium occurs in the form of golden-yellow crystals; under the microscope these crystals generally appear as elongated parallelograms, of which the acute angle is about 68°; they act on polarised light, and have a position of extinction parallel to one of the sides of the parallelogram. When dried in the cold between blotting-paper these crystals do not change in the air.

They contain 5 molecules of water of crystallisation, which they lose with difficulty when heated; ten days in an oven at 110—120° are not sufficient to dehydrate them completely. It is only at about 200° after several hours that their dehydration can be effected.

The examination of this dehydration denotes the probable existence of at least two distinct hydrates, of which it will be of interest to estimate the saturated vapour tension. We observe, in fact, that on gradually heating a sample of the salt it commences to effloresce at about 70°, and at the same time its colour changes to cinnabar-red; this gradually becomes deeper and deeper until it is almost black. A weighing made at this moment shows that the salt has lost nearly three molecules of water out of the five. On continuing the dehydration the colour becomes less deep again, changing first to bright red, and then to bright orange-red; it finally becomes orange-yellow, and ceases to lose water; the dehydration is then complete.

If the temperature is then raised to 275° we see an altogether different phenomenon analogous to that already described (*loc. cit.*) for platino-oxalonitrite of potassium. The salt decomposes rapidly with considerable swelling up, but with no projections; it becomes completely black, the platinum being set free. But while the decomposition of the potassium salt was accompanied with a disengagement of carbonic acid gas, the potassium remaining in the state of nitrite according to the equation $Pt(C_2O_4)(NO_2)_2K_2 = Pt + 2NO_2K + 2CO_2$, the barium salt, on the contrary, decomposes with the evolution of nitrous fumes, the barium remaining in the state of oxalate (sometimes partly transformed into carbonate, with the evolution of carbonic oxide, as shown by the figures quoted below of the analysis of the salt). This decomposition should therefore be expressed—

$$Pt(C_2O_4)(NO_2)_2Ba = Pt + C_2O_4Ba + 2NO_2.$$

Platino-oxalonitrite of barium is soluble in ten times its weight of boiling water, and in forty times its weight of cold water. This solubility, as well as the facility with which it is prepared, renders it valuable for the preparation of other oxalonitrites by double decomposition with the metallic sulphates. But these solutions are not very stable; very slowly in the cold, and more rapidly when boiling, they deposit crystallised oxalate of barium.

The analysis of platino-oxalate of barium was done by the same methods as were used for the potassium salt except for the estimation of the metals; this dehydrated salt is decomposed at 275°, and then heated to redness, which transforms the oxalate into carbonate; the residue is washed with dilute hydrochloric acid; the remaining platinum is weighed, and the barium in the filtrate estimated as sulphate. In this manner we obtained the following results:—

I. 0·6334 grm. of material, heated to 160°, lost 0·0926 grm. of water. The dry residue, heated to redness, weighed 0·4120 grm.; after washing with dilute hydrochloric acid it gave 0·2047 grm. of platinum, and 0·2247 grm. of sulphate of barium, containing 0·1440 grm. of barium.

II. 0·7200 grm. of material, heated to 200°, lost 0·1085 grm. of water. The dry residue, after decomposition at 275°, weighed 0·4938 grm.; after calcination at a red heat it weighed 0·4639 grm. When treated as before it gave 0·2743 grm. of sulphate of barium, containing 0·1614 grm. of barium.

III. 0·4454 grm. of material, treated in the same manner, gave 0·1442 grm. of platinum.

IV. 0·5803 grm. of material, heated to 200°, lost 0·0857 grm. of water. The dry residue, heated to redness, weighed 0·3766 grm. After washing with dilute hydrochloric acid it gave 0·1879 grm. of platinum, and 0·2180 grm. of sulphate of barium, containing 0·1283 grm. of barium.

V. 0·5056 grm. of material, after decomposition at 275°, gave a residue weighing 0·3474 grm.; after heating to redness, a residue of 0·3303 grm. and after calcination with an excess of sulphuric acid a residue of 0·3605 grm.

3. *Baryto-potassic Platino-oxalonitrite.* — This salt, which is obtained in the manner already described, occurs in the form of small brownish-yellow prisms. Under the microscope its crystals have the appearance of elongated rectangles; they act on polarised light, and their positions of extinction are parallel to the sides of the rectangle. When dried in the cold between filter-papers these crystals do not change in the air.

With regard to the action of heat, their properties are analogous to those which have been described for the normal barium salt. Like the latter the baryto-potassic salt is difficult to dehydrate, and gives rise to very marked changes of colour; at about 253° it decomposes with

efflorescence, giving off nitrous fumes, leaving a residue of platinum and oxalates of barium and potassium—

$Pt_2(C_2O_4)_2(NO_2)_4BaK_2 = 2Pt + C_2O_4Ba + C_2O_4K_2 + 4NO_2$.

This manner of decomposition, in which the baryto-potassic salt behaves quite differently to a mixture of the salt of barium with that of potassium (see above), is of special importance, since it furnishes proof of the individuality of the salt. Beyond this its colour, which is much deeper than that of the salt of barium or potassium, is also sufficient to exclude the hypothesis of a simple mixture, and its proportion of water of crystallisation, which, as has been shown, is not the mean of that of these two salts, further confirms this conclusion.

The solubility of baryto-potassic platino-oxalonitrite in water appears to be a little higher than that of the normal barium salt. Its analysis has given the following results:

I. 0·3584 grm. of material, after calcination at red heat and washing with water, left a residue (Pt and CO_3Ba), of 0·2053 grm.; the washings, evaporated to dryness with sulphuric acid, gave 0·0660 grm. of sulphate of potassium, containing 0·0297 grm. of potassium; the residue, treated with dilute hydrochloric acid, gave 0·1331 grm. of platinum, and 0·0859 grm. of sulphate of barium, containing 0·0505 grm. of barium.

II. 0·6096 grm. of material, heated to 220°, lost 0·0426 grm. of water. The dry residue, after digestion with hydrochloric acid, gave 0·2261 grm. of platinum, 0·0926 grm. of chloride of potassium containing 0·0486 grm. of potassium, and 0·1430 grm. of sulphate of barium containing 0·0841 grm. of barium.

III. 0·5411 grm. of material, after calcination at red heat, left a residue (platinum and carbonates of barium and potassium) weighing 0·3782 grm.; its treatment with dilute hydrochloric acid, and then with sulphuric acid, gave 0·1248 grm. of sulphate of barium containing 0·0734 grm. of barium.

IV. 0·4344 grm. of material, heated to redness with excess of tungstic acid, gave 17·6 c.c. of nitrogen at 760 m.m., weighing 0·0220 grm., and 38·9 c.c. of carbonic acid, weighing 0·0764 grm. and containing 0·0208 grm. of carbon.

4. *The Case of Strontium and Calcium.*—Experiments analogous to those which have been described were made with the chlorides of strontium and calcium. The action of these salts on platino-oxalonitrite of potassium appears to be analogous to that of chloride of barium; at first the liquid becomes strongly yellow. But, even when operating in the cold, we cannot here prevent the appearance, a few moments after mixing, of the alkaline-earthy oxalate precipitate which denotes that Reaction II. has taken place; that is to say, the destruction of the platino-oxalonitrite of strontium or calcium, apparently formed in the first instance, and too soluble to be deposited without previous concentration. Further, this precipitation of strontium or calcium in the form of oxalate is soon finished, especially if we concentrate the mixture by evaporation with a view of obtaining a mixed oxalonitrite. All the platinum passes into the state of platinodichloronitrite of potassium, so that it has not been possible up to the present to obtain salts of strontium and calcium analogous to the salts of barium which have just been described, on account of the instability of their aqueous solutions.—*Bull. Soc. Chim.*, Series 3, vol. xxv., No. 3.

A New Glucoside, Methylene-glucose, obtained with Glucose, Formic Aldehyde, and Hydrochloric Acid.—B. Tollens.—500 grms. of glucose, 500 grms. of formic aldehyde at 40 per cent, 50 grms. of concentrated hydrochloric acid, and 50 grms. of acetic acid are left together in contact for several months; the crystals obtained crystallise in boiling water in needles, and have the formula $C_{10}H_6(CH_2)O_6.\frac{1}{2}H_2O$. This molecule of water goes off at 100°. The body melts at 187—189°, previously softening at 180°, $(\alpha)_D = +9·3°$; it reduces Fehling's solution, absorbing $1\frac{1}{2}O$, while glucose absorbs $2\frac{1}{2}O$. Its osazone, $C_{19}H_{22}N_4O_4$, is a yellow powder, fusible at 164—166°, after softening at 160°. Methylene glucose does not ferment with brewers' yeast; it gives a yellow precipitate with phloroglucine and hydrochloric acid.—*Berichte*, vol. xxxii., p. 2585.

SOME PRINCIPLES AND METHODS OF ROCK ANALYSIS.*

By W. F. HILLEBRAND.

(Continued from p. 138).

VIII. *Aluminum. Total Iron. Indirect Method for Aluminum.*

THE common practice in this laboratory is to find alumina by difference, after deducting from the precipitate produced by ammonia or sodium acetate the sum of all other oxides this precipitate may contain. Of these, only ferric oxide, titanic oxide, and the trace of silica are determined in this portion (see also last footnote, next column), those of phosphorus, vanadium, chromium, and zirconium being looked for in other portions of the rock powder. This throws upon the alumina all errors involved in their separate determinations; but these may balance, and in any case the probable error can hardly be as high as that involved in the direct weighing of the alumina itself, considering the difficulty of effecting a satisfactory separation of it from all the other admixtures—an operation which would, moreover, immoderately extend the time required for each analysis.

Precipitation of Aluminum, Iron, &c.

Precipitation by Ammonia.—Two precipitations by ammonia at boiling heat are usually quite sufficient to separate iron, aluminum, phosphorus, vanadium, chromium, titanium, and zirconium, if all these are present, from nickel, manganese, the alkaline-earth metals, and magnesium, provided ammoniacal salts are present in sufficient quantity. This last point is of special importance as regards magnesium, and failure to observe it is doubtless the reason why many old analyses, and sometimes modern ones, show utterly improbable percentages of alumina, especially as chemists were formerly often satisfied with a single precipitation. The necessary ammonium chloride is better obtained by the use of purified ammonia water and hydrochloric acid than by the addition of the solid salt, which is seldom pure.

Precipitation by the Basic Acetate Method.—But it will occasionally happen that the separation from even very small amounts of manganese is altogether incomplete, and the uncertainty of ensuring this separation has led the writer of late to employ the basic acetate method for the first precipitation in all cases where manganese is present—and the exceptions are few—even though the precipitation of alumina is sometimes less complete than by ammonia, and in spite of other admitted defects, as, for instance, a tendency of the precipitate to run through the filter on washing.† Not more than 2, or at most 3, grms. of sodium acetate need be used. After slight washing and sucking dry at the pump, the precipitate is re-dissolved in a large excess of hydrochloric acid and re-precipitated by ammonia in slight excess. The complete boiling off of this excess is unnecessary, as pointed out by Genth and Penfield, since it is apparently the washing with pure water and not the free ammonia which carries small amounts of alumina into the filtrate. Penfield and Harper (*Am. Journ. Sci.*, 1886, Series 3, vol. xxxii., p. 112) recommend washing with a dilute solution of ammonium nitrate (20 c.m.³ nitric acid, neutralised by ammonia, to the litre), and also the solution of the first precipitate in nitric acid instead of hydrochloric acid, in order to shorten the washing, there being no chloride to remove.

The filtrates are strongly concentrated separately* in platinum, a drop or two of ammonia being added toward the end to the second one, and filtered successively through the same small filter into a flask of 150 to 200 c.m.³ capacity, the ammoniacal filtrate serving as wash-water for the first dish and containing enough ammoniacal salt to prevent precipitation of magnesium in the first filtrate when mixed with it. If manganese has been deposited upon the surface of the dish, it is removed by hydrochloric and a drop or two of sulphurous acids, which mixture is then passed hot through the filter. A re-precipitation by ammonia is then made, and the precipitate collected again on the filter and added to the main one, the filtrate passing into the flask containing the previous one. If much manganese is present, of course a second precipitation by ammonia of the small precipitate may be required. In these cases there is no difficulty in getting all the manganese into the filtrate.

Ignition of the Precipitate.

The combined precipitates of alumina, &c., are ignited moist, in the paper, unless considerable iron is present, when the main one is dried, removed as far as possible from the paper, and the latter ignited separately to prevent partial reduction of a portion of the iron, which cannot then be wholly re-oxidised by heating or by treatment with nitric acid (see p. 101).

Alumina, in the quantities ordinarily found, cannot be fully dehydrated by the full heat of the Bunsen burner; it must be blasted for five or ten minutes. If iron is present in large amount, this last operation must be conducted so as to insure free access of air to the crucible (p. 137).

Recovery of Silica and Possible Barium in the Alumina Precipitate.

The precipitate is dissolved by fusion with acid potassium sulphate, an operation which is accomplished without trouble in from two to four hours if the temperature is kept low and the acid salt has been properly made free from water and excess of acid. The melt is taken up with hot water and considerable dilute sulphuric acid, the residue collected, weighed, and corrected by hydrofluoric and sulphuric acids for silica, which, as said before, rarely amounts to 1 m.grm. in weight, and further examined for barium (see p. 137) by dissolving any remaining residue in hot strong sulphuric acid and diluting with cold water.†

Estimation of Iron in the Precipitate of Alumina, &c.

Without regard to the presence of Vanadium.— The filtrate obtained in the preceding paragraph is reduced, hot, by hydrogen sulphide, boiled to collect sulphur, and the platinum sulphide‡ resulting from the bisulphate

* *Bulletin of the United States Geological Survey*, No. 176.

† The fact must not be overlooked that certain of the rare earths may pass completely into the filtrate if the basic acetate method is followed. If then, later, on rendering the combined filtrates ammoniacal, an unexpectedly large precipitate appears; this should be carefully examined as to its nature. In an analysis of piedmontite from Maryland over 2 per cent of rare earths, including cerium and others not identified, were quantitatively separated in this way from iron, alumina, &c.

* If, instead of sodium acetate, ammonia alone has been used to precipitate alumina, &c., it has sometimes happened in the experience of others than the writer that on concentration of the first filtrate a pale straw-coloured precipitate appeared, which remained on the filter with the traces of alumina that may also separate, although it is slowly soluble in hot water. This is said to be some compound of platinum, and attention is called to it here for the guidance of others who may notice it and be unaware of its character.

† Some years ago, in a series of analyses of rocks from the Leucite Hills, in Wyoming, there was obtained at this stage, when it was customary to dissolve the melt in cold water preliminary to precipitation of titanium by boiling the neutralised sulphuric solution in presence of sulphur dioxide, a white, more or less flocculent residue amounting to 1 to 3 per cent of the rock, which was at first taken to be a mixture of tantalic and columbic acids. Eventually it was found to consist apparently of nothing but TiO_2 and P_2O_5, with perhaps a little ZrO_2. By repeated fusion with acid potassium sulphate and leaching with cold water, it could be gradually brought into solution. It was these rocks which furnished the most striking instance of the peculiar milky sulphate residues mentioned on p. 137 as derived from the ignited silica. Knop (*Zeit. für Kryst.*, 18[8]5, vol. x., p. 73) seems to have obtained a similar mixture in analysing minerals from the Kaiserstuhl, in Baden, but its nature was not ascertained, though suspected to be, if not silica, columbiferous titanic acid.

‡ It may be mentioned that the precipitation of platinum from a hot sulphate solution is far quicker and cleaner than from hydrochloric acid. Further, this platinum sulphide, when ignited in he

fusion, the hydrogen sulphide being allowed to pass for a short time after boiling. It is then filtered* hot into a flask attached to a carbonic acid apparatus and brought to boiling to expel hydrogen sulphide. When this is fully effected, the flask is cooled in water while the carbon dioxide still passes, and the solution is then titrated by potassium permanganate. The results are strictly accurate, with the limitations set forth in the paragraph below, when care is taken with the reduction by hydrogen sulphide. The method is altogether superior to that involving the use of zinc, since no foreign impurity affecting the result is introduced and the ever-present titanium is not affected, nor is vanadium reduced below the condition of V_2O_4, whereas nascent hydrogen converts it, in part at least, to V_2O_3. Titanium can be conveniently estimated by adding hydrogen peroxide to the titrated iron solution (see *prox.*).

Having regard to the presence of Vanadium. — If vanadium is present the value found for iron will be in error by the amount of permanganate required to oxidise V_2O_4 to V_2O_5. The amount of the correction will differ according as titration of the iron is made after reduction by hydrogen sulphide or by nascent hydrogen. If the former is used, as should always be the case, because of the ever present titanium, the vanadium is reduced by it to V_2O_4, which in its action on permanganate is equivalent to two molecules of FeO, while the reduction goes further with hydrogen. After the first transitory pink blush throughout the liquid, the slower-acting vanadium may require the addition of a drop or two more of permanganate before a comparatively permanent colouration appears.

When the amount of vanadium in the rock is known a correction can be applied on the assumption that practically all the vanadium is here collected, a point that needs further investigation. Various authors assert its precipitability with alumina and iron by ammonia and ammonium-acetate, though Carnot (*Comptes Rendus*, 1887, vol. civ., p. 1803; *Zeit. für Anal. Chem.*, 1893, vol. xxxii., p. 223), states that repeated precipitation by ammonia, ammonium carbonate, or ammonium sulphydrate, separates it from iron. The writer's experience with ores very rich in vanadium shows that precipitation along with iron and aluminum is only partial. Ridsdale (*Journ. Soc. Chem. Industry*, 1888, vol. vii., 73), has determined its precipitability with various metals, and gives numerous figures which show an approximation to 90 per cent thus thrown down under the conditions prevailing in analysis of iron slags, the remainder passing into the filtrates, and appearing in small part with the lime, and to a greater extent with the magnesium phosphate. For all practical purposes it is probably safe to assume that the small amounts of vanadium met with in rocks are wholly in the alumina precipitate.

If the amount of vanadium in the rock is not known, and great accuracy is necessary, caution requires the determination of the total iron to be made either in a separate portion or after re-precipitation from the above solution, as follows:—Fuse with sodium carbonate, extract with water, bring the insoluble residue into sulphuric solution, reduce, and titrate as above directed. But unless a certain precaution is here observed an error greater than that which it is designed to avoid will be committed. Contrary to general belief the aqueous extract from the sodium-carbonate fusion carries a small but appreciable fraction of a per cent of iron, as the writer has repeatedly found by actual test. This iron is thrown out with the alumina (and silica, if present), by the usual methods of neutralising the alkaline solution, and can be brought to light when the precipitate thus formed is treated with a fixed caustic alkali, or again fused with sodium carbonate, and leached with water, when it remains wholly or in part undissolved. Hence it is necessary to collect this iron, and add it to the main portion before titration.

Determination of the true Value for Ferric Iron.

Having in one way or another found the total iron in the rock, it remains to deduct an amount equivalent to the ferrous oxide the rock contains, and a further amount corresponding to the sulphides often present, in order to get what may pass for the true value for ferric iron. That this is often only an approximation appears from the difficulties due to the presence of vanadium, and the generally indeterminable effect of sulphides on the ferrous oxide determination. (See *prox.*).

(To be continued).

crucible in which the bisulphate fusion was made, should weigh, together with the crucible itself, what the latter weighed before the main silica precipitate was ignited in it; in other words, the weight of the platinum recovered by hydrogen sulphide should equal the loss in weight of the crucible due to attack by the bisulphate. In somewhat rare instances this will not be so, but the weight will be greater, showing a gain in platinum which may amount to a milligrm. Tests have shown that this is not due to retention of platinum by the main Al_2O_3, &c., precipitate; hence, it must come from platinum mechanically loosened from the dish during the drying and powdering of the silica preparatory to its collection on the filter, or to some insoluble compound of platinum formed during evaporation and drying of the silica. It may also be in part or wholly due to contamination from reduction of platinum during evaporation of the filtrate from the basic acetate separation. It will be remembered that from this filtrate a small amount of iron and alumina is recovered and added to the main precipitate. Hence it is always well in fine work to collect the sulphide and weigh the platinum in the original crucible, deducting any excess from the alumina, or else to get rid of the platinum by hydrogen sulphide before proceeding to the precipitation of alumina, &c. (see p. 138).

* Filtration is not necessary if only precipitated sulphur and no sulphides are in suspension, since this is without reducing action on cold permanganate solution, as Wells and Mitchell, and others before them, have pointed out. The above authors used this method of reducing ferric iron in titanic iron ores (*Journ. Am. Chem. Soc.*, 1895, vol. xvii., p. 78; also Chemical News, 1856, vol. lxxiii., p. 123).

PROCEEDINGS OF SOCIETIES.

PHYSICAL SOCIETY.

Ordinary Meeting, March 22nd, 1901.

Prof. S. P. Thompson, President in the Chair.

By invitation of Professors Callendar and Ramsay, this meeting was held in University College.

A paper "*On the Expansion of Silica*" was read by Prof. Callendar.

The extreme smallness of the thermal expansion of silica (fused quartz) renders the determination of its coefficient of expansion more difficult than is the case with many substances. The author has made experiments upon a rod of pure silica 40 c.m. long and 1 m.m. diameter. This rod was enclosed in a platinum tube about 3 m.m. diameter, which could be raised to various temperatures by the passage of a suitable electric current. Both the rod and the tube were firmly fixed at one end, and the positions of the other ends were accurately observed by a micrometer microscope reading to a thousandth of a m.m. The expansion of the tube, in conjunction with a knowledge of its coefficient of expansion, served as a means of determining the temperature of the tube, and therefore of the rod. The increase in length, the original length, and the range of temperature of the silica being known, the coefficient of expansion can be at once calculated. In some previous experiments the author has investigated the distribution of temperature along a heated platinum rod subjected to cooling at the ends. These experiments prove that the error due to end effect, in the case of the silica rod, can be neglected.

The expansion of silica up to 1000° C. is regular, and is about one-seventeenth that of platinum. Between 1000° C. and 1400° C. silica expands more quickly than below 1000° C., and if left at any temperature for a considerable time continues to slowly increase in length. If a curve be plotted, having temperatures as abscissæ and increases in

length as ordinates, a straight line will represent the expansion of silica up to 1000° C. Above 1000° C. the curve bends upwards, and upon cooling it returns along a path above the ascending curve, so that the final length of the bar is greater than the original length when the lower temperature is reached. The determination of the coefficient of expansion at these high temperatures was made by means of a variable zero; that is, by using for the length of the rod that obtained by suddenly cooling from the higher to the lower temperature. At 1400° C., the properties of silica alter, and the expansion is replaced by a contraction. On cooling from above 1400° C. to ordinary temperatures, there is first an expansion and then a contraction. This property was illustrated by Prof. Callendar, the small changes in length of the rod being magnified by a lever and shown upon a screen by an optical arrangement. The critical point at which contraction occurs on heating has been found by Le Chatelier at about 800° C. His experiments were made by a differential method, using porcelain as a standard substance. As the expansion of porcelain is uncertain, the author thinks it probable that the effect noticed may be due to irregularities in the expansion of porcelain rather than in that of silica.

Mr. BOYS expressed his interest in the experiments and asked if the small coefficient of expansion of slate had ever been measured. The small expansion of silica would make it a useful suspension for pendulums, on account of the small compensation necessary. Its perfect elastic properties might be made use of in hair springs for chronometers.

Prof. THRELFALL said that he had tried to measure the expansion of silica between 0° C. and 70° C. by weighing rods in distilled water, but the method was not accurate. He had made experiments similar in principle to the authors, using temperatures from 0° C. to 100° C. The devitrification of silica is troublesome, and he thought that the rate of devitrification in presence of air increased with the temperature.

Dr. DONNAN thought that the irregularities in the expansion of silica pointed to a complex composition.

Mr. PORTER (Eton) asked if the effect of fused quartz on polarised light had been investigated, and if this effect altered after heating to 1400° C.

Mr. BOYS said quartz rods formed by fusion depolarised light.

The CHAIRMAN said that he had noticed the effect spoken of by Mr. Boys, due to strain, but he had been unable to detect any rotatory power.

Prof. CALLENDAR, in reply to Mr. Lupton, said that the expansion of quartz crystals was much larger than that of fused silica.

The Spectroscopic Apparatus of University College was then exhibited by Dr. BALY.

The Society then adjourned until April 26th, 1901.

Constitution of Gentianose.—Em. Bourquelot and H. Hérissey.—Gentianose is a hexotriose, to which the formula $C_{18}H_{32}O_{16}$ can be given. This formula demands a molecular weight of 504, and the authors have found by Raoult's method 494·3.—*Comptes Rendus*, cxxxii., No. 9.

Action of Cyanide of Potassium on the Fatty Aldehydes.—L. Kohn.—Cyanide of potassium reacts very briskly on formic aldehyde, to such an extent, in fact, that if it is not kept cool the whole begins to boil, and the mixture rapidly becomes black. By keeping it cool we obtain a mixture of glycolate of potassium and hexamethylenetetramine,—

$$10CH_2O + 4CNK + 2H_2O = (CH_2)_6N_4 + 4CH_2OH—CO_2K.$$

By operating with a solution of an equimolecular mixture of cyanide of potassium and chloride of calcium we obtain a deposit of carbonate with crystals of glycolate of calcium.—*Mon. f. Chim.*, vol. xx., p. 903.

NOTICES OF BOOKS.

A Manual of Elementary Science; A Course of Work in Physics, Chemistry, and Astronomy for the Queen's Scholarship Candidates. By R. A. GREGORY, F.R.A.S., Professor of Astronomy, Queen's College, London, and A. T. SIMMONS, B.Sc. (Lond.), Associate of the Royal College of Science, London. London: Macmillan and Co., Limited. New York: The Macmillan Company. 1901.

THIS book is an attempt to give a small amount of knowledge upon a vast number of subjects to meet the requirements of students of elementary science with the view of presenting themselves in that subject at the "Queen's Scholarship examination." The arrangement of the subject matter is good, and much pains have been taken to encourage the student to construct apparatus and make experiments to demonstrate the principles involved. Unfortunately, as is nearly always the case where much has to be condensed into a very small space, many of the descriptions are too meagre to be of any value to the student, and in some cases the authors attempt to describe apparatus of which they apparently have no knowledge. An instance of this is to be seen on page 103 in the drawing and description of a Sprengel air-pump. We should not have thought it possible for such a totally erroneous and absurd description of a common piece of apparatus to appear in an educational book in the year 1901! Similar carelessness is shown in the description of how to make a thermometer on page 112; the student is told to "procure an empty thermometer tube with a bulb at one end. (If a blowpipe is available a bulb can easily be blown upon one end by melting the glass in the flame, and blowing down the open end while the other end is molten)."

Such a description, and what follows as to filling such a tube with mercury are utterly valueless, and would only mean failure and disappointment to any student who attempted to follow it!

There are a large number of illustrations, both old and new, some of which leave much to be desired. By far the best part of the book is that devoted to astronomy; here both the illustrations and the descriptions are exceedingly good, and partly atone for the shortcomings of the preceding chapters. There is a good index, and the price is moderate.

Modern Chemistry, Theoretical and Systematic. In two volumes. By WILLIAM RAMSAY, D.Sc. London: J. M. Dent and Co. 1900. Pp. 330.

THOUGH called "Modern Chemistry" these two volumes have in their title-pages and frontispieces a decidedly "old" appearance; the portraits of the Hon. Robert Boyle and John Dalton remind us of the good old days when practically all chemical science could be carried in one head.

The author first deals with the "phlogiston" theory which was conceived by Stahl early in the eighteenth century. In this connection we note that he suggests the word "burnableness" as the translation of "phlogiston." Surely "inflammability" would be equally good, and less clumsy. He then rapidly passes over the discovery of gases, Dalton's laws, Avogadro's hypothesis, atomic and molecular weights, &c., and in Chapter IV. he considers the classification, periodicity, and valency of the elements.

The second volume is on systematic, or what is more commonly called practical chemistry, though while describing the preparation and properties of the salts and compounds met with in inorganic chemistry it does not appear to deal with any system of chemical analysis.

Some of the ideas introduced by the author are of an original kind, but on the whole we think these two volumes are more suitable for thoroughly grounded chemists than for students.

CORRESPONDENCE.

AMERICAN *v.* ENGLISH SPELLING.

To the Editor of the Chemical News.

Sir,—I entirely agree with your reviewer in his remarks anent American spelling, and cannot see that Dr. Carrington Bolton has made out any case for his objection to them. The way in which Americans spell their words is entirely a matter for themselves: if they prefer "sulfur," as in French, by all means let them have it; but I must emphatically deny that it is English.

English spelling is to a great extent bound up with the history of our nation, but in America they have no history and but little veneration.

It is really absurd to describe *English* spelling as "erroneous" and to sneer at it as "archaic" simply because four American professors appointed as a committee in 1888 decided to alter it—in America.

Dr. Carrington Bolton asks for peace, but we are bound to defend our language from the entirely unnecessary innovations of American spelling "reformers." Does not Dr. Carrington Bolton well know that the addition of an "e" to the word "oxid" changes the sound of the "i" from short to long, "oxīd" to "oxide"? The same applies to "chlorīn," "bromīn," &c.

There is another point to which I should like, Sir, to call your attention, and that is the mischievous American use of the word "billion," which word has recently been brought into prominent notice in connection with the "Steel Trust." Now a "billion" is a million million, or a million to the second power $1{,}000{,}000^2$, that is 1,000,000,000,000; in America the word "billion" is used to express one thousand millions, 1,000,000,000, and is the same as the French milliard.—I am, &c.,

An English Chemist.

SEPARATION OF FERRIC CHLORIDE FROM OTHER METALLIC CHLORIDES BY ETHER.

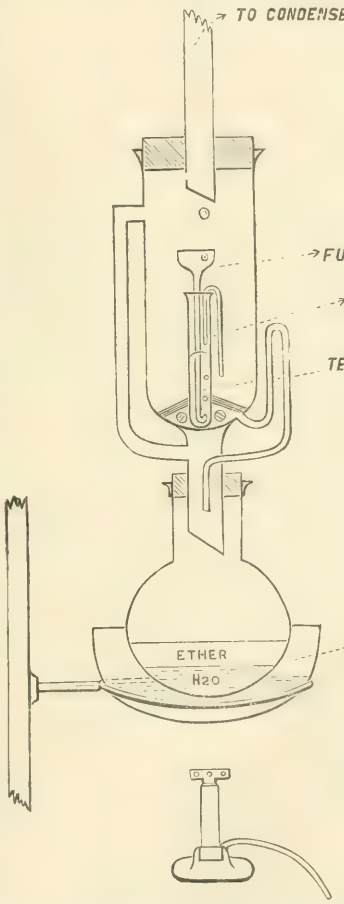
To the Editor of the Chemical News.

Sir,—It may be interesting to Mr. Speller and other readers to give the details of a method used for estimating nickel in steel in a laboratory with which I was connected some time ago. I am indebted to the late Mr. Thomas Hilditch for the details of the method.

1 grm. of the steel was dissolved in HCl, oxidised with HNO_3, and taken to dryness. It was re-dissolved in HCl, and evaporated to a thick syrup, in a small ½-oz. beaker, but not low enough to turn basic; it was now transferred to a small test-tube about 3" long and ⅝" diameter, the beaker being washed into the tube with the *minimum* amount of dilute HCl, made from HCl (1·2) 1 part, and water 1 part. Total bulk should not now exceed 25 or 30 c.c.

The tube was put into a Soxhlet's fat extracting apparatus, and a small funnel put into the tube to cause the ether to circulate through the test liquid. (See diagram). The apparatus is started, and can now proceed without further attention. At the end of one or two hours the ethereal extract will be quite colourless, showing that the iron has been taken out, and a green solution will be present in the test-tube. The ether is decanted off as much as possible, and the solution transferred to a beaker, and boiled to expel all the remaining ether, acidified with a few drops of HCl, and, in the absence of chromium, a slight excess of ammonia added; the traces of iron, if any, remaining behind, are precipitated. These are filtered off, and the clear blue solution titrated with a standard solution of potassic cyanide, using silver iodide as an indicator. The AgI was precipitated in the solution by adding a measured amount of silver nitrate and excess of KI to produce a slight turbidity. The same amount of $AgNO_3$ of course being added to the solution of nickel used in standardising the KCN, and running in KCN until solution is faintly opalescent in each case

The Soxhleting operation can be much shortened by previously giving the solution of the steel "a wash" with ether by pouring ether down the small funnel.



The water in the bottom of the flask washes most of the ferric chloride out of the ether as well as heating the ether more moderately.

If chromium is present as well the nickel is separated after "Soxhleting" by means of bromine and NaHO, the washed precipitate re-dissolved in HCl, boiled, and ammonia added as before.—I am, &c.,

H. Procter Smith.

Harrington Road, Workington.
March 19, 1901.

RAPID ESTIMATION OF PHOSPHORUS IN STEEL.

To the Editor of the Chemical News.

Sir,—As regards the rapid estimation of phosphorus in steel, I have for a considerable period employed the following method, and have found it to yield very satisfactory results, both as regards accuracy and rapidity :—

To 3 grms. of the sample, contained in a 12-oz. assay flask, add 20 c.c. 16E HNO_3 and 20 c.c. of water. (Steels of practically the same chemical composition behave very differently with this acid mixture, some remaining passive in the cold, while others are immediately attacked).

When the sample is dissolved (heat is applied to accelerate the action), the solution is heated to boiling, and while at this temperature a strong solution of $KMnO_4$ added until the colour of the liquid remains a permanent pink and MnO_2 is precipitated, and the boiling continued for two to three minutes. 10 to 12 c.c. of 10E HCl are then added, the solution boiled for two to three minutes, and the clear solution cooled. To the cold solution 20E NH_4HO added (with brisk agitation of the containing vessel) until the whole of the iron is precipitated (generally a semi-solid mass is obtained), and a slight excess, as judged by smell, of NH_4HO is present. 16E HNO_3 is now added (in small quantities at a time, and with brisk agitation of the containing vessel), until a perfectly clear solution is obtained (usually 10 to 12 c.c. 16E HNO_3 are required). To the solution now add 10 c.c. of ammonium molybdate solution (100 grms. ammonium molybdate per litre of water), then 3 to 4 c.c. 16E HNO_3, the solution briskly shaken, and allowed to stand in a warm place for some time. The resulting ammonium phosphomolybdate precipitate collected on an English filter-paper, washed a few times with a 1 per cent solution of nitric acid, dried at about 110° C., and weighed.

With basic and other phosphoric pig-irons containing up to 1·5 to 2 per cent of silicon (working on 0·5 grm. of the sample, filtering before oxidising with $KMnO_4$, and using 20 c.c. of the ammonium molybdate solution and 6 to 8 c.c. 16E HNO_3 for the precipitation of the phosphorus), the above process gives higher results than those yielded by the ordinary methods. This may be due to the formation, in the ordinary methods of analysis, of an insoluble phosphate. On the other hand, the high results obtained by the rapid method may be due to the phosphorus precipitate carrying down along with it silica. What is the real cause of the discrepancies, want of time has prevented me investigating. I am, however, satisfied that it is not due to arsenic, as this element is not present in anything like sufficient quantities to affect the results to such an extent.—I am, &c.,

J. Jas. Morgan, F.I.C.

Wednesbury, March 18, 1901.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Note.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. cxxxii., No. 9, March 4, 1901.

Method of Estimation of Sulphides, Sulphohydrates, Polysulphides, and Hyposulphites coexisting in Solution, especially in Sulphurous Mineral Waters.—Armand Gautier.—The author describes a method of analysis by which sulphides, sulphohydrates, and hyposulphites can be separately estimated in the same water. This method was applied to two waters; the first being prepared by heating finely-powdered granite with its own weight of water to 280°, and th second being the water of Labassère (Ariège).

Preparation and Properties of Sulphammonium.—Henri Moissan.—By the action of sulphur on liquefied ammonia, the author obtains a new compound—sulphammonium. This substance has a dark red colour, and it is completely dissociable at ordinary temperature and pressure. It has the property of giving up its sulphur easily in the cold to a great number of simple and compound bodies.

Germination in Distilled Water.—P. P. Dehérain and M. Demoussy.—The authors' experiments show—(1) That germinating seeds form their roots and start their evolution in water absolutely free from chalk; (2) that the development of the root during germination stops when it is placed in distilled water containing even minute traces of copper; (3) that living seeds can be used to detect infinitesimal quantities of a metal such as copper, which any ordinary chemical reaction would fail to detect.

A New Method of Determining the Atomic Weight of Uranium.—J. Aloy.—From a knowledge of the nitrogen and uranium contained in the same weight of nitrate, the atomic weight of uranium can be determined with respect to that of nitrogen. Taking the latter as 14·04, the author finds that the atomic weight of uranium differs very slightly from 239·4.

Thermal Examination of the Ammoniacal Chlorides of Aluminium.—L. Baud.—In a former paper, the author announces the fact that anhydrous aluminium chloride will combine with ammonia gas in the proportions—$Al_2Cl_6.2NH_3$, $Al_2Cl_6.10NH_3$, $Al_2Cl_6.12NH_3$, $Al_2Cl_6.18NH_3$. All these substances are decomposed by water, and, by using M. Berthelot's calorimeter and system of correction, the author examines these compounds thermometrically, finding their heats of solution and deducing the heats of fixation of a molecule of ammonia. He reserves an examination of the compound $Al_2Cl_6.18NH_3$ for a future research, as it presents interesting peculiarities.

A New Cobalt Silicide.—Paul Lebeau.—The method of preparation of metallic silicides by the action of a metal on copper silicide allowed of the discovery of a new compound of silicon and cobalt corresponding to the formula SiCo. This substance is comparable in its composition and its properties with iron silicide, SiFe. Cobalt silicide is remarkable for the manner in which it resists oxidising agents, and for the very slight action of acids (except hydrochloric acid) upon it.

Mixed Organo-magnesium Compounds.—V. Grignard.—The organo-magnesium halogen compounds present the following properties :—(1) They are solid and not spontaneously inflammable in air; (2) they are formed without liberation of magnesium bromide or iodide; (3) by union with the aldehydes or the ketones, they give compounds which contain all the halogen employed, and which, by the action of water, are decomposed with formation of a secondary or tertiary alcohol without evolution of any gas.

An Isomer of Anethol and its Constitution.—MM. Béhal and Tiffeneau.—When methyl-magnesium iodide acts on anisate of methyl, parapseudopropenylanisol is formed; the reaction being represented by the equation—

$$CH_3{-}O{-}C_6H_4{-}CO_2C_2H_5 + 2I{-}Mg{-}CH_3 =$$
$$= CH_3{-}O{-}C_6H_4{-}C(CH_3){=}CH_2 + MgO + MgI_2 + C_2H_5OH.$$

The propenylanisol thus formed is condensed and doubles its molecule. The substance is then in the form of crystals fusing at 32°; it boils at 222° at ordinary pressure, and possesses a mixed odour of anethol and estragol.

Phenylhydrazones of *d*-Glucose and their Multirotation.—L. J. Simon and H. Bénard.—A preliminary examination of the multirotation of the hydrazones of Fischer and Skraup shows—(1) The hydrazone of Fischer possesses multirotation; (2) the final rotations are the same for the two isomers; (3) the initial rotation, which, for Skraup's

hydrazone is, in absolute value, inferior to the limit, in Fischer's hydrazone is, on the contrary, superior to the limit; (4) the time employed for the two hydrazones to take their rotation limit is of the same order of magnitude.

General Method of Synthesis of Naphthenes.—Paul Sabatier and J. B. Senderens.—The activity of nickel for regularly inducing hydrogenation of benzene is a property peculiar to this metal. The same property is exercised with regard to hydrocarbons homologous to benzene. All the carbides used by the authors were directly hydrogenated towards 170° or 200° in presence of reduced nickel; in all cases the corresponding hexahydride being formed. The above forms a general and very simple method for effecting the synthesis of the naphthenes or substituted cyclohexanes.

Specific Heat and Heat of Fusion of Ethylenic Glycol.—M. de Forcrand.—The author's experiments show that the probable specific heat of solid glycol is 0·265 for 1 grm. towards its point of fusion. As to the latent heat of fusion, it is −2·66 calories for 1 molecule, having been deduced from analogy. The latent heat of vaporisation has been determined by M. Longuinine, and found to be −12·06 cals. for the molecule at 197°.

MISCELLANEOUS.

Bryan Corcoran Limited.—This firm has acquired the name, goodwill, and business of Bryan Corcoran, Witt, and Co. The businesses are now merged in one, and will be carried on under the title of Bryan Corcoran Limited. The business was originally founded in Mark Lane by Bryan Corcoran in 1780. He was succeeded by his son, the late Bryan Corcoran, in 1833. The Managing Director, Mr. Bryan Corcoran, is the only son of the latter, and grandson of the founder. The business was carried on by him for twenty-five years in his own name, and was in 1896 formed into this company, which now unites all interests.

A New General Reaction for Albumenoid Materials.—A. P. Lidof.—If we gently heat a solution of any proteïc material with $AgNO_3$ and a slight excess of KOH, we observe almost immediately a brownish colouration, which increases in intensity until the liquid finally assumes a very deep tint. In certain cases the liquid, after a longer or shorter time, forms a silver mirror on the sides of the vessel; in most cases, however, it does not change in appearance, even after a very long time. The intensity of the colouration is the greater as the precipitate of Ag_2O produced by the KOH is less, which indicates that the Ag_2O gradually becomes reduced to the state of metallic Ag, which remains dissolved. The author has examined eighteen different albumenoid materials, such as caseine, legumine, globuline, vitelline, colloidine, gelatin, hemo globin, &c. In most cases the reaction takes place in the same manner; only with mucine, besides the colouration a black precipitate is formed, which increases with time, while the liquid becomes colourless. As mucine contains a relatively large amount of sulphur, sulphide of silver is no doubt formed. Fibroïne from silk and some other albumenoid bodies show this peculiarity, that the silver in solution is gradually deposited, forming a mirror; this also occurs with myosine, caseine, and spongine, but with this latter the silver separates in the form of a yellow modification. It should be mentioned that the presence of ammonia prevents the formation of dissolved silver. The influence of light is important; with gelatin solution kept in the dark the colouration is not produced; with albumin the thick solution formed by the $AgNO_3$ becomes more fluid and coloured in the light, while it does not change in the dark. The author thinks that in gelatin-bromide photographic plates silver in solution is formed. Silver solutions thus prepared will dye animal or vegetable fibres without the use of any mordant; the tint produced is practically that which exposure to light has given to the liquid. As an insignificant quantity of silver is able to produce an intense colouration, the process may possibly become of practical value.—*Journ. Soc. Phys. Chim. R.*, vol. xxxi., p. 781.

Hydroxylammoniated Compounds of Platinum.—R. Uhlenbuth.—The author describes the hydrate of platoso-dihydroxylammonium, $Pt{<}^{(NH_2OH)_2OH}_{(NH_2OH)_2OH}$ (corresponding to Reiset's first base), and its salts. To a dilute solution (1·5 per cent) of $PtCl_4$ he adds a solution of pure hydroxylamine. A brisk disengagement of nitrogen takes place; on boiling, the solution becomes decolourised, and on cooling deposits the base in white crystals insoluble in water, alcohol, and ether, but soluble in the mineral acids and acetic acid. It is formed according to the following equation:—

$$PtCl_6H_2 + 12NH_2OH = Pt(NH_2OH)_4(OH)_2 + 6NH_2OH.HCl + N_2;$$

this body detonates at 173°. The sulphate, $Pt(NH_2OH.NH_2OH)_2SO_4 + H_2O$, is deposited on cooling in large triclinic crystals slightly soluble in water. The chloride, $Pt(NH_2OH.NH_2OH)_2Cl_2$, is soluble in water, and crystallises in flattened needles. The nitrate crystallises in brilliant colourless needles. Concentration of the mother-liquors of the chloride on the water-bath gives long radial needles, forming a golden-yellow solution in alcohol, and even in ether. The solution of this body hardly becomes cloudy on the addition of NO_3Ag. Its composition is $Pt(NH_2OH)_2Cl_2$ (corresponding to Reiset's second base). We can obtain a salt of the same composition, but in blue crystals by the addition of $PtCl_4$ to the solution of the chloride, $Pt(NH_2OH)_4Cl_2$. The blue salt only gives up half its chlorine to NO_3Ag.—*Lieb. Ann.*, vol cccxi., p. 124.

MEETINGS FOR THE WEEK.

Monday, April 1st.—Society of Chemical Industry, 8. "The Effect on the Marsh Test of some Commercial Products containing Selenium and Tellurium," by A. E. Berry. "A New System for the Manufacture of Borax and Nitrates," by Dr. W. Newton. "Basic Superphosphate—its Preparation and Use as a Manure," by J. Hughes. "The Preparation of Pure Cineol from Eucalyptus Oil by means of the Arsenate," by Watson Smith. "Action of Caustic Potash and Soda on Stannous Sulphide," by Dr. F. Mollwo Perkin.

Wednesday, 3rd.—Society of Public Analysts, 8. "The Maumené Test for Oils," by C. A. Mitchell, B.A., F.I.C. "Some Arsenic Estimations relating to Malt Kilns," by T. Fairley, F.I.C. "The Aeration Test for Effluents," by S. Rideal, D.Sc., F.I.C.

ST. PAUL'S SCHOOL.—An Examination will be held at St. Paul's School, West Kensington, on Tuesday, April 16th, and following days, for filling up about Eight Vacancies on the Foundation.—Full particulars can be obtained on application to the Bursar.

THE MINERAL CONSTITUENTS OF DUST AND SOOT FROM VARIOUS SOURCES.*

By W. N. HARTLEY, F.R.S., Royal College of Science, Dublin, and HUGH RAMAGE, A.R.C.Sc.I., St. John's College, Cambridge.

BARON NORDENSKJÖLD has described three different kinds of dust which were collected by him (*Comptes Rendus*, vol. lxxviii., 236). Of two of these, one consisted of diatomaceæ and another of a siliceous and apparently felspathic sand; both were found on ice in the Arctic regions. The third variety was quite different and appeared to be of cosmic origin. He observed that some sand collected at the end of a five or six days continuous fall was mingled with a large quantity of sooty-looking particles, consisting of a material rich in carbon. It appeared to be similar to the dust which fell, with a shower of meteorites, at Hessle, near Upsala, in the beginning of the year 1869. As in this particular instance it might be supposed that the railways and houses of Stockholm had contributed some of this matter to the atmosphere, and that the snow had carried it down, he requested his brother, who then resided in a desert district of Finland, to give his attention to the subject, with the result that he collected a similar powder. The snow gathered in the latitude of 80° N. in an expedition to Spitzbergen, and that collected from floating ice in the Arctic regions, and on the glaciers of Greenland, leaves, after it has melted, a greyish residue, which consists largely of diatomaceæ, but mixed with these organisms there were also particles of a carbonaceous dust of considerable size, which on analysis were found to contain metallic iron, cobalt, and nickel, also silicon, carbon, and phosphorus. The origin of this mineral matter was at first doubtful. Two of its constituents, cobalt and nickel, were believed to be of very uncommon occurrence in terrestrial matter, while, on the other hand, they are elements invariably associated with the metallic iron of meteorites, the nickel being more particularly in large proportion. If we suppose that this dust is discharged from the mouth of a distant volcano, or that it may be sand carried up by a whirlwind, we have yet to explain the peculiarities in its composition which render it similar to that of meteorites.

Nordenskjöld arrived at the conclusion that it was meteoric matter which had descended upon the earth in a shower similar to that which occurred near Upsala. By the facts which he had collected it appears to have been proved that cosmic dust is falling imperceptibly and continually. It seems that this view is either generally not accepted, or that the facts are not commonly known.

Very little is really known about the composition of atmospheric dust, notwithstanding that searching investigations were made by Pasteur and Angus Smith, aided by the microscope, and later by Liveing and Dewar by the aid of the spectroscope.

Professor O'Reilly, M.R.I.A., supplied us with small quantities of a material concerning the nature of which he was desirous of obtaining information. On inspection it appeared to be of an unusual character for mere town dust, and accordingly we submitted it to a spectrographic analysis, and determined the principal metallic elements which enter into its composition. The following specimens in particular have been examined with care:—

I. Solid matter which fell in or with hail in a hail-storm on Wednesday, April 14th, 1897, and was collected by Professor O'Reilly at a window facing the large open space of Stephen's Green, at the Royal College of Science, Dublin. It contained iron, sodium, lead, copper, silver, calcium, potassium, nickel, manganese a trace; gallium and cobalt gave doubtful indications.

II. Solid matter from hail and sleet collected by Professor O'Reilly from a window-sill of the Royal College of Science, Dublin, during a very heavy shower, from 2.30 till 3 o'clock, in the afternoon of March 28th, 1896.

Total weight of the dust 0·1018 grm., of which 0·08 grm. was burnt in the oxyhydrogen flame. The colour of the dust was steel-grey, and it was magnetic. It contained iron, copper, and sodium, lead, calcium, potassium, manganese, nickel, silver, thallium a trace, gallium, and rubidium a trace, doubtful.

III. Pumice from Krakatoa eruption, 1883; from Professor O'Reilly. By decomposing the silicate with ammonium fluoride and sulphuric acid, and precipitating the solution with ammonia, the following bases were separated:—Iron, copper, silver, sodium, nickel, potassium, rubidium, manganese, gallium, and indium a trace (*Trans. Chem. Soc.*, 1901, vol. lxxix., p. 61).

The salt separated by filtration and evaporation of the filtrate contained sodium, potassium, calcium, copper, silver, strontium, nickel a trace, rubidium, and manganese. With the very notable exceptions of strontium, nickel, and cobalt we have found these constituents in ninety-seven irons, ores, and associated minerals (nickel was found in twenty-three, *Trans. Chem. Soc.*, 1897, vol. lxxi., p. 533). On the other hand, in the examination of six meteoric irons, we have found the same elements invariably associated with nickel and cobalt, the last-named being always in much smaller proportion than the nickel (*Sci. Proc. Dublin Soc.*, New Series, vol. viii.). Had it been possible to operate on larger quantities, we quite expect that cobalt would have been found in this dust, but the small amount of 8 centigrms. is insufficient for such a purpose, even in the case of most meteoric irons. It is rather a striking fact that in the dust No. 2 there is a trace of thallium. This is rather suggestive of its being probably pyrites flue dust, a substance which might occur in hail or rain in a neighbourhood where sulphuric acid is manufactured. It might possibly come from an admixture of soot yielded by a coal containing thalliferous pyrites.

There are three vitriol works within two or three miles of the College, but after taking all the facts into consideration, we are not able to admit this source as a probable means of contamination, for, as will be seen from analyses to be presented, there is one notable constituent we have found in flue dust which is absent from the samples I. and II., namely indium.

In 1897, in order to push this inquiry somewhat further, dust was collected in porcelain dishes placed upon a grass plot in the garden of a residence just on the outskirts of Dublin[1] during a period from the 15th November to the 15th December. A considerable fall of a carbonaceous-looking matter occurred on the 16th and 17th of November; some of the particles were 2 or 3 m.m. in diameter, and had a steel grey appearance rather like hard coke or graphite. These particles all sank in the rain-water which collected on the 17th or 18th, while a large number of sooty particles floated; as the dish became over-filled, the sooty matter was automatically washed away, and only the heavier particles remained. The contents of the dishes were poured into glass cylinders, and after the heavier particles had been deposited the water was removed by decantation.

Subsequently it became interesting to ascertain what substances are to be found in ordinary soot and flue dust—dust from volcanic eruptions, &c. We have tabulated the results and arranged together those substances which we know to have the same origin.

The specimens of soot required no preliminary treatment before being burnt, and the analysis of each is given

* A Paper read before the Royal Society, February 21, 1901.

* Lithium was found in all these dusts.

† Bismuth was found in this dust.

in the tabular statement only, but the different kinds of volcanic dust and flue dust were dissolved, and the silica removed, after which the bases were separated into groups, and the spectra of these groups were photographed; each spectrum receives a detailed description preceding the tabulated statement.

Flue Dust.

Plate 386.—Dust from the flue of Crewe gasworks. May 28, 1899 The silica was removed from 1 grm. by treatment with ammonium fluoride.

Spectrum 1.—The insoluble residue contained—
Ca, Sr, Na, Pb, Fe, Cu, Ag, K.

Spectrum 2.—The precipitated yielded by sulphuretted hydrogen—
Pb, Cu, Ag, Ca, Na, Fe, K.

Spectrum 3.—The ammonium hydrate precipitate—
Fe, Ga, Cu, Ag, Pb, In, Ni trace,
Ca, Na, K.

Spectrum 4.—The ammonium sulphide precipitate—
Mn, Na, K, Cu, Ag, Ni, Fe.

Spectrum 5.—The less soluble sulphates—
Ca, Sr, Cu, Na, K.

Spectrum 6.—Magnesia and the alkalis—
Na, K, Ca, Sr, Ni, Rb trace.

Plate 388.—Spectra 4 and 7.—Insoluble residue after treating the dust with hydrochloric acid—
Fe, Ga, Na, K, Ca, Cu, Ag, Ni, Mn.

Plate 347.—Flue dust from Cleveland iron furnaces.

Spectrum 1.—Samuelson's samples, No. 6—
Na, K, Ca, Fe, Rb, Pb, Mn;
traces of Cu, Ag, Ni, Ga, Tl.

Spectrum 2.—Flue dust from basic iron furnace. Samuelson's No. 9—
Na, K, Ca, Fe, Rb, Pb, Mn;
traces of Cu, Ag, Ni, Tl, Ga, In, Cs, Sr.

Spectrum 3.—Flue dust, Gjers, Mills, and Co.—
Na, K, Ca, Fe, Rb, Pb, Mn;
traces of Cu, Ag, Ni, K, Ga, In.

Plate 354—

Spectrum 4.—Flue dust, Gjers, Mills, and Co.—
Fe, Ca, Cu, Mn, Na, K, Pb, Rb;
traces of Ni, Tl, Ag.

Plate 325.—1. Flue dust from Nicholson's copper smelting works, Hunslet, Leeds—
Na, Cu, Pb, Tl, Ag, In, Fe, K,
Ca, Ga, Rb.

Plate 312.—Iron pyrites from coal—
Fe, Cu, Tl, Pb, Ag, and possibly a trace of gallium.

Volcanic Dust.

Specimens received from Professor J. P. O'Reilly.

Plate 311.—*Te Ariki.*—After complete solution of the substance, the heavy metals were precipitated with ammonia and the filtrate with ammonium oxalate, after which the solution containing magnesia and the alkalis was examined.

Spectrum 1.—The ammonia precipitate—
Fe, Ca, Pb, Na, K trace, Ga trace, Cu trace.

Spectrum 2.—The ammonium oxalate precipitate—
Ca, Sr, Mn, traces of Na, K, Pb, Fe, and Ag.

Spectrum 3.—Magnesia and the alkalis—
Na, K, MgO, Mn, Rb, Cu;
Ni the merest trace.

Taurunga.

Plate 311.

Spectrum 4.—The ammonia precipitate—
The constituents are similar to No. 1.

Spectrum 5.—Ammonium oxalate precipitate—
Similar to No. 2.

Spectrum 6.—Magnesia and the alkalis—
Similar to No. 3.

Te Hape-o-Toroa.

Plate 312.

Spectrum 1.—The ammonia precipitate—
Similar to Nos. 1 and 4.

Spectrum 2.—The oxalates—
Similar to Nos. 2 and 5, but the silver was not so strong.

Spectrum 3.—Magnesia and the alkalis—
Similar to Nos. 3 and 6.

It is necessary to explain that the symbol for magnesium and the alkaline-earth metals refers generally to the oxides. With magnesium, in fact, this is always so, since the bands of the oxide magnesia alone are visible. In the case of calcium, the blue line 4226 is photographed when only a small quantity is present, but the bands of calcium oxide are the chief feature of the spectrum when the base is in larger proportion. Where the symbol is printed in italics, it indicates a trace of the substance, and where followed by a note of interrogation it is not quite certain if even a trace is present, as, for instance, where only one or two rubidium lines is seen, there being two iron lines occupying almost the same positions; or where one of the gallium lines is barely visible, and the second is enveloped by manganese lines. The relative strength of the lines, as seen by comparing the different spectra, are, in some instances, indicated on the tabulated statement by suffixes, the number 1 indicating the weakest line, and 10 the strongest.

The difference in the number of the iron lines is a measure of the quantity of iron present as metal or otherwise, and a comparison of the strength of the lines also indicates the relative quantity of substances. The results in many cases are quantitative, inasmuch as the same weight of material was taken.

(To be continued).

COMPOSITION AND NATURE OF THE RED RAIN.

By Dr. T. L. PHIPSON.

The newspapers of various countries of Europe have recently called attention to a red rain which fell between the 11th and 13th of March, 1901, in Sicily, Naples, Leghorn, Venice, Coburg, Hamburg, Schleswig-Holstein, and at Malvern, in Worcestershire.

The deposit left by this rain in the form of an exceedingly fine dust is described as reddish or fawn-coloured, and greasy to the touch. At Leghorn 4½ grms. were swept from the marble table in front of a café, and it was calculated from this that many thousands of tons of this fawn-coloured dust must have fallen throughout Italy between the dates above-mentioned.

I am indebted to Captain C. J. Gray, F.R.G.S., for a small quantity of a precisely similar product that fell with the rain at Melbourne, Australia, on the 12th December, 1896, and I have submitted it to as full an examination as the very minute quantity would allow.

In my recently published work, "Researches on the Earth's Atmosphere," I have alluded to salt rain, and to coloured rain produced by volcanic ash, or desert sand uplifted by the wind and suspended in the air; there have been also blood-red deposits found upon the ground, which consist of cells of the *Protococcus nivalis*, or *Palmella sanguinea*, and similar microscopic plants that have shown themselves after a fall of rain or snow. I have invariably found abundance of unicellular algæ in the first fall of snow in early winter, and the red rain deposit examined formerly by the French chemist Cahours (in

1852), was found to consist of organic cells, and burnt away entirely, leaving little or no residue.

The fawn-coloured dust left by red rain is, on the contrary, of a mineral nature; it is always similar in colour, fineness, and microscopic appearance. I have made a careful examination of this reddish deposit, and the result has been rather unexpected and interesting.

When dry it is of a fawn-colour, rather paler than oxide of cerium, but becomes darker when wet. Under the microscope it is seen to consist of exceedingly minute grains, *mostly flat*, and of various colours; they are also of various shapes and sizes. The largest are about 2/100ths of a m.m.; the greater number are about 5/100ths, and the smallest 5/100,000ths of a m.m. in diameter. The irregularity of their forms gradually disappears as they get smaller, so that to the eye the smallest appear circular. Many are white, and more or less transparent, grey, greenish-grey, slate-coloured; others are yellow, and brown, and translucent; a few are ruby-red, and others are dark and opaque.

When calcined at a red heat this dust darkens, and loses 14·3 per cent of water and organic matter (this is exactly the amount of water and organic matter found in the Orgueil meteorite). On cooling after calcination it becomes fawn-coloured again, and the colours of the grains seen under the microscope have not been much altered by calcination.

When boiled in hydrochloric acid (finally adding a few drops of nitric acid), a notable portion is dissolved, and yields a solution containing *iron*, and other substances, *among which is nickel*.

After this boiling in acid the fawn-colour becomes much darker, similar to the dark crust seen on meteorites where it is very thin. Having placed the existence of nickel in this substance beyond doubt, I am of opinion that it is partly, if not wholly, of cosmic origin, and not merely desert sand uplifted by the wind, nor volcanic dust; it would appear to be the mineral dust left in the higher regions of the air by the explosion of meteors, or shooting stars.

The only thing that makes me hesitate to assert this absolutely is the fact that oxide of nickel has once been said to have been found in the *rapilli* of the Kölerberg, in Silesia, to the extent of 0·1 per cent (the analysis by Zulkowski is given in my work on "Meteors, Aërolites, and Falling Stars," p. 118). In the fawn-coloured products of the red rain I estimate that there is considerably more nickel than that, more than ten times as much; and in the ash or cinders of Etna and Hecla no nickel has ever been found, nor in those of Vesuvius.

I may add to this that both March and December are known to be meteoric "periods."

ANTIMONIATES OF COPPER.

By A. E. DELACROIX.

Ammoniacal Antimoniate of Copper.—Tetra-antimoniate of copper, $(Sb_2O_5)_2CuO$, treated with ammonia, gives, among other products, small blue hexagonal crystals, which, when dried in the air, have the formula $Sb_2O_5,CuO,3NH_3,9H_2O$.

Antimoniate of copper, freshly precipitated from acetate of copper by antimoniate of potash, dissolves completely in dilute ammonia. Crystals, identical in appearance and of the same composition as the preceding, are not long in forming.

If we make use of a precipitate of antimoniate of copper dried on the filter-pump, and concentrated ammonia, there is still solution, after which a deep blue viscous mass is quickly formed, which soon solidifies. The bi-cupric tri-antimoniate, $(Sb_2O_5)_3(CuO)_2$, partially dissolves in ammonia; it then crystallises as cupram monic antimoniate, similar in appearance to the preceding salts.

According to MM. Beilstein and Blaese (*Bull. Acad. de Saint Petersbourg*, vol. xxxiii., p. 100), Raschig has prepared, in another manner, an ammoniacal antimoniate of copper only differing from ours by $3H_2O$.

Antimoniate of Copper and Potash.—Freshly prepared and washed tetra-antimoniate of copper, $(Sb_2O_5)_2CuO$, was treated with potash. After digesting for several days it was again washed by decantation to free the precipitate of the mother-liquor. After the second decantation the green precipitate dissolves in the water added for the third washing. Presuming that the resulting green solution contained a double antimoniate of copper and potash, a part of it was congealed. The salt, in the form of green flakes, was found to consist of $Sb_2O_5CuO_{0\cdot569}K_2O_{0\cdot399}$.

Basic Antimoniate of Copper.—A part of the above-mentioned green solution was heated to 80°. A voluminous precipitate then separated; this was thoroughly washed by thirty-five decantations. Analysis gave for the product dried at 100°, $(Sb_2O_5)_2CuO_4\cdot86,7\cdot06H_2O$. — *Bull. Soc. Chim.*, Series 3, vol. xxv., No. 6.

ON ANTIMONIC ACIDS.

By A. E. DELACROIX.

The Preparation of Antimonic Hydrate.—The method described by M. Senderens (*Bull. Soc. Chim.*, vol. xxi., p. 47), gives a gelatinous precipitate, difficult to wash. By making use of the following modification we obtain a pulverulent hydrate similar to that formed by pentachloride of antimony, and easily washed:—

Dissolve 1 kilogrm. of trichloride of antimony in 1 litre of hydrochloric acid (D = 1·19). The mixture is heated to 100°, and 250 c.c. of nitric acid (D = 1·38), added as quickly as the violence of the reaction will allow.

To prepare the hydrate a certain quantity of the cooled liquid is treated with water.

Preparation of Tetra-antimonic Acid.—We must use heat to get concentrated solutions. The hydrate being rubbed up with water at 50° is then boiled for four or five minutes; the liquid becomes nearly clear; it is then divided up into small portions, and cooled rapidly.

The product does not contain any triantimonic acid. A saturated solution, prepared at 70°, contained 53·89 grms. of Sb_2O_5 per litre, of which only a very small quantity was in the tri-antimonic state. The density of this solution was 1·0497.

The Action of Alkalis and Alkaline-earthy Bases on Tri-antimonic Acid. Soda.—The neutralisation of this acid by soda, in the presence of phthalein, takes place with the formation of $(Sb_2O_5)_3(Na_2O)_2$.

Potash.—In the cold the neutralisation takes place, forming $(Sb_2O_5)_2K_2O$.* The same relation was observed with tetra-antimonic acid, but the salt formed is different. It is not precipitable by alcohol, as is the case with tetra-antimoniate of potash.

The freezing of the acid thus neutralised gives a crystalline powder, for which the formula $Sb_2O_5(K_2O)_{0\cdot53}$ has been found. This antimoniate may be looked upon as a mixed salt, $(Sb_2O_5)_3K_2O.(Sb_2O_5)_3(K_2O)_2$.

I may here mention that the salt $(Sb_2O_5)_3(K_2O)_2$ is formed by the addition of an excess of potash to cold tri-antimonic acid. The triantimonic solution, neutralised as has been described above, becomes acid when it is boiled. However, by alternate neutralisations and boilings we can reach a definite neutralisation expressed by the formula $(Sb_2O_5)_5(K_2O)_4$, a mixture or combination of the bi- and tri-potassic tri-antimoniates, $(Sb_2O_5)_3(K_2O)_2.2Sb_2O_5.K_2O$. After standing for a long time it deposits an amorphous salt, and the clear liquid contains a flocculent antimoniate.

* This corrects an error unfortunately made in the publishing of my first paper on this subject (*Journ. de Pharm. et de Chim.*, [6], vol. vi., p. 337).

Lithia.—With this base we arrive at the same results as with potash. After neutralising hot, there is an iridescent deposit after a few hours, composed of hexagonal tables of $Sb_2O_5Li_2O$.

Ammonia.—No indicator gives any results with this alkali.

Baryta.—Neutralisation in the presence of phthalein in the cold gives $(Sb_2O_5)_5BaO_4$, and when hot, $(Sb_2O_5)_{10}BaO_2$.

The salt $(Sb_2O_5)_5BaO_4$ is also formed by the prolonged action of a large excess of acetate of baryta.

In the presence of luteol and of perezol the neutralisation takes place, forming $(Sb_2O_5)_3(BaO)_2$.

Strontia and Lime.—The reaction, which is slow with baryta, is still more so with strontia and with lime. The results are less marked, but appear to be the same.

With methyl-orange the alkaline earths give results very closely approaching those given by luteol.—*Bull Soc. Chim.*, Series 3, vol. xxv., No. 6.

EIGHTH ANNUAL REPORT OF THE COMMITTEE ON ATOMIC WEIGHTS. DETERMINATIONS PUBLISHED IN 1900.*

By F. W. CLARKE.

DURING the year 1900, fewer new determinations of atomic weight than usual have appeared. The data are given in the following pages, together with Herzfeld's research upon calcium, which appeared three years ago. It was unfortunately published through an unusual channel, and was therefore overlooked at the time. Attention may also be called to the Presidential Address (*Journ. Am. Chem. Soc.*, xxii., 51) of Professor Morley before the American Chemical Society, which is a valuable discussion of the probable accuracy of our knowledge as to the ratio between hydrogen and oxygen.

Nitrogen.

Dean's research (*Journ. Chem. Soc.*, lxxvii., 117) upon the atomic weight of nitrogen, which was noticed in abstract in the report for 1899, has now appeared in full. Weighed quantities of silver cyanide were dissolved in nitric acid, and the nitrate solutions were titrated with a standard solution of potassium bromide. As the latter was not absolutely pure its silver value was independently determined, and the titrations give therefore the quantity of silver proportional to the cyanide. The last experiment of the series was made by solution of the cyanide in sulphuric acid instead of the nitric acid previously used. Attempts to reduce silver cyanide in hydrogen gave unsatisfactory results, due to the formation of paracyanogen and silver carbide. The final data are subjoined.

Weight of AgCN.	Weight Ag.	Equivalent of CN.
6·2671	5·0490	26·039
17·60585	14·18496	26·026
17·1049	13·7801	26·049
17·9210	14·43881	26 030
12·11215	9·75875	26·028
14 6672	11 81727	26·029
Sum, 85·67820	69·02889	26 032

If C=12 001, then N=14·031, the value finally adopted. All weights were reduced to a vacuum standard.

Another determination of the atomic weight of nitrogen has also been announced by Scott (*Proc. Chem. Soc.*, xvi., 205). From ammonium bromide he finds $NH_4Br=97·996$. For the chloride, $NH_4Cl=53·516$. The first value is lower than that found by Stas, the second is in agreement with Stas. The full paper will appear early in 1901.

Calcium.

The following determinations by Herzfeld (*Zeit. des Vereins fur die Rübenzucker-Industrie*, xlvii., Heft 497), made in 1897, were overlooked at the time, and are now recorded here for the sake of completeness. Calcium carbonate was prepared from the bicarbonate, and reduced to oxide by ignition at a temperature of from 1300° to 1400°.

Weight $CaCO_3$.	Weight CO_2.	Weight CaO.	Atomic weight Ca.
3·9772	1·7504	2·2268	39·687
2·3614	1·0396	1·3218	39·655
3·2966	1·4510	1·8456	39·677
		Mean	39·673

Calculated with H=1, C=11·92, O=15·879. With O=16, Ca=39·975.

Iron.

The determinations by Richards and Baxter (*Zeit. Anorg. Chem.*, xxiii., 245) of the atomic weight of iron are based upon the reduction of pure Fe_2O_3 in a current of electrolytic hydrogen. Two series of results are given, representing ferric oxide prepared by two distinct methods. For details of manipulation the original paper must be consulted.

First Series.—Ferric oxide obtained by calcination of ferric hydroxide :—

Weight Fe_2O_3.	Weight Fe.	Atomic weight Fe.
3·17485	2·22096	55·885
3·61235	2·52750	55·916
	Mean	55·900

Second Series.—Ferric oxide obtained by calcination of ferric nitrate :—

Weight Fe_2O_3.	Weight Fe.	Atomic weight Fe.
3·97557	2·78115	55·883
4·89655	3·42558	55·891
4·35955	3·04990	55·891
7·14115	4·99533	55·870
6·42021	4·49130	55·882
	Mean	55·882

Mean of all seven determinations, 55·89, when O=16. With H=1, Fe=55·47. All weights were reduced to a vacuum.

Gadolinium.

Atomic weight determined by Benedicks (*Zeit. Anorg. Chem.*, xxii., 393), by synthesis of the sulphate from the oxide. Data as follows :—

Weight oxide.	Weight sulphate.	At. wt. gadolinium.
0·4308	0·7171	156·57
0·5675	0·9451	156·35
0·5726	0·9534	156 44
0·6785	1·1301	156·29
0·7399	1·2329	156·10
1·3253	2·2063	156·52
	Mean	156·38

Calculated with O=16 and S=32. The final result agrees well with the determination by Bettendorf, who found Gd=156·33.

Thorium.

Atomic weight re-determined by Urbain (*Ann. Chim. Phys.*, [7], xix., 223). The thoria was purified by conversion into the acetyl acetonate, which was crystallised from solution in chloroform. It was then converted into sulphate. The atomic weight determinations (with O=16) were made by calcination of anhydrous $Th(SO_4)_2$. Data as follows :—

Weight sulphate.	Weight ThO_2.	Atomic weight Th.
1·0925	0·6815	233·30
0·5926	0·3699	233·75
1 0230	0·6384	233·58

Calcination of the hydrous sulphate gave lower values, probably because the octohydrated salt used contained traces of the sulphate with 9 molecules of water.

* *Journal of the American Chemical Society*, xxiii., No. 2.

Miscellaneous Notes.

Muthmann and Böhm (*Ber. d. Chem. Ges.*, xxxiii., 42), have prepared pure yttria by fractional precipitation with neutral potassium chromate. The final sample was practically pure, and gave a good atomic weight determination. 2·46585 grms. sulphate yielded 1·19523 grms. of oxide. Hence Yt = 88·97, when O = 16.

Samarium has been studied by Demarçay (*Comptes Rendus*, cxxx., 1185). By synthesis of the sulphate he finds the atomic weight of the metal to range from 147·2 to 148·0, when O = 16. The higher values, about 150, obtained by other investigators, he attributes to the presence of other earths. In a second paper (*Comptes Rendus*, cxxx., 1469) he describes one of these earths, which is intermediate between samarium and gadolinium, with an atomic weight of the metal equal to 151, nearly. This, however, is only a rough approximation, as the oxide was not sufficiently pure for exact work.

The density of krypton has been carefully determined by Ladenburg and Krügel (CHEM. NEWS, lxxxi., p. 205). From it the atomic weight of the element becomes, in two experiments, 58·67 and 58·81, or 58·74 in the average.

Ramsay and Travers (CHEM. NEWS, lxxxii., p. 257) give density determinations and atomic weights for the new gases of the atmosphere as follows:—

	Density.	Atomic weight.
Helium	1·98	3·96
Neon	9·97	19·94
Argon	19·98	39·96
Krypton	40·88	81·76
Xenon	64·00	128·00

Metargon is abandoned, as non-existent. Why the value for krypton should diverge so widely from that found by Ladenburg and Krügel, is unexplained. It will be noticed that most of these gases fall between the halogens and the alkali metals in the periodic system, although argon is still slightly divergent from theory.

Mdme. Curie has continued her studies upon radium (*Comptes Rendus*, cxxxi., 382), which were referred to in the report for 1899). She now describes a radiferous barium chloride in which the mixed metals have a mean atomic weight of 173·6 to 174. In this sample, judging from spectroscopic evidence, there was probably rather more radium than barium.

Table of Atomic Weights.

The following table of atomic weights differs but little from that issued last year. First, your Committee gives its own list, in two columns, representing both standards of value, H = 1, and O = 16. The only change here is in iron, due to the work of Richards and Baxter. Richards's table is unchanged, except in the same item. The table of the German Committee is that which was issued in January, 1901, as an insert to the first number of the *Berichte*.

	Clarke.			
	H = 1.	O = 16.	Richards.	German.
Aluminum ..	26·9	27·1	27·1	27·1
Antimony ..	119·5	120·4	120·0	120·
Argon	?	?	39·9?	39·9

Royal Institution.—A General Monthly Meeting of the Members of the Royal Institution was held on the 1st inst., Sir James Crichton-Browne, Treasurer and Vice-President, in the Chair. Mr. J. H. Batten, Dr. R. Barnes, Dr. R. L. Bowles, Mr. G. L. Johnston, Mr. J. Lawrence, and Mr. E. T. Sturdy were elected Members. The special thanks of the Members were returned for a donation of £50 from "A Friend" to the Fund for the Promotion of Experimental Research. It was announced from the Chair that His Majesty The King had graciously consented to become a Patron of the Royal Institution.

A BIBLIOGRAPHY OF STEEL WORKS ANALYSIS.

Part VIII.
VANADIUM AND TITANIUM.

By HARRY BREARLEY.

(Continued from p. 64).

VANADIUM.

I. Separation from other Elements.

Iron (or Al).—

1079. Bettendorf (*C. N.*, xxxvii., 113).—AmHO precipitates vanadate of Al, which is decomposed by Am_3PO_4, the V passing into solution. The reaction with ferric salts is similar.

1080. Carnot (*C. N.*, lvi., 16).—Fe is separated by repeated precipitations with AmHO, acetate, or H_2S; not so Cr or Al.

1081. Bamber (Process 953).—Separates Va and Fe. (See also 1112).

1082. Helouis (*J. S. C. I.*, 1896, 657).—From Al-Va alloys the Al is dissolved by HCl. The residual Va is not attacked by HCl or alkalis. Influence of Va on physical properties of irons.

Chromium.—

1083. Classen (*J. C. S.*, l., 428).—Fuse the mixed oxides with Na_2CO_3 and S; the Cr remains as oxide. Analytical characters of insoluble Va compounds of Pb, Ba, and NH_4 given.

1084. Klecki (*C. N.*, lxix., 54).—The V is precipitated from acetic solution with Ur; the chromate is easily soluble.

Arsenic.—

1085. Field and Smith (*C. N.*, lxxv., 26).—Heat the mixed sulphides below 250° in HCl gas; As is volatilised. As oxides, both metals volatilise, and are thus separated from vanadinite.

1086. Friedheim and Michaelis (*J. C. S.*, lxviii., ii., 415).—Eliminate As by distilling with methyl alcohol and HCl, after adding SO_2 to form V_2O_4. (See also 1098).

1087. *Titanium.*—Deville (*C. N.*, iii., 226).—Fuse rutile with $KHO+KNO_3$, leach, filter, pass H_2S, and drive H_2S from acidified filtrate; Va is precipitated. Used (*C. N.*, v., 86) for estimating Va in cryolite.

1088. *Uranium.*—Lallemand (*C. N.*, xliii., 72).—The filtered nitric acid solution of pitchblende is precipitated with Na_2CO_3. Ur in solution; Fe, Va, W, &c., precipitated (see 1112).

1089. *Zinc.*—Halberstadt (*C. N.*, xlvii., 101).—Evaporate HCl solution, digest with Am oxalate, and boil with acetic acid. Va is dissolved; Zn, Ba, Ca, and Pb are precipitated.

1090. *Gallium.*—Boisbaudran (*C. N.*, xlviii., 86).—From HCl solution mixed with As_2O_3 and Am acetate, Ga is precipitated by H_2S; or mix neutral solution with Am_2S, and precipitate V with HCl.

II. Gravimetric Estimation of Vanadium.

1091. Phipson (*C. N.*, vii., 210).—Fuse clay ironstone with KNO_3, add KHO to filtrate, then H_2S, and precipitate sulphovanadate with HNO_3 and $BaCl_2$. Decompose precipitate with H_2SO_4, and precipitate as ammonia salt. Some French processes described. TiO_2 interferes with the microcosmic blowpipe test (1122).

1092. Riley (*C. N.*, viii., 261 and 277).—When solution of iron is evaporated, Va accompanies Ti and Si. Va is precipitated with Fe on adding AmHO. On boiling $KHSO_4$ fusion, Va is precipitated with the basic sulphate. Dissolve Fe in HCl, wash residue with KHO, and burn off C; the final residue nearly pure V oxides.

1093. Classen (*C. N.*, lv., 74).—Digest magnetite with H_2SO_4, drive off SO_3, fuse with Na_2CO_3+S, precipitate as sulphovanadate by acidifying, and weigh as V_2O_5; Cr remains insoluble.

1094. Gerland (*C. N.*, xxxvi., 29).—V precipitated with AmCl, carries down K but not Na salts.

1095. Pope (*J. I. S. I.*, 1899, ii., 489).—Fuse ore with $NaNO_3$, precipitate with Ba, dissolve in H_2SO_4, convert to $AmVO_3$, and ignite to V_2O_5.

1096. Ditte (*C. N.*, lv., 203).—Precautions in precipitating, washing, and igniting $AmVO_3$ so as to avoid loss through solubility, volatility, &c.

1097. Boettger (*C. N.*, xxix., 62).—Heat ore with nitre and soda, leach, nearly neutralise with HNO_3, and precipitate V with $Ba(NO_3)_2$.

1098. Carnot (*C. N.*, lvi., 35).—V is completely precipitated from alkaline solutions as dibarium vanadate, and may be thus ignited. P, As, and partially W and Mo, are precipitated free from Va by substituting Sr for Ba.

1099. Gerland (*C. N.*, xxxvi., 271).—Va is almost quite precipitated with PbA_3. Decompose precipitate with HNO_3, add H_2SO_4, and ignite evaporated filtrate to V_2O_5 (readily reduced by dust and flame gases).

1100. Carnot (*C. N.*, lvi., 42).—Hg', Hg'', Pb, and Bi solutions all completely precipitate Va from neutral or faintly alkaline solution. Precipitates can also be formed with Co, Ni, Zn, Cd, and Cu.

1101. Carnot (*C. N.*, lvi., 16).—V precipitated with uranium nitrate is free from alkaline earths, Zn, Mn, Cu, &c. P, As, W, and Mo interfere. The ignited precipitate contains 24·22 per cent V. MnO solutions also precipitate V quantitatively; Mo does not interfere.

1102. Rosenheim and Friedheim (*C. N.*, lxvi., 27).—Difficulties of estimating V in the presence of As, P, Mo, and W. Weighs the CO_2 evolved in the reaction $V_2O_5+H_2C_2O_4=V_2O_4+H_2O+2CO_2$. Above elements do not interfere.

III. Volumetric Estimation of Vanadium.

1103. Genth (*C. N.*, xxxiv., 79).—Reduce to V_2O_4 with SO_2; oxidise to V_2O_5 with permanganate. Excess of H_2SO_4 without influence.

1104. Gerland (*C. N.*, xxxvi., 272).—As 1103. The *first* appearance of the pink colour is the final point. $KMnO_4$ can be repeatedly standardised by pure V compounds.

1105. Osmond and Witz (*C. N.*, xlvii., 12).—Slag decomposed with H_2SO_4, permanganate added to faint colour, and then standard $FeSO_4$, using ferricyanide indicator. Excess H_2SO_4 should be considerable. Also by comparing colour of hypovanadic solutions.

1106. Ditte, Carnot, &c. (*C. N.*, lxviii., 77, 89, &c.).—Separation of Ba and Sr from Va. Process 1103 is not affected by Mg, Ca, or (with modification) W. Analysis of vanadio-tungstates. (See also 227 to 230).

1107. Rosenheim (*J. S. C. I.*, 1891, 164).—The titration of V_2O_4 with $KMnO_4$ is obscured by a violet colouration when WO_3 is present.

1108. L'Hote (*C. N.*, lv., 191).—The ore mixed with C is heated in Cl. Vanadyl chloride is condensed and titrated with $KMnO_4$ in hot solution after reducing with zinc (see 1131).

1109. Stead (*J. I. S. I.*, 1893, i., 164).—In the presence of CrO_3, titrate with $FeSO_4$ and $KMnO_4$, which gives Va+Cr, and then with $FeSO_4$ and $K_2Cr_2O_7$, which gives Va only. V_2O_4 is not oxidised by $K_2Cr_2O_7$.

1110. Ridsdale (*J. S. C. I.*, 1888, 73).—Va in slags estimated by modification of 1105. Separation of various constituents of slag, and relative tendency of precipitates to carry down V_2O_5.

1111. Hillebrand (*C. N.*, lxxviii., 217 and 295).—Neither Cr_2O_3 nor H_3PO_4 affect process 1103; Mo and As do. Describes H_2O_2 test.

1112. Fritchle (*C. N.*, lxxxii., 258).—Fe and Ur are precipitated free from V by Na_2CO_3+NaHO. The V in carnotite is found indirectly by estimating the Ur, the Fe+V, and then Fe+Ur+V by permanganate.

1113. Holverscheit (*J. C. S.*, lviii., 1343).—The precipitated Ba or Pb salt is boiled with HCl and KBr. The liberated Br is estimated iodometrically.

1114. Browning (*C. N.*, lxx., 205).—Reduce to V_2O_4 with tartaric acid, alkalise with $NaHCO_3$, add excess of iodine, and titrate with As_2O_3.

1115. Browning and Goodman (*J. C. S.*, lxxii., ii., 234).—Above process interfered with by Mo (not W) unless the reduction with tartaric acid is effected slowly in the cold.

1116. Browning (*C. N.*, lxxiv., 203).—Reduce acid V_2O_5 solution with HI or HBr, and titrate as 1114.

1117. Friedheim (*C. N.*, lxxv., 125).—In 1116 it is better to collect the liberated halogen and estimate as 1113. In the presence of syrupy H_3PO_4, the reduction may be carried to V_2O_3.

1118. Klecki (*J. C. S.*, lxvi., ii., 162).—Dextrose added to a sulphuric solution of V in the presence of Fe gives a green colouration from which the V may be approximately deduced.

1119. Maillard (*C. N.*, lxxxii., 19). — Ether saturated with H_2O_2 is added and the colour compared with standards. Heavy metals may be removed by H_2S or Am_2S, and soluble alkaline salts do not interfere.

IV. Detection of Vanadium.

1120. Deville (*C. N.*, iv., 241).— The sulphovanadite formed on passing H_2S through an alkaline solution is a very delicate test for Va. In *C. N.*, v., 103, it is used for approximately estimating V in cast-iron.

1121. Apjohn (*C. N.*, xxvi., 183).—Fuse mineral with Na_2CO_3, remove SiO_2 and metals precipitable with H_2S, and apply 1120.

1122. Deville (*C. N.*, v., 86).—Tested with P salt, V gives intense green in the R. F., yellow in the O. F. (See 1091).

1123. Sonstadt (*C. N.*, xxvi., 215).—If strong KIO_3 be added to sea-water, V can be detected in the precipitate by blowpipe reactions.

1124. Guyard (*C. N.*, xxxiii., 71).—Add salt of aniline and a chlorate to HCl solution; rapid formation of aniline-black = V.

1125. Witz and Osmond (*C. N.*, liii., 252).—Soak prepared calico strips in solution to be tested, and compare with standard strips after treating with aniline-black mixture minus the hypovanadate.

1126. Hayes (*C. N.*, xxxi., 167).—Gall forms a greenish black precipitate in acid V solutions. In the presence of MnO, AmHO gives a blue solution, like Cu.

1127. Smith (*C. N.*, lxi., 20).—Add dilute ferrocyanide to H_2SO_4 solution; a green colour = V. Both NaHO and KHO may contain V.

1128. Elbram (*J. C. S.*, lxxii., ii., 522).—Faintly acid solution of KCNS gives a yellow colour; more strongly acid, a blue colour with V.

1129. Levy (*J. C. S.*, lii., 305).—The dark green colour given by V_2O_5 with resorcinol distinguishes it from MoO_3 or P_2O_5.

1130. Stead (*J. I. S. I.*, 1893, i., 170).—V is always present in British chromiferous pig-irons. Detects with H_2O_2.

V. Miscellaneous.

1131. Roscoe (*C. N.*, xvii., 135).—In acid solution, zinc forms V_2O_2; magnesium, V_2O_3; and SO_2 or H_2S, form V_2O_4. The relation of V to N, P, As, Sb, &c.

1132. Roscoe (*C. N.*, xx., 37).—V is insoluble in HCl, soluble in H_2SO_4+HF or HNO_3, and fused with formation of vanadates.

1133. Genth and Vom Rath (*C. N.*, liii., 218).—Outline of process for analysis of V minerals containing Pb, Cu, Zn, Mn, Fe, As, P, &c.

1134. Hintz and Weber (*C. N.*, lxx, 157).—How to precipitate V with AmCl; precipitation with Ba in the presence of alkaline salts; and the main portions of 1101 and 1106.

1135. Cowper-Coles (*C. N.*, lxxix., 147). — Electrodeposition of V. Some chemical properties and commercial uses.

1136. Read (*J. C. S.*, lxv., 314).—At high temperatures V_2O_5 gives off O. It readily re-oxidises on cooling. V_2O_4 crystals may be thus obtained.

1137. Witz and Osmond (*J. I. S. I.*, 1882, 770).—V concentrates in (notably the Thomas-Gilchrist) slags.

(To be continued).

SOME PRINCIPLES AND METHODS OF ROCK ANALYSIS.*

By W. F. Hillebrand.

(Continued from p. 151).

Methods aiming at the more or less Direct Estimation of Aluminum.

After First Removing Iron as Sulphide.

Should it be desirable for any reason to effect an actual separation of aluminum, this may best be done, up to a certain point, after the bisulphate fusion (p. 150), by removal of the iron† by ammonium sulphide in ammonium tartrate solution, evaporation of the filtrate, ignition of the residue with sodium carbonate and nitrate, and extraction with water, whereby titanium and zirconium are left on the filter as sodium salts, while chromium and vanadium are carried into the filtrate as chromate, and vanadate along with aluminum and phosphorus. The further separation of the last two from the chromium and vanadium is outlined under "Phosphorus." (See *prox.*). This is as far as the separation can well be carried, and the Al_2O_3 must still be found by subtracting the P_2O_5 from the combined weights of the Al_2O_3 and P_2O_5. The possibility of loss of some P_2O_5 by volatilisation‡ during the bisulphate fusion must be borne in mind here, for if it takes place the final weight of $Al_2O_3+P_2O_5$ will not contain all the P_2O_5.

Some writers recommend dissolving the ignited alumina, iron oxide, &c., in hydrochloric acid, but when the precipitate has been heated over the blast, as it should be, this is very ineffective.

By Extraction with a fixed Caustic Alkali.

A favourite practice in some countries of Europe is to fuse the ignited precipitate containing Al_2O_3, Fe_2O_3, TiO_2, P_2O_5, &c.—or that of the Al_2O_3, TiO_2, P_2O_5, &c., after separation of iron by ammonium sulphide in tartrate solution—with sodium hydroxide in a silver crucible, or to boil the freshly precipitated mixture with a solution of the alkali, on the assumption that the titanium oxide is hereby rendered wholly insoluble, and thus separated from the

* *Bulletin of the United States Geological Survey*, No. 176.

† This being first reduced to the ferrous condition by hydrogen sulphide in acid solution in order to obviate the possibility of precipitating some titanium, which otherwise is likely to happen. (Cathrein, *Zeit. fur Kryst.*, 1882, vol. vi., p. 246; and 1883, vol. viii., p. 259).

‡ H. Rose speaks of such loss when volatilising sulphuric acid in sulphuric acid in presence of phosphoric acid. (*Handb. f. Quant. Anal.*, Finkener Edition, vol. ii., p. 575, and elsewhere).

alumina. This, however, is in part an error, long since pointed out by Gooch (*Proc. Amer. Acad. Arts and Sci.*, 1885, vol. xii., p. 436; *Bull. U.S. Geol. Survey*, No 27, pp. 16 and 17), who showed that pure titanic oxide is markedly soluble under both conditions of treatment. Experiments very recently made by the writer to test the extent of this error brought out the following interesting results:—

When 0·045 grm. of titanic oxide was fused by itself with sodium hydroxide, the clear aqueous extract of the fusion held 0·0031 TiO_2, or about 7 per cent, determined colorimetrically. When freshly precipitated and boiled with the alkali the solubility was less. When fused with sodium carbonate but an infinitesimal trace was dissolved, which required strong concentration for its detection. When mixed with a large excess of alumina and fused with the caustic alkali, the solubility was still very marked, though less than when alumina was absent. With a large excess of ferric oxide, with or without alumina, no titanium could be detected in the unconcentrated filtrate.

It thus appears that fusion with caustic alkali after first removing iron involves an error in the gravimetric determination of both aluminum and titanium which does not appear if the iron has not been removed.

Direct Precipitation of Alumina.

A recent and promising method for the "direct determination of alumina in presence of iron, manganese, calcium, and magnesium," is that of Hess and Campbell (*Journ. Amer. Chem. Soc.*, 1899, vol. xxi., p. 776; Chem. News, 1900, vol. lxxxi., p. 158), but, as with the methods just considered, it involves finally weighing aluminum and phosphorus together, and the behaviour of titanium has not been investigated. For this latter reason the details of the method will not be given. Suffice it to say that precipitation of the aluminum and phosphorus is made by phenylhydrazine, after first neutralising the (preferably chloride) solution by ammonia, and reducing iron by a saturated solution of ammonium bisulphite. Phenylhydrazine "precipitates aluminum from its solutions quantitatively as the hydroxide without a trace of the precipitate being re-dissolved in excess of the precipitant."

IX. *Manganese, Nickel, Cobalt, Copper, Zinc.*

Ammonia is added to the flask containing manganese, the earths, &c. (p. 150), and hydrogen sulphide gas is introduced, whereby manganese, nickel, cobalt, copper, zinc, and a small part of the platinum from the dish are precipitated. The flask is set aside, corked for at least twelve hours, and preferably twenty-four, or even longer; the precipitate, collected and washed on a small filter with water containing ammonium chloride and sulphide, is extracted by hydrogen-sulphide water acidified with one-fifth its volume of hydrochloric acid (sp. gr. 1·11), manganese and zinc, if present, going into solution.

Manganese and Zinc.

The filtrate is evaporated to dryness, ammonium salts are destroyed by evaporation with a few drops of sodium-carbonate solution, hydrochloric and a drop of sulphurous acids are added to decompose excess of carbonate, and to dissolve precipitated manganese, and the latter is re-precipitated at boiling heat by sodium carbonate after evaporation of the hydrochloric acid. If zinc is present, it can be separated from the manganese after weighing. For the small quantities of manganese usually found the sodium-carbonate method of precipitation is to be preferred to that by bromine or sodium phosphate, as equally accurate, and a great time saver.

The precipitation of manganese in alkaline solution by hydrogen peroxide, as proposed by Jannasch and Cloedt (*Zeit. fur Anorg. Chem.*, 1895, vol. x., p. 405), a method which appeared to be simple and accurate, besides affording a separation from zinc, has been shown by Friedheim and Brühl (*Zeit. für Anal. Chem.*, 1899, vol. xxxviii., p. 681), to be valueless, as also other separation methods of Jannasch based on the use of hydrogen peroxide.

The employment of ammonium sulphide instead of bromine for the separation of manganese from the alkaline earths and magnesia has the advantage that, by a single operation, nickel, copper, and zinc are likewise removed if present. There need be no fear of overlooking nickel or copper, for under the conditions of the precipitation they are not held in solution. Now and then a trace of alumina may be found in the precipitate, and magnesia, too, would contaminate it if ammonium salts were not present in sufficient quantity. Regard must therefore be had to these possibilities, and also to the rather remote possibility of the presence of rare earths which were not thrown out by the basic acetate precipitation. (See footnote, p. 150).

Nickel, Cobalt, Copper.

The paper containing these is incinerated in porcelain, dissolved in a few drops of aqua regia, evaporated with hydrochloric acid, the copper and platinum thrown out warm by hydrogen sulphide, and nickel and cobalt thrown down from the ammoniacal filtrate by hydrogen sulphide. This is then rendered faintly acid by acetic acid, and allowed to stand. The sulphide of nickel is simply burned and weighed as oxide, its weight being always very small, and is then tested for colbalt in the borax bead.

It is somewhat unsafe to consider traces of copper found at this stage to belong to the rock if the evaporations have been conducted, as is usually the case, on a copper water-bath, or if water has been used which has been boiled in a copper kettle, even if tinned inside. Therefore, and because of its contamination by a little platinum, it is better to determine copper in a separate portion if its presence is indicated with certainty. (See p. 138).

X. *Calcium and Strontium (Barium).*
Separation from Magnesium.

Precipitation and Ignition of the Oxalates together.—The platinum derived from the dish in the silica evaporation, except for the small portion precipitated with the manganese sulphide, is now wholly in the filtrate from the latter. Its separation at this or any other stage is quite unnecessary; nor is the removal of ammonium chloride usually demanded, since there is no undue amount present in most cases, the first precipitation of alumina, &c., having been by sodium acetate.* Therefore, without destroying ammonium sulphide the calcium and strontium are thrown out by ammonium oxalate at boiling heat, the precipitate, often darkened by deposited platinum sulphide, is ignited and re-dissolved in hydrochloric acid, boiled with ammonia to throw out traces of alumina sometimes present, and re-precipitated as before, but in a small bulk of solution. It is weighed as oxide, transferred to a small flask of 20 c.m.³ capacity, dissolved in nitric acid, evaporated to dryness at 150 to 160° C., and the separation of strontium from calcium effected by ether-alcohol as described below. (See Fresenius, *Zeit. fur Anal. Chimie*, 1893, vol. xxxii., pp. 189, 312, for the latest improvements in this method).

The weight of strontia found deducted from that of the two oxides gives that of the lime.

Necessity for two Precipitations by Ammonium Oxalate.—It may be said with regard to the separation of calcium from magnesium that two precipitations by ammonium oxalate are essential to the attainment of correct results, not only for the complete removal of magnesium but of sodium as well, the retention of compounds of the latter element by calcium oxalate being now generally known. For the treatment of the filtrates, see "Magnesium," *prox.*

* If two or three precipitations by ammonia alone are depended on, the second and third filtrates are evaporated rapidly to dryness, and the ammonium salts removed by ignition.

Separation of Strontium (Barium) from Calcium by Ether-alcohol.

The thoroughly dried nitrates are treated with as little (rarely over 2 c.m.³) of a mixture in equal parts of absolute alcohol and ether as may be needed to dissolve the calcium salt, solution being hastened by occasional gentle agitation. After standing over night in a corked flask the insoluble matter is collected on the smallest possible filter, and washed with more of the above mixture of alcohol and ether. After drying a few c.c. of hot water are passed through the filter, on which may remain a few tenths of a m.grm. of residue which does not usually contain any lime or other alkaline earth, and whose weight is therefore to be deducted from that of the lime, unless it can be shown that it is derived from the glass of the little flask in which the nitrates of calcium and strontium were evaporated. To the solution of strontium nitrate in a small beaker sulphuric acid and then alcohol is added, whereby the strontium is precipitated as sulphate, in which form it is weighed and then tested spectroscopically as to freedom from calcium and barium.

Because of the slight solubility of strontium nitrate in amyl alcohol the method of Browning (*Amer. Journ. Sci.*, 1892, Series 3, vol. xliii., pp. 50, 314), does not appear to be adapted to the separation from calcium of the small amounts of strontium met with in rocks, though with barium the case is different, since its nitrate according to Browning is insoluble in absolute amyl alcohol.

Behaviour of Barium.

Barium will, after two ammonium oxalate precipitations, never be found with the ignited calcium and strontium in more than spectroscopic traces, unless originally present in excess of 3 or 4 m.grms., and very often only when in considerable excess (W. F. Hillebrand, *Journ. Amer. Chem. Soc.*, 1894, vol. xvi., p. 83; CHEM. NEWS, 1894, vol. lxix., p. 147). If present with them, however, it will be separated with the strontium by ether-alcohol or amyl alcohol, and these two must then be treated by the ammonium-chromate method, given below, in order to arrive at the strontium. The barium is best estimated in a separate portion. (See "Barium," *prox.*).

Separation of Barium from Strontium.

Fresenius has shown (*Zeit. fur Anal. Chemie*, 1890, vol. xxix., p. 428), in what manner only a correct separation of barium and strontium can be made by the ammonium-chromate method, involving double precipitation when the amounts are at all large. This procedure is here given for the amounts used by him, but a single precipitation will suffice for the small amounts met with in rock analysis. The volumes of solutions used should be largely reduced, and the operations otherwise shortened.

The chlorides corresponding to 0·2774 grm. BaO and 0·4864 grm. SrO were dissolved in 300 c.m.³ of water with addition of 6 drops of acetic acid (1·065 sp. gr.). To the hot solution was added an excess (10 c.m.³) of ammonium chromate solution (1 c.m.³ = 0·1 grm. neutral chromate). After settling and cooling for an hour the precipitate was washed, mainly by decantation, with water holding ammonium chromate till the filtrate gave no precipitate with ammonia and ammonium carbonate (100 c.m.³ used). The washing was continued with warm water till silver nitrate gave but a very slight reddish colouration (110 c.m.³). The precipitate was then washed into the precipitating dish, the filter rinsed with warm dilute nitric acid (1·2 sp. gr.), and more nitric acid (2 c.m.³ in all added) to the dish. The solution having been diluted to 200 c.m.³ and heated, 5 c.m.³ of ammonium acetate solution (1 c.m.³ = 0·31 grm. ammonium acetate) was very gradually added, and then ammonium chromate till the odour of acetic acid had wholly disappeared (10 c.m.³). After one hour the supernatant liquid was passed through the filter, and the precipitate digested with hot water, which was then cooled; thereupon the precipitate itself was brought on the filter and washed with cold water till silver nitrate gave a scarcely perceptible reaction. The strontium was thrown down from the filtrate by ammonia and ammonium carbonate, after concentration in presence of a little nitric acid, and weighed as carbonate; or the carbonate can be re-dissolved, precipitated by sulphuric acid and alcohol, and weighed as sulphate. The barium is weighed as chromate after ignition, the filter being burned separately.

(To be continued).

CORRESPONDENCE.

MARSH'S TEST FOR ARSENIC.

To the Editor of the Chemical News.

SIR,—The preparation of the material for the production of the little book which has just been published has led me to make an interesting observation on the action of Marsh's test for arsenic. It is this, viz., that even the description of this test in so admirable a work as the "Dictionary of Chemistry," edited by Watts, is misleading and inadequate. Marsh's test (when it is properly worked), is applicable to thick soup, port wine, porter, gruel, tea, coffee, and other alimentary liquors, without as a preliminary operation resorting to the destruction of the organic matter.

It is notorious that the very contrary of all this has been recently put forward on what is termed "high authority."

The explanation is that the original Marsh's test, as it left the hands of its discoverer in the year 1836, was capable of accomplishing the task; but that, in the hands of other chemists, Marsh's test underwent changes—so-called improvements, which did not improve it—and that, as a result of these changes, the so-called Marsh's test as worked in official England is in decay, and cannot accomplish that which Marsh accomplished.

The remedy for such a state of things is the restoring of the text of Marsh's original contribution dating back to the year 1836.

My book contains a reprint of Marsh's paper, and such comparatively slight alterations as are recommended by me tend towards attainment, and not towards the frustration and belittlement of the achievement of Marsh in the year 1836.—I am, &c.,

J. ALFRED WANKLYN.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. cxxxii., No. 10, March 11, 1901.

Total Synthesis of Acetylpropylene and Terpilenic Carbides.—M. Berthelot. — During the course of the author's researches on the direct combination of hydrocarbons with one another, he particularly noticed the reaction of acetylene on ethylene and the formation of acetylethylene by the union of equal volumes of these gases. He has since studied the analogous combination of propylene with acetylene, $C_2H_2+C_3H_6=C_5H_8$. This latter reaction is important on account of its forming a method of synthesis for the terpilenic carbides, and more generally for the carbides represented by the formula $C_{10}H_{16}$, the latter being formed in considerable quantities in vegetables.

Reduction of Molybdosulphuric Acid by Alcohol.—E. Péchard.—The reduction of acid molybdates gives rise to blue compounds resulting from the combination of molybdic acid and molybdenum dioxide. These com-

pounds are decomposed by alkalis, since they set free the molybdenum dioxide and give an alkaline molybdate. The author has, however, managed to obtain certain blue molybdenum compounds containing the dioxide, which are comparatively stable in presence of alkalis. He dissolved molybdic acid in strong sulphuric acid and then added alcohol in small quantities. A blue liquid resulted which on evaporation deposited blue crystals, some being hexagonal plates and corresponding to the formula—

$$5NH_3.MoO_2SO_3.7MoO_3+8H_2O,$$

the others prismatic crystals having the formula—

$$3NH_3.MoO_2SO_3.7MoO_3+10H_2O.$$

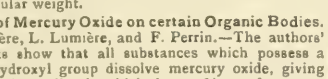
A New Bi-primary Glycol, Butanediol 1 4, or Tetramethylenic Glycol, and its Diacetine.—**J. Hamonet.**—The author's researches on the bi-primary derivatives of butane led him to consider again the question of the synthesis of tetramethylenic glycol. To do this he prepares diacetine of butanediol 1.4—

$$CH_3CO_2CH_2CH_2CH_2CH_2.O_2C.CH_3.$$

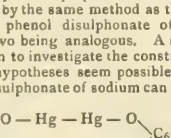
This is a neutral liquid with a pleasant smell. It boils without decomposition at 230° at ordinary pressure. From this again is prepared butanediol 1.4, or tetramethylenic glycol, $HO.CH_2.CH_2.CH_2.CH_2.OH$, a viscous liquid miscible with water in all proportions. It is evident that the constitution of this butanediol and its diacetine can be naturally deduced from that of diiodobutane 1.4, from which each is prepared.

Action of Zinc Powder on Saturated Fatty Acids.—**A. Hébert.**—Zinc powder decomposes the saturated fatty acids, in certain cases into carbon dioxide and water, and in others into carbides of which the major part consists of a mixture of ethylenic carbides of very high molecular weight and boiling point. During this reaction the molecules divide and polymerise at the same time, without apparently giving rise to new bodies related in any way to the original ones. This reaction forms, therefore, an easy method of preparation of the ethylenic carbides of very high molecular weight.

Action of Mercury Oxide on certain Organic Bodies.—**A. Lumière, L. Lumière, and F. Perrin.**—The authors' experiments show that all substances which possess a phenolic hydroxyl group dissolve mercury oxide, giving organometallic bodies in which the reactions of mercury are masked. They have prepared mercury-gaïacol-sulphonate of sodium by the same method as they previously prepared mercury phenol disulphonate of sodium, the properties of the two being analogous. A study of these two bodies led them to investigate the constitution of their molecules. Two hypotheses seem possible, by which the mercury-phenol-disulphonate of sodium can be represented by—



or equally well by—



Further experiments will be necessary to decide which of these two is correct.

MISCELLANEOUS.

Royal Institution.—The following are the Lecture Arrangements at the Royal Institution, after Easter:—Dr. Allan Macfadyen, six lectures on "Cellular Physiology, with special reference to the Enzymes and Ferments"; Professor William Knight, two lectures on "The Philosophical Undertones of Modern Poetry" (the Tyndall Lectures); Mr. Roger Fry, two lectures on "Naturalism in Italian Painting"; Sir Alex. Campbell Mackenzie, three lectures on "Arthur Sullivan" (with vocal and instrumental illustrations); Professor Dewar, three lectures on "The Chemistry of Carbon"; Professor W. M. Flinders Petrie, three lectures on "The Rise of Civilisation in Egypt"; Professor J. B. Farmer, two lectures on "The Biological Characters of Epiphytic Plants"; Mr. J. Y. Buchanan, three lectures on "Climate: its Causes and Effects." The Friday Evening Meetings will be resumed on April 19th, when a Discourse will be delivered by Professor J. J. Thomson on "The Existence of Bodies Smaller than Atoms." Succeeding Discourses will probably be given by Dr. Hans Gadow, Mr. Charles Mercier, Professor Jagadis Chunder Bose, Mr. Richard T. Glazebrook, Mr. A. Henry Savage Landor, Earl Percy, M.P., and other gentlemen.

The Chemical Laboratory at Wiesbaden.—During the Winter Term of 1900—1901, the Chemical Laboratory Fresenius was attended by forty-four Students. Of these, twenty-nine were from Germany, five from Austria-Hungary, three from England, two from France, and one from Luxemburg, Italy, Russia, Transvaal, and Rhodesia in South Africa. There were three Assistants in the Instruction-Laboratory, and twenty-four in the Versuchsstationen (private laboratories). In the teaching staff of the institution there has been no change. To this body belong the Directors, Prof. Dr. H. Fresenius, Prof. Dr. W. Fresenius, Prof. Dr. E. Hintz, and also Dr. Med. G. Frank, Dr. W. Lenz, Dr. L. Grünhut, and (Architect) J. Huber. The Summer Term begins on April 24th. In the Winter Term, 1900—1901, besides scientific work, there were many examinations carried on in the different departments of the private Laboratory (Versuchsstationen) in the interest of trade, industry, mining, agriculture, hygiene, justice, and government.

Preparation and Properties of Non-hydrated Perchloric Acid.—**D. Vorlaender and R. V. Schilling.**—The method of preparation recommended by Roscoe gives only a small return. The authors have modified it by distilling the mixture of H_2SO_4 and $KClO_4$ in vacuo. A mixture of 50 grms. of powdered $KClO_4$ and from 150 to 175 grms. of H_2SO_5 at 96 to 97·5 per cent is heated on the oil-bath in a fractionating flask. Between the pump and the receiver (cooled by a mixture of ice and salt), is placed a tube containing soda-lime; the joints are made with asbestos and water-glass. At a pressure of 50 to 70 m.m. anhydrous perchloric acid passes over at 135—145°. The temperature of the oil-bath is raised successively to 155—160° and to 180—196°. The vapour of $HClO_4$ in vacuo will stand a temperature without decomposition much higher than that given by Roscoe at the normal pressure, viz., 92°. The distilled acid, which is coloured yellow by a little ClO_2, and containing about 1 per cent of H_2SO_4, is immediately afterwards rectified on the water-bath at a pressure of 50—70 m.m., the temperature of the bath being 45—65°; the $HClO_4$ is then collected pure and colourless. It boils at 30° at a pressure of 56 m.m., its density at 22° is 1·764. It does not become solid in a mixture of solid CO_2 and ether. It is insoluble in CCl_4, but dissolves in $CHCl_3$, and this solution takes a red colour in the air, giving crystals of the monohydrate. When kept in sealed flasks it gradually becomes yellow, and then brown, and, finally, decomposes with a violent explosion. When mixed with its own volume of benzene it forms a green emulsion, and then explodes. It also explodes when mixed with phosphoric acid. The stability of $HClO_4$ partly depends on the concentration of the sulphuric acid used in its preparation. The stability increases as the strength of the acid decreases. The use of 98 per cent H_2SO_4 may be dangerous, but with acid at 92—93 per cent perchloric hydrate may distil over and solidify in the tube, blocking it up. Even with a large excess of H_2SO_4 some perchloric acid remains in the flask, as the presence of $KHSO_4$ interferes with the complete decomposition of the $KClO_4$. Phosphoric acid and pyrophosphoric acid do not decompose $KClO_4$.—*Lieb. Ann.*, vol. cccx. p. 369.

THE CHEMICAL NEWS.

Vol. LXXXIII., No. 2159

SECOND ANNUAL REPORT OF THE INTERNATIONAL COMMITTEE ON ATOMIC WEIGHTS.*

Your commitee upon international action with reference to standard atomic weights, has the honour to submit the following report. Since our report of a year ago (*Journ. Am. Chem. Soc.*, xxii., 70), various other societies have taken part in the discussion; and in the co-ordination of their work, the German Chemical Society has rendered important service. Partly through the initiative of the latter organisation, and partly through the agency of our own Society, a large international committee has been formed, and some of its deliberations are already before the chemical world for consideration.

On March, 30th, 1899, the special committee of the German Chemical Society, Professors Landolt, Ostwald, and Seubert, issued an invitation to other organisations having an interest in chemistry to appoint delegates to the international body. At the December meeting of 1898, the American Chemical Society had already taken action, and your present committee was appointed. The American Academy of Arts and Sciences also designated representatives, and important societies in Germany, Austria Hungary, Belgium, England, Switzerland, Italy, Japan, Holland, Russia, and Sweden also accepted the invitation. A body of 57 representative chemists was thus formed; but France, Norway, and Denmark do not appear in the list. We are informed, however, that the Chemical Society of Paris has recently appointed delegates, and their names will doubtless appear in the next report of the International Committee. Another committee of three was also named by the Fourth International Congress of Applied Chemistry, which met in Paris during the last week of July, 1900.

In October, 1899, the committee of the German Chemical Society sent to each of the international delegates a circular letter proposing three questions. These questions were as follows:—

1. Shall O=16 be fixed as the future standard for the calculation of atomic weights?

2. Shall the atomic weights be given with so many decimals that the last figure is certain within half a unit, or what other procedure shall be adopted?

3. Is it desirable that a smaller committee should be formed, which should undertake the continual revision of the yearly atomic weight table and its publication? In case of agreement upon this point it is proposed that each association shall name a single delegate to the smaller committee.

To these questions forty-nine replies were received. As regards the first question, forty chemists favoured the oxygen standard, seven preferred to retain the hydrogen unit, and two were willing to accept either or both standards. The replies are published in full (*Ber. d. D. Chem. Ges.*, 1900, xxxiii., 1853), some writers giving only categorical answers, and others citing arguments in behalf of the position which they favoured. The majority for the oxygen standard was overwhelming; but, as we shall see later, it has not yet been universally accepted as a final decision. At the Congress of Applied Chemistry, in the section devoted to analytical chemistry, the question was discussed, and in this case the decision of the International Committee was sustained. As only two members of the latter committee were present at this discussion, representing opposite sides, the action of the congress is to be regarded as a ratification of the decision, and not as a mere duplication of votes by the same men. An attempt was made to secure an actual meeting of the International Committee at the congress, but it did not succeed. Too few of its members were in attendance.

The second and third questions of the German Committee were also answered affirmatively, by a large majority in one case, and unanimously in the other. Balloting for the smaller committee has already taken place, and the result will probably be known before this report is presented. As to the second question, the replies and printed criticisms seem to indicate some misunderstanding as to its real significance; and for this reason it ought to receive further and more careful consideration. In the opinion of your committee atomic weights should be printed with so many decimals as have any real significance, even though, in the calculation of ordinary analyses, rounded off values may be employed.

In spite of the great majority given in the International Committee in favour of O=16 as the standard for atomic weights, a vigorous protest against the decision has been made. In the original balloting, the seven dissentients were one American and six German chemists, the latter being delegates from the Verein Deutscher Chemiker. These six chemists, Bredt, Erdmann, F. Fischer, Volhard, Winkler, and Wislicenus, issued a new circular letter (see *Zeit. Angew. Chem.*, July 24th, 1900; Chemical News, August 10th, 1900), addressed to the teachers of chemistry in the German universities and technical schools, asking for a further and fuller expression of opinion. At the date of writing, the result of this canvass has not been published; but Professor Erdmann, in a letter dated November 23rd, 1900, informs us that 143 replies have been received, of which 118 favour the retention of the older standard, H=1. In the new edition of Erdmann's "Lehrbuch der Anorganischen Chemie," this standard is adopted throughout, and other voices have also been raised in protest against O=16. A pamphlet by Lassar-Cohn ("Ueber der Ungeeignete der Newendings für die Berechnung der Atomgewichte vorgeschlagenen Grundzahl 16·000," Hamburg, Voss, 1900), furnishes a case in point, and another paper by Dr. A. R. L. Dohme (*Druggist's Circular and Chemical Gazette*, September, 1900), is noticeable as foreshadowing the probable action of the committee for the decennial revision of the United States Pharmacopœia. In this important work the hydrogen scale is likely to be adopted.

From what has been said so far, it is evident that chemical opinion is still divided on the question of the basis for atomic weights, and that the desired unity of action has not been reached. Neither standard can be forced into general acceptance and further discussion is unavoidable. Even your own committee is divided upon the subject, and therefore asks from the members of the American Chemical Society an expression of their preferences. In order to facilitate such an expression we submit the following summary of arguments which have been used for and against each standard. These may be classified as historical, theoretical, and arguments from convenience,* even though the three categories are not absolutely separable.

Historically, it is urged, the hydrogen unit has the advantage of being the original Daltonian standard; and except temporarily, during the Berzelian period, it has been almost universally recognised. Berzelius made oxygen the standard, and based his scale upon O=100; but oxygen as 16, considered as a basis for atomic weights, is a recent innovation. It is true that the atomic weight of oxygen, referred to hydrogen as unity, was long thought to be 16, but this belief is now known to be an error. To the believer in precedent and priority the adoption of the oxygen standard would seem to be the perpetuation of an error, as well as a break in the historical continuity of science.

* *Journal of the American Chemical Society*, xxiii., No. 2.

* For an elaborate argument in favour of the oxygen standard, see Richards, *Am. Chem. Journ.*, xxiv., 377; see also Brauner, *Zeitschr. Anorg. Chem.*, xxvi., 186.

To the advocates of oxygen as a basis for atomic weights the foregoing argument appears to be irrelevant and fallacious. They claim that hydrogen has only been a nominal unit, since actual determinations of atomic weight are commonly referred to hydrogen through the medium of oxygen, the latter being the experimental standard of reference. To retain the hydrogen scale means to take the ratio H : O as a fundamental base line; and every change in that implies changes throughout the entire table. Historically, at least as viewed from the experimental side of the question, hydrogen has been only the theoretical standard; oxygen, taken as 16, has been the real basis for calculation. The ordinary, familar atomic weights are all in harmony with the oxygen basis, and, with other constants which rest upon the same foundation, they permeate all chemical literature. The retention of the hydrogen unit implies confusion in the interpretation of a great mass of recorded data; and apparent historical conservatism really involves widespread and radical change. After all, the historical argument tends to obscure the essential issue, the true problem being the establishment, on a permanent basis, of the best possible scale.

On theoretical grounds it is claimed that the hydrogen unit is the most natural basis for atomic weights, partly because the hydrogen atom is the lightest atom known, and partly because hydrogen is also the standard for gaseous densities and for valence. The atomic weight scale and the density scale rest upon the same foundations; and if the oxygen standard is adopted, then all vapour-densities must be changed to a corresponding degree. Furthermore, unity, or some number logarithmically equivalent to unity, such as 10 or 100, would seem to be a better starting-point for calculations than some other quantity, arbitrarily chosen, whose selection might be troublesome to explain. An approximate unity, like 1·008, is meaningless, and the value 16·000, taken as a standard, can only be explained by reference back to hydrogen, the unit from which it was originally derived. The explanation, then, is somewhat in the nature of an apology, and concedes much to the opposite side.

To the theoretical arguments the advocates of the oxygen scale attach little importance, regarding the question as one of practice and convenience rather than as one of theory. They point out, however, that elements lighter than hydrogen may yet be discovered, and that then the theoretical considerations would be radically changed. If Prout's so-called law held good, a valid reason for the hydrogen unit would exist; but as matters stand now that unit is as arbitrary as any other, and rests upon no necessary foundation of principle. Which standard, then, is the more convenient for general use?

The answers to this question suggest two quite distinct points of view; that of the teacher on the one hand, that of the laboratory chemist on the other. The teacher argues in favour of the hydrogen unit, that it is easily intelligible to beginners, whereas the oxygen standard is somewhat difficult to explain. The difficulty, moreover, becomes greater when gaseous densities are considered, and the teacher is forced to decide whether he shall adopt a dual standard, or reject the hydrogen basis altogether. A few teachers claim that these difficulties are much overrated, while others propose to evade them, either by giving to the beginner round numbers which are confessedly approximate, or by abandoning hydrogen as a standard of specific gravity, and taking oxygen instead. If the latter policy were followed it might lead to discordance between the allied sciences of chemistry and physics, for the physicist prefers hydrogen as a standard because it is not only the lightest of all substances, but also the one which most nearly approaches the ideal perfect gas. In the hydrogen thermometer its nearly uniform rate of expansion is considered, as well as the fact that at low temperatures it is the last gas except helium to assume the liquid state. The graduation of the hydrogen thermometer is the ultimate standard of reference in all exact thermometry, whether for low temperatures or for high. This question of harmony between different branches of science is one which needs to be seriously considered; and so far, at least as regards our choice of atomic weights, it seems not to have been adequately discussed.

When we consider the use of atomic weights in the calculation of analyses, the oxygen table has the great advantage of familiarity to chemists, and perhaps also the minor advantage that a larger proportion of the values are nearly integers. The latter consideration, however, is of little importance, for many analysts use tables of logarithms or of factors; but to the chemist who employs atomic weights directly, integral numbers are more easily remembered than figures which involve one or two decimal places. In commercial work the ordinary round numbers are likely to hold their own, and no serious inaccuracy of results is to be feared from this practice. The usual errors of analysis far outweigh any uncertainty of calculations which may be due to neglect of decimals in the commoner atomic weights. There are cases to which this argument does not apply, and in which a greater exactness of data is indispensable;* but these are few in number, and should be known to the specialists in whose practice they arise.

The unfamiliarity of the hydrogen scale is easily illustrated by the following table, in which a few of the more common atomic weights, as given under both standards, are compared:—

	H = 1.	O = 16.	Difference.
Hydrogen	1·000	1·008	0·008
Oxygen	15·879	16·000	0·121
Chlorine	35·18	35·45	0·270
Potassium	38·82	39·11	0·290
Copper	63·10	63·60	0·500
Bromine	79·34	79·95	0·610
Silver	107·11	107·92	0·810
Iodine	125·89	126·85	0·960
Barium	136·40	137·40	1·000
Mercury	198·50	200·00	1·500
Lead	205·36	206·92	1·560

The difference increases with increasing atomic weight, and amounts in each case to about 0·75 per cent of the entire value. With small atomic weights the difference appears trifling; in the higher parts of the table the discordance is much more evident.

Clearly then, the adoption of the modern hydrogen scale would compel chemists to drop certain old values and to learn the new. Whether this is desirable or undesirable is for chemists to decide. To the older chemists, who first learned the Daltonian equivalents, and then discarded them for the atomic weights of Cannizzaro, the change will not seem difficult; to the younger men the anticipation of annoyance is likely to be worse than the reality. At all events, the inconvenience, be it great or small, is evident, and it must be taken into account in arriving at the final conclusion.

Your committee hope that the members of the American Chemical Society will consider the questions and considerations which are presented in this report, and express their views upon them. Which system of atomic weights is the better, not merely for temporary purposes, but regarded broadly with a view to the permanent interests of science? That is the real question upon which a consensus of opinion is desired, and which ought to be considered from all points of view. Replies should be addressed to the chairman of this committee, F. W. Clarke, U.S. Geological Survey, Washington, D.C., before June 1st, 1901.

Respectfully submitted,—

F. W. Clarke, Chairman.
J. W. Mallet,
Edward W. Morley,
Theo. W. Richards,
Edgar F. Smith.

A BIBLIOGRAPHY OF STEEL WORKS ANALYSIS.

Part VIII.

VANADIUM AND TITANIUM.

By HARRY BREARLEY.

(Continued from p. 164).

TITANIUM.

I. Separation from other Elements.

Iron.—

1138. Streit and Franz (*C. N.*, xxi., 120).—Ti is precipitated by boiling the H_2SO_4 solution, containing considerable acetic acid, free from Fe or Zr.

1139. Baskerville (*J. C. S.*, lxvi., ii., 401).—The separation by boiling is more easy and accurate when the metals exist as chlorides.

1140. Deville (*C. N.*, v., 102).—To H_2SO_4 solution add AmHO, evaporate the whole to dryness, and dissolve out Fe and Al with dilute HNO_3; the residual Ti is calcined and weighed.

1141. Walker (*J. C. S.*, lxxiv., ii., 540).—The Fe is repeatedly precipitated with ammoniacal H_2O_2; Ti in the filtrates.

1142. *Aluminium.*—Gooch (*C. N.*, liii., 55, &c.).—Separation with NaHO or by boiling acid solution inexact. Separate with AmHO and acetic acid, or microcosmic salt and formic acid. Fe is precipitated by H_2S from alkaline tartrate solutions.

Tin.—

1143. Rose (*C. N.*, v., 87).—Fuse oxides with soda and sulphur. The Sn is dissolved out with water.

1144. Hilgar and Haas ((*C. N.*, lxi., 209).—Reduce the mixed oxides in H; dissolve out Sn with HCl. Silicates are decomposed with H_2SO_4+HF (see also Haas, *J. C. S.*, lviii., 1029).

1145. *Silica.*—Holland (*C. N.*, lix., 27).—If H_2SO_4 be not present, Ti is volatilised on treating with HF. Even after two precipitations, TiO_2 contains Fe. TiO_2 dissolves in HCl if Al_2O_3 is also present. A scheme for the analysis of Ti silicates.

1146. *Niobium.*—Marignac (*C. N.*, xvii., 119 and 121).—Fuse the acids with fluorhydride, reduce HCl solution of the melt with zinc, and titrate (Ti only) with $KMnO_4$ (see 1172). Demarçay (*J. C. S.*, xlviii., 639) treats the HF solution of the oxides (including Zr) with KHO short of alkalinity; the Ti remains in solution.

1147. *Gallium.*—Boisbaudran (*C. N.*, xlviii., 164).—Precipitate Ti with KHO from boiling solution. Four other methods given.

II. Gravimetric Estimation of Titanium.

1148. Scheerer (*C. N.*, i., 143).—Decompose silicate as usual, vaporise SiO_2 with HF, and add the residue to precipitate formed in the filtrate with AmHO. Fuse with $KHSO_4$, reduce Fe with H_2S, and precipitate TiO_2 by boiling.

1149. Tosh (*C. N.*, xvi., 168).—Solution and residue treated as 1148. Precipitate Fe and Ti from solution of $KHSO_4$ fusion with AmHO, dissolve out Fe with Am_2S and SO_2, and weigh residual TiO_2; results approximate.

1150. Forbes (*C. N.*, xviii., 275).—Fuse ore with $KHSO_4$, separate SiO_2, and precipitate TiO_2 by boiling much diluted filtrate after acidifying with HNO_3.

1151. Bettel (*C. N.*, xxviii., 93).—As 1150; but omits HNO_3, and adds SO_2 before boiling.

1152. Forbes (*C. N.*, xix., 3).—Decompose powdered mineral with H_2SO_4 or $NaHSO_4$, and proceed as before. The Ti, which goes into solution on dissolving Fe in aqua regia, is all contained in a small precipitate formed with AmHO.

1153. Roussel (*C. N.*, xxviii., 313).—Decompose the mineral with soda. Separate TiO_2 and SiO_2 with concentrated H_2SO_4; Ti from the filtrate with SO_2, &c., and from co-precipitated Al_2O_3 by digesting with HCl (see 1145).

1154. Anon. (*J. I. S. I.*, 1895, i., 514).—Reduce ore in H, dissolve in HCl, fuse residue, dissolve insoluble titanate in HCl, precipitate Fe and Al from tartrate solutions with H_2S, and precipitate TiO_2 by boiling with glacial acetic acid.

1155. Ledebur (*J. I. S. I.*, 1885, 300).—Dissolve ore in HCl, re-treating the insoluble portion; evaporate filtrate with H_2SO_4, partially neutralise, and precipitate by boiling with SO_2. HNO_3 solution of iron evaporated and treated as ore.

1156. Parry and Morgan (*C. N.*, lxvii., 260).—Decompose pig-iron with HCl, fuse ignited residue with $KHSO_4$, and precipitate Ti by boiling. Describe also Riley's process, in which Ti is carried down by a little basic ferric acetate.

1157. Classen (*J. C. S.*, liv., 532).—Precipitate Fe with KHO+H_2O_2 (see 1141), filter, boil off H_2O_2, and precipitate Ti with AmHO. Any Ti carried down with the iron remains suspended when the oxalate solution of the latter is electrolysed.

1158. Brakes (*J. S. C. I.*, 1899, 1097).—Dissolve ore and fusion of the residue in HCl, nearly neutralise, boil with SO_2, remove SiO_2 with HF, and weigh TiO_2.

1159. Baskerville (*J. S. C. I.*, 1900, 419).—Fuse ore with NaF+$KHSO_4$, neutralise HNO_3 solution of the melt, and from faintly HCl solution precipitate TiO_2 by boiling. The estimation of Si, S, P, &c., described.

1160. Hunt, Clapp, and Handy (*C. N.*, lxv., 235).—Decompose Al-Ti alloy with KHO, fuse residue of Fe and Ti with $KHSO_4$, and precipitate TiO_2 by boiling.

1161. Ziegler ((*C. N.*, lxvi., 321).—Fe-Ti alloy fused with $NaHSO_4$, SiO_2 eliminated, and TiO_2 precipitated by boiling. H_2SO_4 driven from the precipitate by igniting with Am_2CO_3.

1162. Jennings (*J. I. S. I.*, 1888, 331).—Decompose ore with HCl, boil with SO_2 and acetic, fuse precipitate and residue, dissolve soda titanate in H_2SO_4, and re-precipitate by boiling.

1163. Austen and Willbur (*C. N.*, xlviii., 113).—TiO_2 can be precipitated from HCl solution of FeO as well as by the usual method if acetic acid be added.

1164. Morgan (*C. N.*, lxxv., 134).—Evaporate acid solution of iron with H_3PO_4, fuse insoluble phosphotitanate successively with K_2CO_3 and $KHSO_4$, and precipitate TiO_2 with acetate.

1165. Levy (*C. N.*, lvi., 209).—The liquid should contain exactly 0·5 per cent free H_2SO_4, and then boiled for six hours. Zn, Cu, Mg, Al, no effect; Fe, results high.

1166. Apjohn (*C. N.*, xxvi., 183).—Decompose rock with $KHSO_4$, precipitate Ti by boiling, and weigh as titanofluoride of potassium.

1167. Drown and Shimer (*C. N.*, xlii., 299).—Heat iron in Cl, absorb Si and Ti in water, evaporate with HCl and H_2SO_4 to separate SiO_2, and precipitate Ti by boiling. Results higher than Riley's process (1156).

1168. Shimer (*C. N.*, lv., 156).—Agreeing determinations of Ti in pig-iron were made—(1) By fusing HCl residue with $KHSO_4$; (2) by dissolving Ti from residue with HNO_3 (see 463), and by 1167. The precipitate formed by boiling always contains P; it is separated by fusion with soda.

1169. Carnot and Goutal (*J. C. S.*, lxxii., ii., 521).—Decompose Fe with neutral cupro-potassic chloride, fuse residue with $KHSO_4$, and precipitate TiO_2 with SO_2 and acetate.

1170. Moissan (*C. N.*, lxxi., 103).—Ti is decomposed by KNO_3 and K_2CO_3, and precipitated with AmHO. Some properties of the metal.

1171. Pennington (*C. N.*, lxxv., 31).—Na_2HPO_4 completely precipitates Ti from its double fluoride solution.

III. Volumetric Estimation of Titanium.

1172. Pisani (*C. N.*, x., 218).—Reduce HCl solution with Zn, and titrate with $KMnO_4$; Zr does not interfere. By using KCNS test, Ti can be titrated in presence of iron, since Ti is first oxidised. H_2S and SO_2 do not reduce Ti. Wiegand (*J. S. C. I.*, 1883, 363).—The estimation in the presence of Fe is unreliable.

1173. Wells and Mitchell (*C. N.*, lxxiii., 123).—Decompose ore with acids and $KHSO_4$, reduce, and titrate H_2SO_4 solution (even in the presence of iron) as 1172.

1174. Weller (*J. S. C. I.*, 1882, 506 and 508).—Mo, V (see 1119), and Cr interfere with the H_2O_2 colour estimation of Ti; NH_3 and K salts, and excesses of the reagent do not appreciably. The yellow colour is due to a higher oxide, TiO_3. (Also Classen, *J. S. C. I.*, 1888, 344).

1175. Dunnington (*C. N.*, lxv., 65).—Evaporate powdered rock with HF, fuse with $KHSO_4$, extract with H_2SO_4, and apply 1174.

1176. Dunnington (*C. N.*, lxiv., 302).—The $KHSO_4$ fusion should be taken up with 5 per cent H_2SO_4 to prevent the formation of meta-titanic acid, which gives no colour with H_2O_2.

1177. Wells (*J. I. S. I.*, 1886, 399).—Dissolve Fe in nitro-sulphuric, evaporate to SO_3, dilute, add H_2O_2, and compare with standard. Will estimate 0·01 per cent Ti.

1178. Noyes (*J. S. C. I.*, 1891, 485).—Open up ore with $KHSO_4$ and NaF, and apply 1174. Very small amounts of Fe interfere, but may be allowed for.

IV. Detection of Titanium.

1179. Riley (*C. N.*, iv., 84).—Treat SiO_2 with HF, fuse residue with Zn and microcosmic salt in order to detect Ti in pig-iron.

1180. Deville (*C. N.*, iv., 241).—Titanate of K in HCl gives with Zn a violet-blue colour. The precipitate formed with AmHO in HCl solution gives a deeper colour when heated with Sn in R.F.

1181. Jackson (*C. N.*, xlvii., 157).—Yellow colour with H_2O_2 in HCl or H_2SO_4 solution; easily detects 1 part in 50,000.

1182. Hillebrand (*C. N.*, lxxii., 158).—HF interferes with H_2O_2 test. H_2O_2 may contain HF.

1183. Fresenius (*C. N.*, lii., 104).—H_2SO_3 which has been momentarily in contact with Zn produces an orange-red colour; about as sensitive as the H_2O_2 test.

1184. Levy (*C. N.*, liv., 301).—Moisten with H_2SO_4, and add morphine; a crimson colour = Ti.

1185. Ludeking (*C. N.*, lxiii., 24).—Fuse in bead of Na_2CO_3 and heat in R.F.; red (cyano-nitride) colour = Ti.

V. Miscellaneous.

1186. Riley (*C. N.*, i., 159).—Analysis of New Zealand iron sands. Ti determined by difference.

1187. Mushet (*C. N.*, i., 231 and 276).—Contention that the "body" and general excellence of certain steels is due to Ti.

1188. Riley (*C. N.*, viii., 224, &c.).—Two or three not very satisfactory processes for estimating Ti (see 1156).

1189. Jones (*C. N.*, lxv., 8).—Refractory Ti minerals containing Al, Mg, Cr, &c., are decomposed by heating with H_2SO_4 in sealed tube.

1190. Blondel (*C. N.*, lxxix., 305).—Beyond 200°, H_2SO_4 solutions of TiO_2 deposit crystals which stop the decomposition of the mineral. TiO_2 slowly precipitated at ordinary temperatures.

1191. Hogg (*C. N.*, lxviii., 163).—As isolated crystals of cyano-nitride Ti exists in ferro-manganese.

1192. Hillebrand (*C. N.*, lxxviii., 94).—Description of H_2O_2 colour test. Zr prevents precipitation of TiO_2 by boiling acetic solutions. Separates Fe and Al from Ti as 1139.

1193. Nau (*J. I. S. I.*, 1892, ii., 437).—Ti may not be detectable in pig-iron even when the slag contains 8 per cent or more TiO_2.

1194. Reinhardt (*J. S. C. I.*, 1888, 326).—Separation of cyano-nitride (Ti_5CN_4) from slags, and analysis thereof. (Also Franck, *J. S. C. I.*, 1897, 942).

(END OF PART VIII.).

A METHOD FOR PREPARING NORMAL, SEMINORMAL, DECINORMAL, &c., SULPHURIC ACID OF EXACT STRENGTH.*

By RICHARD K. MEADE.

The principal beauty of the normal system in volumetric analysis is the doing away with calculations. If then it is necessary to use a factor for converting to normal with a solution much of the usefulness of the system is destroyed. Unfortunately with by far the larger number of reagents used in volumetric analysis it is only with the greatest care that such solutions can be made of normal strength. Of the commonly used acid and alkali solutions, only oxalic acid and sodium carbonate can be prepared of exact strength, without first having another standard solution against which to balance a preliminary and then the exact solution. Even then, the latter is frequently too wide of the normal value to be used without a factor. The writer has been for some time preparing normal, seminormal, and more particularly decinormal sulphuric acid of exact strength by the method given below. The solution as prepared by this method needs no checking, except as a safeguard against errors of manipulation on the part of the analyst.

If the electric current is passed through a solution of copper sulphate the salt is decomposed, copper separating upon the cathode and sulphuric acid at the anode. This latter remains in solution and is not decomposed by the current. Hart and Croasdale (*Journ. Anal. Chem.*, iv., 424) took advantage of this reaction to standardise alkali solutions. Their results were highly accurate. The writer has frequently made use of this method of standardising alkali and has obtained results far more satisfactory than by any other method.

The method of preparing tenth-normal sulphuric acid by means of this reaction is as follows:—

12·487 grms. of pure crystallised copper sulphate are dissolved in about 750 c.c. of distilled water in a lipped beaker capable of holding about a litre. Into this solution, after cooling, is introduced a cylinder of copper foil attached to the minus (−) wire of an electric circuit. This copper cylinder may be made from 0·015 inch copper foil. The foil is cut the required length (three times the diameter of the beaker + one-half inch), curled so that the ends lap, and holes punched through the two thicknesses of foil with a sharp nail. Wire is then run through the holes, fastening the two ends of the foil together. A platinum rod for an anode is next passed through a perforated watch-glass covering the beaker into the copper sulphate solution. A current of electricity of from one to one and a-half ampères is now passed through the solution for about eight hours; or all night if the decomposition is

* Contribution from the Chemical Laboratory of Lafayette College. From the *Journal of the American Chemical Society*, xxiii., No. 1.

begun in the afternoon. In the morning the watch-glass is removed and rinsed off together with the cylinder and the rod into the beaker. The solution is then transferred to a litre graduated flask; any copper which may have dropped off the cylinder into the beaker is to be washed well by decantation, rinsing the beaker at the same time into the flask. The contents of the latter are then diluted to the mark.

The first few solutions made in this way were subjected to the following tests:—

A portion of the solution was carefully evaporated to small bulk and hydrogen sulphide passed into the liquid. No precipitate formed.

Another portion of the solution was evaporated to a few cubic centimetres, ammonia added, and the test-tube stood upon white paper. No blue colour.

A third portion of the solution, after evaporation, was placed in a bright platinum dish, a drop of nitric acid added, and a weak current passed through the solution. After one hour no copper stain appeared on the dish and the platinum was still bright.

The results given by the first solution made, when checked by volumetric and gravimetric methods, are given below:—

An exactly tenth-normal solution of sodium carbonate, made by igniting pure bicarbonate and then dissolving 5·305 grms. of the resulting sodium carbonate in a litre of water, was first used.

Check No.	Sodium carbonate solution taken.	Sulphuric acid solution required to neutralise.
	C.c.	C.c.
1	25·0	25·0
2	25·0	25·1
3	15·0	15·05
4	15·0	14·9

A tenth-normal sodium hydroxide solution was next used. This solution was made by dissolving freshly cut clean bright pieces of metallic sodium in water contained in a silver dish and covered with a large inverted funnel. It was preserved in a large bottle, and drawn off for use by means of a syphon passing through the stopper of the bottle. All air entering the bottle passed through a soda-lime tube, capped when not in use. This sodium hydroxide solution had been checked against a fifth normal hydrochloric acid solution, which in its turn had been standardised by precipitation with silver nitrate. It was also checked by the copper sulphate and battery method of Hart and Croasdale. These checks established a factor, 0·99501, for converting to tenth-normal.

Check No.	Sodium hydroxide solution taken.		Equivalent volume of N/10 solution.	Sulphuric acid solution required.
	C.c.		C.c.	C.c.
1..	10	× 0·995 =	9·95	10·0
2..	10	× 0·995 =	9·95	9·9
3..	20	× 0·995 =	19·9	19·9

Finally, 25 c.c. of the sulphuric acid solution were acidified with a few drops of hydrochloric acid, heated to boiling, and an excess of a hot 10 per cent solution of barium chloride slowly added with constant stirring. After standing all night, the precipitate was filtered off, ignited, and weighed.

1. Weight of barium sulphate .. 0·2923 grm.

The molecular weight of barium sulphate is 233·46; hence, 25 c.c. of a tenth-normal solution should give—

$$\frac{233{\cdot}46 \times 25}{2 \times 10 \times 1000} = 0{\cdot}29183 \text{ grm. barium sulphate.}$$

The solution is therefore a little under tenth normal, or 2923 : 2918 :: x : 1; x = 1·002, which gives the factor for converting to tenth-normal.

2. Weight of barium sulphate ..	0·2938 grm.
Factor is in this case	1·003
Average factor for the two determinations	1·0025

Of course, the results by precipitation with barium sulphate would be worthless if the absence of copper had not been previously proved.

Since making this solution, the writer has repeatedly made normal and fifth-normal solutions by this method; it was not until recently though, that he had occasion to make a normal solution. In this case, 124·87 grms. of copper sulphate were dissolved in 800 c.c. of water and decomposed by a current of 2·5 ampères. The decomposition was complete in about twelve hours, though the current was allowed to run nearly eighteen. After making up to a litre, the strength of the solution was taken against the sodium carbonate solution mentioned above, with the following results:—

Sulphuric acid solution taken.	Sodium carbonate solution required.
C.c.	C.c.
5·0	50·1
5·0	50·2
5·0	49·8
5·0	49·95
Average	50·025

100 c.c. of the normal solution were then diluted to 1000 c.c. in a graduated flask, and, after mixing, tested against the N/10 sodium hydroxide solution mentioned above.

Sodium hydroxide solution taken.			Equivalent volume of N/10 alkali solution.	Sulphuric acid. required.
C.c.			C.c.	C.c.
10·0	× 0·995	=	9·95	10·1
10·0	× 0·995	=	9·95	10·0
10·0	× 0·995	=	9·95	10·0
10·0	× 0·999	=	9·95	9·95
10·0	× 0·995	=	9·95	9·95
Average				10·00

All of the solutions made by this method have been checked against the sodium hydroxide solution, with the result that the strength of the sulphuric acid solution is always the desired one.

THE MINERAL CONSTITUENTS OF DUST AND SOOT FROM VARIOUS SOURCES.*

By W. N. HARTLEY, F.R.S., Royal College of Science, Dublin, and HUGH RAMAGE, A.R.C.Sc.I., St. John's College, Cambridge.

(Concluded from p. 159).

On the Nature of Dust from the Clouds.

The principal characteristic of dust which has fallen directly from the clouds or collected by hail, snow, sleet, or rain, is its regularity in composition—each specimen appears to contain the same proportions of iron, nickel, calcium, copper, potassium, and sodium. The proportion of carbonaceous matter must be small, otherwise a diminution in the proportion of the metals present would render the metallic lines weaker. There is a very considerable difference between the dust from sleet, snow, and hail suddenly precipitated, the difference being in the proportion of lead, which, in the dust from sleet, is much larger than in the other specimens, though dust from hail and one quantity collected from rain contain more than is found in any other specimens with such an origin. The only meteorite which contains as much lead as this is the siderolite from Atacama.

Of Volcanic Dust.

If we examine the spectra of specimens of volcanic dust it is noticeable that the heavy metals are, without excep-

tion, in comparatively small proportions—lead and iron, for example—while lime, magnesia, and the alkalis are the chief basic constituents. The spectra of the heavy metals, the alkaline earths, and the magnesia with the alkalis appear on separate photographs.

Of Soot from different Chimneys.

The nature of soot from different sources is characterised by the small proportion of iron in most specimens and of metals precipitated as hydroxides; its large proportion of lime, and the greater variability in the proportions of its different constituents distinguishes it from other kinds of dust collected from the clouds or in the open air. It was certainly unexpected when nickel, calcium, manganese, copper, and silver were found to be constant constituents of soot fron different chimneys and flues. The proportions of lead, silver, and copper are much larger in the soot from the assaying furnace and the laundry chimney.

To illustrate the differences observable in dust and soot of various kinds, a list is appended of the wave-lengths of the iron lines observed in the spectra from soot obtained from the laundry, laboratory, kitchen, and bedroom chimneys. A second list gives the wave-lengths of lines belonging to other elements, and observed in other substances as well as dust and soot.

It will be seen that there is an extraordinary difference between the kitchen and the laundry soot, which is probably caused by a higher temperature and more complete combustion of the fuel in the laundry fire.

Flue Dust.

In flue dust from different sources the chief character-

3618·5, 3609·8, 3571·2, 3461·0, 3433·0 The lines observed are near the positions of such as are here indicated, and are probably identical with them. There is also a line 3525, the only one observed in Cleveland pig-iron. It does not appear in these analyses.

Some of the lines were measured with a micrometer and the wave-lengths deduced from a curve on an enlarged scale drawn from Rowland's measurements of iron lines in the solar spectrum.

istics are the presence of lead, silver, and copper in larger proportions than in other varieties of dust or of coal ashes which have also been examined. Nickel and manganese also are in larger proportions. But the most striking feature is the quantity of rubidium, gallium, indium, and thallium in all samples examined.

It is evident now that we can state with absolute certainty whether two kinds of dust have the same composition, or in what constituents they differ substantially.

When dust is collected in the open air it is liable to become mixed with other dust and soot, and we cannot be certain whether it comes from only one source or not, but soot, as a rule, can be separated by washing it away from the heavier matter. The occurrence of nickel in soot and flue dust was certainly unexpected. It is probably disseminated in extremely minute traces in coal, and its concentration in soot is owing to the conditions in a coal fire being favourable to the formation of nickel tetra-carbonyl and its subsequent decomposition.

Conclusions.

(1). The presence of nickel, as shown by the examination of soot, is not positive evidence that the dust from the clouds comes from other than a terrestrial source.

(2). The dust which fell on the 16th and 17th of November, 1897, with its regularity in composition and its similarity to meteorites, being magnetic, also its comparative freedom from extraneous matter, exhibits properties which are quite in favour of its cosmic origin. Moreover, its composition is totally unlike that of volcanic dust and flue dust from various chemical and metallurgical works. This dust for the most part fell on a perfectly calm fine night, and there was no rain for twenty-four hours or more afterwards.

We beg to draw attention once more to the very wide distribution of gallium in minute proportions; it occurs in all aluminous minerals, flue dust of very different kinds, soot and atmospheric dust, also in a great variety of iron ores. Bauxite contains it in larger proportion than any other mineral, but the quantity even in this substance is very small. We have hopes of finding it concentrated in some mineral, as thallium, cæsium, germanium, and indium are. Indium and thallium, the other members of the same group of elements, are found in blende and pyrites, and accordingly we might expect gallium to occur in a concentrated state in a sulphide, arsenide, or similar compound. Judging, however, from its analogy with aluminium, there does not seem to be much probability of this.

SOME PRINCIPLES AND METHODS OF ROCK ANALYSIS.*

By W. F. HILLEBRAND.

(Continued from p. 166).

XI. *Magnesium.*

Precipitation.

The first precipitation of magnesium is made without special precautions in the filtrate from the first calcium oxalate separation (p. 165), by sodium-ammonium-hydrogen phosphate (microcosmic salt)† in indefinite decided excess, and without the great excess of ammonia usually prescribed. It is not necessary to first remove ammoniacal salts unless very little magnesium is present, and then only in order to hasten precipitation. Neubauer (*Zeit. fur Angew. Chemie*, 1896, p. 435), has shown that precipitation is complete even in presence of large quantities of salts of ammonium, including the oxalate.

* *Bulletin of the United States Geological Survey*, No. 176.

† The objection that has been made by one writer to the use of this salt instead of disodium-hydrogen phosphate is, so far as our experience teaches, entirely groundless.

He has, however, also shown that the composition of the precipitate is largely affected by ammonium salts, and also by the way in which the precipitation is made. These points are only of importance when a single precipitation is to be made or in the final of two or more, as will be discussed later.

Platinum sulphide usually strongly contaminates the separated phosphate, but this matters not, as it remains on the filter when the phosphate is re-dissolved in hydrochloric acid, of which not more than the amount really needed should be used. The solution thus obtained is united with that of the residue from evaporation and ignition of the second filtrate from calcium oxalate, and is diluted if necessary. A few drops of sodium-ammonium phosphate solution are now added, and ammonia in slight excess, with constant stirring till the crystalline precipitate has well formed. The large excess of ammonia of 0·96 specific gravity (one-third the original volume), usually prescribed has been shown by Gooch and Austin (*Amer. Journ. Sci.*, 1899, Fourth Series, vol. vii., p. 187; Chemical News, 1899, vol. lxxix., pp. 233 *et seq.*; *Zeit. fur Anorg. Chemie*, 1899, vol. xx., p. 121), to be quite unnecessary, in fact disadvantageous.

Neubauer in the above-cited paper has shown, and Gooch and Austin (*loc. cit.*) have confirmed his statements, that it is only by working under these conditions —absence of any large excess of precipitant, of ammoniacal salts, and of ammonia—that a precipitate of normal composition is obtainable. It usually differs from the normal in containing relatively more ammonium and less magnesium—for instance, an admixture of such a molecule as $Mg(NH_4)_4(PO_4)_2$—the result being that when ignited in the ordinary way too much magnesium is found, because of formation of some metaphosphate. To obviate this error Neubauer considers it absolutely necessary to blast the precipitate for half-an-hour, and then to repeat the blasting for a second half-hour to see if a constant weight has been reached. The phosphate is then entirely pyrophosphate, which is quite unaffected by further blasting. The intense heat has caused a decomposition of the metaphosphate with volatilisation of P_2O_5, as follows:— $2Mg(PO_3)_2 = Mg_2P_2O_7 + P_2O_5$. Neubauer worked with the usual excess of ammonia, and it remains to be seen whether by precipitating and working according to Gooch and Austin the composition of the precipitate is always close enough to the ideal $MgNH_4PO_4$ to obviate the necessity for blasting.

From the labours of Neubauer and of Gooch and Austin it is clear that the common way of adding the phosphate precipitant to the ammoniacal solution of the magnesium salt is not calculated to produce a precipitate of normal composition. The precipitant should be added to the acid solution of the magnesium, and ammonia should then be added in slight excess.

Gooch and Austin call attention to a modification proposed some years ago by Wolcott Gibbs (*Amer. Journ. Sci.*, 1873, Third Series, vol. v., p. 114), whereby the phosphorus and magnesium salts are first boiled together in neutral solution for a few minutes, and to the cooled solution ammonia is added. The results are said to be remarkably exact.

Methods of Collecting and Igniting the Precipitate.

If the blast has not to be employed, the weight of the pyrophosphate can doubtless be most accurately arrived at by collecting and igniting the precipitate in a Gooch crucible, provided the asbestos felt is well constructed, and not of the serpentine variety so largely on the market.

Neubauer ignites slowly in platinum after drying, without removing from the paper, applying the blast only when the carbon has been wholly burned off (*Zeit. fur Anal. Chemie*, 1894, vol. xxxiii., p. 362; *Journ. Amer. Chem. Soc.*, 1894, xvi., p. 289).

Almost as exact are the two modifications of the method in use for phosphate analyses at the agricultural experiment stations at Danzig and Lisbon, described by Schmoeger (*Zeit. fur Anal. Chemie*, 1898, xxxvii., p. 308), and Mastbaum (*Zeit. fur Anal. Chemie*, 1898, xxxvii., p. 581). According to the former the precipitate after drying is detached from the paper and placed in a platinum crucible, followed by the folded filter. To the covered crucible the full flame of a burner is applied, and after a short time the burning off of the carbon is accomplished with the crucible open. A short blasting follows. In a number of experiments on quantities ranging from 0·06 to 0·28 grm. of pyrophosphate the results were, with a few exceptions, naturally lower than those obtained on duplicates by the ordinary method of igniting, but only by 0·0013 grm. in maximum.

Mastbaum, to shorten time, applies the full flame to the moist precipitate wrapped in its filter. Later, when most of the carbon is burned off, he moistens the residue with two or three drops of strong nitric acid, evaporates this carefully, heats with full burner for a few minutes, then blasts for half a minute. He describes the results as irreproachable. In this laboratory only the Mastbaum modification has been tried, and it certainly seems to be satisfactory when the extreme of accuracy is not required.

At one time the procedure first recommended by Ulbricht, later by Broockmann, and also by L. L. de Koninck, was used. It consists in dissolving the ammonium-magnesium phosphate off the filter with nitric acid, collecting the filtrate in a weighed crucible, evaporating the contents to dryness,* and subsequently igniting, the product being presumably pyrophosphate. But it was soon observed that the ignited salt, especially when large in amount, does not always dissolve completely in hydrochloric acid, but that sometimes a white residue is left in light lumps which appears to be quite insoluble in acids. This residue contains no silica, but only the constituents of a magnesium phosphate, and it may be a peculiar metaphosphate. Whether its appearance is due to an abnormal composition of the original magnesian precipitate or to conceivable change during evaporation in the crucible with nitric acid remains to be determined. Until this is done the employment of this method of igniting is not to be recommended.

Contamination by and Removal of Barium and Calcium.

Barium phosphate will not contaminate the second magnesian precipitate unless there are notable amounts of barium in the rock, in which case it must be removed by sulphuric acid prior to the final precipitation of the magnesium. Calcium, however, is probably never absent, and has to be estimated and allowed for as follows:—

To the ignited pyrophosphate, dissolved in but slight excess of hydrochloric acid, is added ammonia to alkalinity, and then acetic acid, drop by drop, till the solution, which should not be hot, clears. It now and then happens that a little flocculent matter fails to dissolve. This is to be removed, ignited, and subtracted from the original weight. It is likely to consist, in great part or wholly, of phosphates of iron or manganese, or both, and shows often a reddish colour on ignition. If an excess of acetic acid has been used, this is cautiously removed by ammonia. Then a drop or two of solution of ammonium oxalate is added, and the small beaker is set aside for twelve hours if necessary. Almost invariably a small precipitate soon shows itself, which if fine-grained and non-adherent to the glass may be regarded as pure calcium oxalate; otherwise it contains, or may largely consist of, magnesium oxalate. It is in that case to be collected, ignited, re-dissolved, and re-precipitated. Its final weight, averaging perhaps one-half milligrm., is to be added to that of the lime already found, and subtracted as tricalcium phosphate from that of the magnesium pyrophosphate in order to arrive at the true figure for magnesia. This separation, to be satisfactory, requires great care.

* A pink colour of varying intensity almost invariably becomes apparent as the mass approaches dryness, a most delicate test for the traces of manganese which always escape precipitation by ammonium sulphide or bromine.

XII. *Titanium.*

Colorimetric Estimation with Hydrogen Peroxide, Weller's Method (*Ber. Deutsch. Chem. Gesell.*, 1882, xv., p. 2593).

The method consists in comparing the colour of a known bulk of solution to be tested with that of a standard solution of titanium sulphate, both having been fully oxidised by hydrogen peroxide. The strength of the peroxide should be approximately measured by titration with permanganate on opening a fresh bottle, and again after a few weeks, otherwise very serious error may arise through its deterioration.

Mere traces of hydrofluoric acid, either in the peroxide or the titanium solution, render this method inexact (Hillebrand, *Journ. Amer. Chem. Soc.*, 1895, xvii., p. 718; Chemical News, 1895, lxxii., p. 158; *Bull. U.S. Geol. Survey*, No. 167, p. 56), hence care should be exercised as to the character of the peroxide, which, as sold in the market, often contains fluorine.

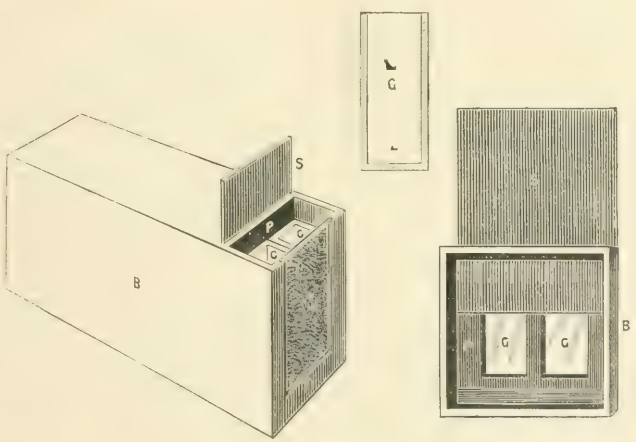

Fig. 12.—Apparatus for Colorimetric Determinations in Different Aspects.

G, One of two glasses of square or rectangular section, 8 to 12 c.m. high and 3 to 3½ c.m. inside measurement between those sides through which the liquid is to be observed; the other sides are blackened on the outside. B, Rectangular box, about 35 c.m. long and 12 c.m. square, stained black inside and out, one end closed by a ground-glass window, W, the other open, and a portion of the top removed. P, Blackened partition, with openings corresponding to the interior dimensions of the glasses when in position. S, Blackened cardboard shutter sliding stiffly up and down between partition and glasses, so as to shut off all light above the lowest surface of the liquid in the glasses

Dunnington (*Journ. Amer. Chem. Soc.*, 1891, xiii., p. 210), has pointed out the necessity for the presence of at least 5 per cent of sulphuric acid in solutions which are to be thus tested for titanium, in order, as he concludes, to prevent partial reversion to metatitanic acid which does not give a colour with hydrogen peroxide. The standard solution of titanium sulphate, holding conveniently about 1 centigrm. TiO_2 in 10 c.m.^{3}, equivalent to 1 per cent of TiO_2 in 1 grm. of rock, contains therefore 5 per cent or more of sulphuric acid. Of this 10 c.m.^{3} are mixed with a sufficiency of hydrogen peroxide (2 c.m.^{3} of most commercial brands is ample), and diluted to 100 c.m.^{3} in a measuring flask.

Titanium can be estimated, as a rule, most conveniently in the solution which has served for the titration of total iron (p. 150). This, having been evaporated, if necessary, to less than 100 c.m.^{3}, is to be fully oxidised with hydrogen peroxide, and if the colour is less intense than that of the standard, is made up to 100 c.m.^{3} with dilute sulphuric acid in a measuring flask, and mixed; otherwise, in a flask of sufficient size to insure that its colour shall be less intense. One of the rectangular glasses described below being filled with the solution to be tested, 10 c.m.^{3} of the diluted standard are run into the other from a burette, and water is added from a second burette until there is no distinction as to colour. A second and a third portion of the standard can be run in and diluted, and the mean of several determinations struck, when a simple calculation gives the percentage of TiO_2 in the rock.

If the convenient but expensive Soleil-Duboscq colorimeter is used, or the simple Nessler tubes, it is of course unnecessary to dilute the rock solution to the extent above required, should it be stronger than the standard. Experience has shown, however, that differences can not be sharply estimated in strongly coloured solutions, and that the results are much more satisfactory when the colour intensity is not much, if any, greater than that given by a standard of the above concentration. For the percentages of titanium found in rocks, clays, and soils, usually under 1 per cent, but rising to 2 or even 3 per cent or more occasionally, the colorimeter method gives results which are fully equal to those of the best gravimetric method, besides being a great time saver. The error introduced by iron, in consequence of the yellowish colour of its sulphate solution, is practically negligible unless its percentage is very high; then either the iron must be removed prior to making the colour test, or correction should be applied for known amounts of ferric sulphate in solutions of the requisite dilution.

The exact correction to be applied in such cases is difficult of determination because of the impossibility of matching the colours of titanium peroxide solutions with those of ferric sulphate; but tests made go to show that the colouring effect of 0·1 grm. of Fe_2O_3 in 100 c.m.^{3} 5 per cent sulphuric acid solution is about equal to 0·2 milligrm. of TiO_2 in 100 c.m.^{3} when oxidised by hydrogen

peroxide. This amounts to a correction of only 0·02 per cent on 1 grm. of rock containing the unusual amount of 10 per cent Fe_2O_3. It will be more satisfactory, when much iron is present, to remove this as described hereafter, and to colorimetrically estimate the titanium thus freed from iron.

Alternative Mode of Preparing the Test Solution.

As said above (pp. 150 and 177), the solution that has been used for volumetric estimation of total iron can most conveniently be used for the colorimetric determination of titanium, but if desired this can, of course, be made on some other portion of rock powder. At one time it was the practice in this laboratory to combine it with the determination of barium, as described in *Bulletin* 148 *of the United States Geological Survey*, by decomposing the powder by sulphuric and hydrofluoric acids,* expelling the latter by repeated evaporations with sulphuric acid, taking up with dilute sulphuric acid,† filtering from barium sulphate, &c., and estimating the titanium colorimetrically in the filtrate. The expulsion of fluorine must be thorough, or else the titanium result will be low, as already stated (p. 177), and it is not always easy to effect this complete removal, though the time required to do so seems to be in no slight degree dependent on the nature of the fluorides to be decomposed. Long after every trace of fluorine seems to be gone, the formation of a crust on the evaporating solution sometimes allows an accumulation of enough hydrofluoric acid gas to become plainly manifest to the smell on breaking the crust.

The Colorimetric Apparatus and its Use.

The glasses G (Fig 12) may be of square or rectangular section, 8 to 12 c.m. high, and 3 to 3½ c.m. inside measurement between those sides through which the liquid is to be observed.‡ These sides should, of course, be exactly parallel; the others need not be, but should be blackened externally. In order to further exclude the effect of side light in this and other similar methods (chromium, for instance, see *prox.*), it is very convenient to have a simple light box (B, Fig 12) that can be easily held in one hand about 35 c.m. long and 12 c.m. square, stained black inside and out, and with one end closed by a piece of ground glass, W, the other open. For a space equal to the width of the glasses the cover is removed at the top next the glass end to permit of the insertion of the glasses side by side in such a way that no light shall penetrate around their sides or between them. Immediately back of the glasses is a partition, P, with openings of appropriate size cut in it. A stiffly sliding black cardboard shutter, S, is movable up and down immediately back of the partition, so that all light can be cut off except that which comes through the liquid.

Precautions of this kind are necessary if accurate results are to be counted on. Except for mere traces, this combination of glasses and darkened box insures greater accuracy and rapidity of work than Nessler tubes, and is preferable likewise, so far as the writer's experience goes, to expensive instruments like the colorimeter of Soleil-Duboscq, &c. In making the colour comparisons the box is best held close to a window, so as to get a full, strong light. Daylight is far preferable to artificial light.

(To be continued).

* It is to be borne in mind that evaporation with hydrofluoric acid alone results in loss of titanium by volatilisation, but that there is no loss if excess of sulphuric acid is also present.

† With acid rocks solution is very complete, and it can be made nearly so with the most basic by transference to a small beaker, and gentle boiling. The residue thus obtained may contain, besides barium sulphate, a little calcium sulphate, zircon, andalusite, topaz, and possibly a trace of titanium in some form. It is therefore to be thoroughly fused with sodium carbonate, leached with water, fused with potassium bisulphate, dissolved in dilute sulphuric acid, filtered, and the filtrate added to the main one. The insoluble matter will now be chiefly barium sulphate, for the further treatment of which see *prox.*

‡ The allowable error in distance between the corresponding pairs of sides of the two glasses should not in any case exceed 1 per cent. Unfortunately there seems to be a disinclination or inability on the part of dealers in this country to furnish glasses fulfilling this requirement, and held together by a durable cement which shall be proof against dilute sulphuric acid. Canada balsam answers well for a time, but sooner or later it cracks, leaks then appear, and the sides soon drop off. It is, however, but a simple matter to cement them on again. A pair of entirely satisfactory glasses can be made from a couple of square or rectangular 3 to 4 ounce bottles by cutting off one pair of sides from each, and grinding down till the calipers show that agreement is perfect. The tops are then to be sawed off and pieces of plate glass cemented on the sides.

NOTICES OF BOOKS.

The Theory of Ions and Electrolysis (La théorie des ions et l'électrolyse). By Auguste Hollard. Paris: Georges Carré and C. Naud. 1900. Pp. 159.

Of late years electrolysis has been the subject of a large amount of work, both from the theoretical and the practical point of view. Chemistry has been enriched by new methods for the separation and estimation of the elements, while in metallurgy the progress have been so great that practically new industries have been created.

Unfortunately, in electrochemistry the purely scientific researches on the one hand, and the purely practical ones on the other, have too often been carried out with absolute independence; up to quite recent times the practical man has wasted a great deal of time and money by not being acquainted with the facts which have been discovered by his scientific brother. Now, however, the books which have been written on electrochemical science have given to the world a number of new facts, and on these facts the *theory* of electrochemistry has been built up, by means of which not only that which is known can be explained, but even the unknown can be foretold to a certain extent.

The author, who is well-known in connection with this subject, gives in this volume a full and clear account of the present views held on the theory of ions applied to electrolysis; he, however, deals mostly with electrolytic phenomena in aqueous solutions when using continuous currents, and more particularly with the electrolysis of metallic salts.

The phenomena examined may be summarised as follows:—The manifestations of electric energy in the electrolyte: this energy may be looked upon as the product of two factors, *quantity* and *tension*; the author prefers this latter expression to the older form, "difference of potential."

This leads to the examination of the constitution of electrolytes, their conductibility, and, finally, the electric *tension* and the *work* necessary to effect the electrolysis. The book is well printed and bound, and makes a far more handsome and durable volume than we are accustomed to receive from French publishers.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Note.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. cxxxii., No. 11, March 18, 1901.

Action of Acids on the Carbonates of the Alkaline Earths in presence of Alcohol.—C. Vallée.—M. Carette found that hydrochloric and nitric acids attack calcium carbonate in presence of absolute alcohol, sulphuric acid attacks it but slightly, and certain organic acids, such as acetic, have no action at all. The author substitutes for ethyl alcohol acetone and methyl alcohol, and finds that apparently there is no difference in the behaviour of the

acids. He further investigates the action of sulphuric acid, by adding normal sulphuric acid to absolute alcohol and placing the mixture in presence of excess of chalk. Titrations taken from time to time show that four months is necessary for the neutralisation to be complete, even when the mass is frequently agitated. Such an experiment shows that the reaction is simply very slow and is not limited.

Compounds of Cæsium.—C. Chabrié.—Cæsium was the first of the metals discovered by means of spectrum analysis (1861). It has not been very much examined owing to its rarity. The author obtains the metal from Pollux and from this prepares a number of cæsium compounds—the bromide, CsBr, the iodide, CsI, in the form of white cubic crystals, the fluoride, CsF.HF, in long hygrometric needles, neutral cæsium chromate, CrO_4Cs_2, and cæsium bichromate, $Cr_2O_7Cs_2$.

Constituents of Industrial Ferrosilicons.—P. Lebeau.—The author's investigations on the compounds of iron and silicon definitely establish the existence of the silicides, $SiFe_2$, SiFe, and Si_2Fe, in industrial ferrosilicons. He prepares all these compounds in a pure crystalline form and makes a study of their principal properties. The results obtained facilitate researches concerning the structure of silicated alloys. Finally, the siliciuration of iron by electro-metallurgical methods can have two limits, corresponding to the formation of the compounds SiFe and Si_2Fe, according to the nature of the original materials used.

Action of the Chlorides of Acids and the Anhydrides of Acids on the Organo-metallic Compounds of Magnesium.—MM. Tissier and Grignard.—In a former paper M. Grignard explained the importance of the organo-metallic compounds of magnesium for syntheses in organic chemistry. The authors now apply these substances for the study of the chlorides and anhydrides of certain organic acids.

Action of Caprylic Alcohol on its Sodium Derivative. Synthesis of Dicaprylic and Tricaprylic Alcohols.—Marcel Guerbet.—The author continues a former research on the action of the primary alcohols of high atomic weight on their sodium derivatives. He now extends his researches to the secondary alcohols, taking as an example caprylic alcohol, $C_8H_{18}O$. By the action of this alcohol on its sodium derivative dicaprylic alcohol, $C_{16}H_{34}O$, and tricaprylic alcohol, $C_{24}H_{50}O$, are obtained, the reactions apparently taking place according to the equations—

$$C_8H_{18}O + C_8H_{17}NaO = C_{16}H_{34}O + NaOH.$$
$$C_{16}H_{34}O + C_8H_{17}NaO = C_{24}H_{50}O + NaOH.$$

Vaporisation and Hydratation of Ethylenic Glycol.—M. de Forcrand.—The author finds the boiling-point of glycol under varied pressures, from which the curve of vapour tensions can be constructed. He notices also that glycol is extremely hygroscopic, absorbing water vapour from the air in the same way as sulphuric acid or absolute alcohol, and he determines a number of heats of solution.

Dissociation and Thermic Examination of the Compound $Al_2Cl_6.18NH_3$.—E. Baud.—When a current of ammonia gas is passed over dodecammoniacal aluminium chloride cooled to 0°, no increase in weight is observed. The same is the case at a temperature of −10·7°, but if the whole is cooled down to −18° or −20° a body is obtained having the composition $Al_2Cl_6 + 16·43NH_3$. At −22° or −23° the compound becomes $Al_2Cl_6 + 17·7NH_3$. A new substance is evidently produced having for its probable formula $Al_2Cl_6.18NH_3$ and whose dissociation tension is equal to atmospheric pressure between −10·7° and −18°.

Direct Nitration in the Fatty Series.—A. Wahl.—The author examines the action of fuming nitric acid on the non-saturated compounds, and afterwards on the other derived ethers of ethyl acrylate, such as ethyl crotonate, ethyl tiglate, and ethyl isolauronolate.

The Pretended Bi-naphthylene Alcohol.—R. Fosse.—The author's researches show that the pretended bi-naphthylene of Rousseau appears to be, in reality, nothing else but a derivative of tri-naphthyl methane.

Ethyl-β,β-Diacetylpropionate.—F. March.—In a former paper the author announced the preparation of ethyl-ββ-diacetyl propionate—

$$(CH_3—CO)_2—CH—CH_2—COOC_2H_5$$

and its action on phenylhydrazine. He now prepares certain derivatives of this compound and also the barium, potassium, sodium, copper, and silver salts.

Properties of the Alcoyl Substitution Products of Acetone Dicarbonate of Monocyano-ethyl. Action of Cyanogen Chloride on Methyl Acetone Dicarbonate.—J. Derôme.

Action of Butyryl Chloride on Methyl Sodacetylacetate.—L. Bouveault and A. Bongert.

Bulletin de la Société Chimique de Paris.
Series 3, Vol. xxiii., No. 22.

Composition of the Orange Pigment of Uraster rubens.—Dr. A. B. Griffiths and F. W. Warren.—The analysis of this pigment has given the following results:—

I. Substance used	0·2460 grm.
CO_2	0·5786 „
H_2O	0·1344 „
II. Substance used	0·0855 „
Volume of nitrogen	13·75 c.c.
Barometric pressure	758 m.m.
Temperature	19° C.

	Found. I.	Found. II.	Calculated for $C_{16}H_{18}N_4O_2$.
Carbon	64·15	—	64·43
Hydrogen	6·07	—	6·04
Nitrogen	—	18·5	18·90
Oxygen	—	—	10·63

These results answer to the formula $C_{16}H_{18}N_4O_2$. Solutions of this pigment (urasterine) do not give any characteristic absorption bands in the spectroscope.

No. 23.

Combustible Gases in the Air. The Presence of Free Hydrogen in the Atmosphere.—Armand Gautier.—Already noticed.

MISCELLANEOUS.

Royal Institution.—On Thursday next, April 16th, Dr. Allen Macfadyen will deliver the first of a course of six lectures at the Royal Institution on "Cellular Physiology," with special reference to the Enzymes and Ferments. On Thursday, April 18th, Mr. Roger Fry will begin a course of two lectures on "Naturalism in Italian Painting," and on Saturday, April 20th, Mr. John Young Buchanan will deliver the first of a course of three lectures on "Climate—its Causes and its Effects." The Friday Evening Discourse on April 19th will be delivered by Professor J. J. Thomson, his subject being "The Existence of Bodies Smaller than Atoms."

New Compounds of Bromide of Aluminium with Organic Substances.—M. Konovalof and V. Plotnikof.—The authors have already described the compounds

$AlBr_3.CS_2C_2H_4Br_2$ and $CS_2(C_2H_5Br.AlBr_3)_2$. The second of these substances, not being crystallisable, is rather unstable, and the results of the analysis do not agree very well with the formula. The ebullioscopic method in bromide of ethyl has given:—Solution at 6 per cent, M=940 (instead of 828); solution at 20 per cent, M=1778; thus in concentrated solutions the molecules are doubled. If to 1 molecule $AlBr_3$, dissolved in an excess of CS_2, we add 1 molecule of bromoform, an oily layer is gradually formed; at 20° it goes on increasing for several months; at about 40° to 45° the reaction is more rapid, and the oily mass becomes crystalline. To obtain the crystals in a pure state it is necessary to leave the mass at 30° for several months in sealed tubes, then wash with bromide of ethyl, and dry in a current of CO_2. The crystals have the appearance of platinocyanide of barium, and are polychromatic. Their fusing-point is 120·7—121·3°; they are insoluble in benzene, CS_2, bromoform, and bromide of ethylene; slightly soluble in bromide of ethyl, and fairly soluble in dry ether; their composition is $CS_2AlBr_3CHBr_3$. Water decomposes this body according to the equation—

$$CS_2-AlBr_3-CHBr_3+4H_2O=$$
$$=Al(OH)_3+5HBr+CO<\begin{matrix}S\\S\end{matrix}>CHBr.$$

The product $COS_2.CHBr$ forms colourless crystals fusible at 52—52·5° with decomposition. With bromide of ethylidene and tribromopropane we obtained in the same manner the compounds $CS_2AlBr_3C_2H_4Br_2$ and $CS_2AlBr_3C_3H_5Br_3$, the latter not crystallised.—*Journ. Soc. Chim. Phys. R.*, vol. xxxi., p. 1020.

The Critical Temperature of some Sulphurised Organic Compounds.—L. Ferretto.—Altschul's method was used for the following bodies:—C_2H_5SH; $CH_3>CH-CH_2-CH_2SH$; $(CH_3)_2S$; $(C_2H_5)_2S$; $(C_2H_5.CH_3)S$. The compounds $(C_2H_5)_2S_2$, $(C_5H_{11})_2S$, and $(C_3H_5)_2S$ were decomposed at a high temperature, and the critical point was determined by the method of mixtures, using Pawlewski's formula. The following results were obtained:—Ethylic mercaptan, 228°; sulphide of methyl, 231·2°; sulphide of ethyl, 284·67°; sulphide of ethyl and methyl, 259·66°; sulphide of isoamyl, 391°; sulphide of allyl, 380°; and isoamylic mercaptan, 334° (?). Pawlewski's law relative to the constant difference between the critical temperature and the boiling-point was confirmed very exactly by the first four, $(\theta-t)=191·8°$ to 193·9°, and not quite so well with the last four, $(\theta'-t)=176°$ to 241°. Guldberg's law (the constant relation $C=\frac{273+\theta}{273+t}$) was closely verified, C=1·38 to 1·63. By comparing these compounds with their analogues in which the S is replaced by O, we find for the sulphydrates that the critical temperature is lower by 14·3° to 16°; with the sulphides, on the other hand, it is higher by 92° to 101·6° and with bisulphide of ethyl we obtain +181·76=2×90·88°; that is to say, about double that observed in the case of the sulphides.—*Gazz. Chim. Ital.*, vol. xxx., p. 296.

Compounds of Uranic Acid with Sulphurous Acid.—V. Kohlschutter.—The author regards these compounds not as salts of the sub-oxide of uranium, UO_2 (with U=240), but as mixed or complex acids. The most simple of these compounds was described by Girard in 1852; it is the body $UO_3SO_2.4H_2O$, soluble in an excess of sulphurous acid, from which it separates in felted green needles, insoluble in pure water. It loses 14·85 per cent of water at 105°, that is 3·5 H_2O. Its formula may therefore be written $O(UO_2.SO_3H)_2+7H_2O$. Its solution either in an excess of sulphurous acid, water, or alcohol no doubt contains $SO_3(UO_2.SO_3H)_2$, that is to say, $2UO_3.3SO_2.H_2O$. The alcoholic solution, treated with ether, gives a yellowish-green flocculent precipitate, which, when drained, dries very rapidly, and then suddenly deliquesces, giving off SO_2. On the addition of SO_3KH to the solution of sulphite of uranium in SO_2, heated on the water-bath, a more or less crystalline anhydrous precipitate is obtained, which may be expressed as $2UO_3.3SO_2.K_2O$ or $SO<\begin{matrix}O-UO_2-SO_3K\\O-UO_2-SO_3K\end{matrix}$. In the same manner the salts of $(NH_4)_2O$ and Na_2O may be obtained. By operating in the same way Scheller obtained salts to which he assigned the general formula $UO_2(OH)SO_3M$; however, the author has never been able to obtain these salts. If we heat the salt $UO_3.SO_2.4H_2O$ on the water-bath, with a quantity of SO_2, insufficient to dissolve it entirely, the green solution becomes yellow, as also does the crystalline deposit of long, pointed, microscopic prisms, whose composition is $UO_3.SO_2.2·75H_2O$ or $(UO_3)_4(SO_2)_4+11H_2O$; the anhydrous compound may be expressed thus:—$SO_3<\begin{matrix}UO_2.SO_3.UO_2\\UO_2.SO_3.UO_2\end{matrix}>SO_3$. By operating in the same manner with the amorphous precipitate obtained from SO_3KH with a solution of sub-nitrate of uranium, we obtain a green micro-crystalline precipitate in rhomboidal tables, consisting of $4UO_3.5SO_2.K_2O$ after desiccation at 105°; the same salts have been obtained with NH_4 and Na, and they may be expressed $SO_3<\begin{matrix}UO_2-SO_2-UO_2-SO_3M\\UO_2-SO_3-UO_2-SO_3M\end{matrix}$. These salts are decomposed by water, giving a green solution and a pulverulent yellow deposit. The green solution gradually deposits the salt $UO_3SO_2.4H_2O$, and the composition of the pulverulent deposit is $3UO_3.2SO_2.K_2O$, or $UO_2<\begin{matrix}UO_3-SO_3K\\UO_3-SO_3K\end{matrix}$. This same salt is deposited from the acid mother-liquor of $4UO_3.5SO_2.K_2O$ when all the excess of SO_2 is evaporated off. We can also obtain the salt $3UO_3.2SO_2.K_2O$ by gradually adding a solution of SO_3K_2 to a solution of sub-nitrate of uranium. When we treat uranic hydrate or one of the above compounds with an excess of an alkaline bisulphite, we obtain a salt with the composition $UO_3.2SO_2.M_2O$, or $UO_2<\begin{matrix}SO_3M\\SO_3M\end{matrix}$. The salt of NH_4 is a green crystalline precipitate composed of microscopic tables. The salt of potassium is formed of bisected prisms.—*Lieb. Ann. Chem.*, vol. cccxi., p. 1.

MEETINGS FOR THE WEEK.

Tuesday, 16th.—Royal Institution, 3. "On Cellular Physiology, with special reference to Enzymes and Ferments," by Allan Macfadyen, M.D., B.Sc.

Friday, 19th.—Royal Institution, 9. "The Existence of Bodies Smaller than Atoms," by J. J. Thomson, M.A., &c.
Saturday, 20th.—Royal Institution, 3. "Climate, its Cause and Effects," by John Young Buchanan, M.A., F.R.S.

THE CHEMICAL NEWS.

Vol. LXXXIII., No. 2160.

HINTS ON TESTING TOOL-STEEL.

By SERGIUS KERN, M.E., St. Petersburg.

It is rather strange that having most elaborate rules and specifications for testing steel used for structural and mechanical purposes, we have no rules for testing tool-steel, except well-known empirical tests, which are less useful to those who are engineers than to well experienced workmen. The results obtained are quite dependent on the individuality of the workman.

Engineers daily test different specimens of soft and medium steel, and having the results of tensile strength and elongation, may judge with great certainty upon the suitableness of the material.

Tool-steel, taking into consideration the percentage of carbon, could be also tested for a certain tensile strength and elongation. Such tests should not exclude the forging and hardening tests, but, made together at one time, are able to give a basis for further development of rules for testing tool-steel delivered by different firms to Government establishments, which usually test the products they buy. But for tool-steel the rules are thoroughly empirical, and cause at present much confusion to the establishments and to the producers.

This is a very serious question, especially if we think that, more often than is believed, we receive, instead of crucible tool-steel, hard open-hearth steel. Some of the latter tool-steel, delivered for certain purposes as good tool-steel, was found by us to be not only too soft, but, being used as a turning tool for cast-iron and bronze, freely crumbled on its sharp edge. The steel analysed contained 0·90 per cent of carbon, 0·39 per cent of manganese, and 0·07 per cent of silicon, and thus showed its origin. Good tool-steel never contains so much manganese, and the small percentage of silicon confirmed the view that the steel was melted by open-hearth process and not in crucibles. Crucible steel has been my speciality for about twenty-five years, and I never saw crucible tool-steel with less than 0·14 per cent of silicon. It is well known that a nearly definite percentage of silicon and carbon is taken by the melting charge from the crucible. Some inferior tool-steels made in crucibles contain the above-mentioned percentage of manganese, but it is a mistake to produce such steels by the dear crucible process. Good tool-steel contains, as maximum, 0·25 per cent of manganese.

The following shows some results of my experiments on crucible and open-hearth tool-steels:—

Crucible.

Percentage of carbon.	Tensile strength in tons per sq. in.	Elongation in 2 ins.	Contraction of area.
		Per cent.	Per cent.
0·60	45	12	30
0·80	58	6	14
0·90	62	5	12

Open Hearth.

0·60	42	15	50
0·80	50	12	28
0·90	55	10	23

Besides carbon the steels contained:—

Crucible—Manganese, 0·25 per cent; silicon, 0·16 per cent; sulphur + phosphorus, 0·03 per cent.

Open Hearth—Manganese, 0·42 per cent; silicon, 0·08 per cent; sulphur, 0·01 per cent; phosphorus, 0·04 per cent.

These experiments may be taken only as a commencement of the question of testing tool-steel mechanically, but speaking generally, hard open hearth tool-steel has the following well-defined properties:—It has less tensile strength as compared with crucible steel of the same percentage of carbon, has a well marked tendency to temper badly after being hardened, and tools made of such steel, under impact, very soon crumble on their sharp edge: the latter defect I entirely attribute to high percentages of manganese (0·35—0·45), which always are found in open hearth tool-steel, and are essential to the process itself. The more oxidised open hearth steel demands more manganese.

ON A TITANIFEROUS IRON ORE FROM NORWAY.

By NICHOLAS J. BLUMAN.

I have recently analysed a titaniferous iron ore from Norway, with the following result:—

Ferrous oxide	40·01 = 31·1 % Fe.	
Titanic acid	43·75	
Magnesia	3·11	
Manganous oxide	0·23	
Alumina	4·00	Gangue.
Silica	8·90	Gangue.
	100·00	

The ore contained crystals aggregated in rosette-like groups; fracture conchoidal, hardness 6, specific gravity 5·163, streak black, and slightly magnetic.

THE ACTION OF IODIC ACID ON URIC ACID, AND THE ESTIMATION OF URIC ACID.

By H. BOUILLET.

If we cause an excess of iodic acid to act on uric acid in the presence of water, we observe, when the temperature is raised, that gas is given off and iodine set at liberty. The reaction is complete at boiling-point. If we collect and weigh the gas and the iodine, we find that the gas is carbonic acid, and that five molecules of uric acid give off five molecules of carbonic acid, while a double atom of iodine is set free.

If, instead of using an excess of iodic acid, we take the theoretical quantity, the reaction is incomplete. The uric acid is not entirely decomposed, and the liquid, which was acid, colourless, and limpid in the first operation, is neutral and rose-coloured in the latter case. This rose-coloured liquid, when evaporated to dryness, leaves a residue which, when taken up with boiling alcohol at 90°, gives alloxane, which can be precipitated with ether.

The alloxane has been recognised by the reactions described by Krasser. The red aqueous solution eventually becomes colourless; it stains paper and albumenoid matters, first yellow, then purple, passing to violet on the addition of ammonia. If, to the clear colourless liquid resulting from the action of the excess of iodic acid on the uric acid, we add baryta-water, an abundant precipitate is formed and ammonia is given off. This precipitate, treated with dilute acetic acid, is partially dissolved and insoluble iodate of barium remains; this is filtered off, and the filtrate neutralised with ammonia. After standing for a few hours, the liquid gives crystals, of which the analysis answers to the formula of mesoximidate of barium,—

$$\begin{matrix}(CO)_3{-}N\\(CO)_3{-}N\end{matrix}\!\!>\!Ba\,3H_2O.$$

	Theory.	Found.
Water of crystallisation ..	13·95	14·00
Carbon	18·60	18·66
Nitrogen	7·235	7·26
Barium	35·4	35·32

With this body we can obtain the mesoximide by precipitating the barium with the theoretical quantity of sulphuric acid. On evaporation, a viscous amber-coloured substance is obtained, crystallising in anhydrous acetone, decomposing slowly in the dark, rapidly in the light, and very hygroscopic; when neutralised with baryta-water, the original salt is formed. Its aqueous solution is acid, it reduces nitrate of silver, and forms a mirror when heated. When boiled for some time with HCl, carbonic acid is given off and oxalic acid formed.

To the liquid containing the products of decomposition of uric acid and free iodic acid, baryta-water is added as before, the precipitate of iodate and mesoximidate of barium is removed, a current of carbonic acid is passed through the liquid, which is heated rapidly to boiling; to this liquid freed from baryta, soda and hypobromite of soda are added, when nitrogen is given off in the cold. The solution, treated with soda and brought to boiling-point, gives off ammonia, which is characteristic of urea. From a consideration of all these reactions and estimations, we have deduced the following course of the reaction:—

Iodic acid decomposes uric acid, giving first alloxane and urea, $C_5H_4N_4O_3+O+H_2O=C_4O_4N_2H_2+CON_2H_4$; then the alloxane itself is hydrated, carbonic acid is given off, and the ammonia combines with the excess of iodic acid, and nothing remains but the mesoxalic group in the state of amide, $C_4O_4N_2H_2+H_2O=CO_2+NH_3+C_3O_3NH$. The final equation shows the action of the iodic acid on uric acid, viz.,—

$$5C_5H_4N_2O_3+I_2O_5+10H_2O=$$

$$=5\left\{\begin{matrix}CO\\|\\CO\\|\\CO\end{matrix}\right\}NH+5CON_2H_4+5CO_2+5NH_3+I_2.$$

This equation agrees with all the experiments and results obtained.

Estimation of Uric Acid.

According to the preceding equation, we observe that, to estimate uric acid by means of this reaction, we can either determine the iodine, as in Causse's method, or the carbonic acid, or again the amount of iodic acid decomposed by the uric acid; the last is the method we adopted. As will be seen, it obviates the separation of the iodine, which is necessary when using Causse's method.

Causse's Method.—The uric acid is precipitated in the form of insoluble urate of barium, the washed precipitate is introduced into a retort with a solution of iodic acid, the retort is connected with a condenser and a flask containing iodide of potassium. On distilling, the iodine is volatilised, and then dissolves in the iodide; the iodine is estimated by means of a N/100 solution of hyposulphite of soda, of which 1 c.c. = 0·00419 of uric acid.

Bouillet's Method.—This method requires a titrated solution of iodic acid and N/10 hyposulphite of soda. To make the iodic acid solution, weigh out 1 grm. of iodic acid, dissolve it in 100 c.c. of distilled water, measure out 10 c.c. of this solution, and add to it 10 c.c. of 1/10th HCl, 30 c.c. of 1/10th KI, and 200 c.c. of distilled water; titrate the iodine set free with a N/10 solution of hyposulphite, and note the volume, V, of hyposulphite used.

Estimation of Uric Acid.—Precipitate the uric acid in the form of insoluble urate of barium by adding to 100 c.c. of urine, previously neutralised with soda, chloride of barium until no more precipitate is formed, then acidulate with 5 c.c. of acetic acid at 1/100th, let stand for fifteen or twenty minutes, filter, and wash the precipitate, which consists of urate, phosphate, and sulphate of barium; wash the precipitate into a porcelain crucible, using about 100 to 150 c.c. of water; add 20 c.c. of H_2SO_4 at 1/10th, so as to set free the uric acid, then boil. At this moment add 10 c.c. of the titrated solution of I_2O_5, and keep boiling gently until the whole of the iodine is liberated. Sometimes the liquid remains yellow, on account of the presence of the last traces of iodine, which are difficult to remove; this, however, can be easily effected by adding a little marble—the carbonic acid given off carries the iodine with it. After cooling, titrate the undecomposed I_2O_5; for this purpose, 10 c.c. of HCl at 1/10th and 30 c.c. of KI at 1/10th are successively added to the cold solution, and the iodine set at liberty is titrated with N/10 hyposulphite. The difference between the original volume of the hyposulphite solution, V, and the present volume, v, gives the amount of iodic acid decomposed; this difference multiplied by the factor 0·007 gives the weight of uric acid. In a general way, the formula is $(V-v)\times 0{\cdot}007=$ uric acid.

The process we have just described has the advantage over the methods of precipitation of the uric acid by salts of silver and copper of not including the xanthic compounds in the estimation. Further, in estimating the amount of iodic acid decomposed, the operation is both simple and rapid, and as for its accuracy, the following table shows that the figures obtained are very close to those given by the Causse method, and nearer the truth than those given by the Salkowski method, which we used as a check.

Urine.	Salkowski.	Causse.	Bouillet.
100 c.c.	0·0285	0·0304	0·0305

—*Bull. Soc. Chim.*, Series 3, vol. xxv, No. 5.

SILICIDES OF IRON.

By AD. JOUVE.

The presence of silicon in metallurgical products has always been known, and for some time past attempts have been made commercially to obtain alloys containing a large proportion of silicon, both from blast-furnaces, when the proportion hardly exceeds 10 or 12 per cent of silicon, or by means of the electric furnace, when as high a figure as 50 per cent is reached.

In what state does the silicon exist in these ferro silicons?

This question has already been closely studied. MM. H. Sainte-Claire Deville and Caron have obtained silicised castings, but of no definite composition. Winkler, by direct combination, obtained silicised iron which was non crystalline. Carnot and Goutal, in 1897, during a research on the conditions in which the elements existed in metallurgical products, observed the presence of FeSi, and suspected the existence of other products, such as Si_2Fe_3 and Si_2Fe_5, without, however, having isolated these compounds.

By direct combination, M. Moissan obtained the body Fe_2Si perfectly definitely.

The silicide FeSi obtained by Fremy and Hahn, then by Carnot and Goutal, was prepared in the crystalline state by M. Lebeau by means of the reciprocal action of silicides of copper and of iron.

Other silicides have also been described, such as $FeSi_2$ and Fe_3Si_2, which, according to M. Chalmot, are the only ones which exist in commercial ferro-silicons.

The Silicide Fe_2Si.—The existence of this compound has been perfectly well shown by the recent work of M. Lebeau on ferro-silicons containing about 20 per cent of silicon.

All the experiments I had previously made confirm the results obtained with Fe_2Si, the existence of which is beyond question. With some samples we are able to obtain it directly in well-crystallised prisms.

The Silicide FeSi.—This silicide is the one found whenever the proportion of silicon exceeds 25 per cent.

Ferro-silicons containing a higher proportion than 25 per cent give tetrahedric crystal (33·3 per cent silicon), sometimes macled, forming a long series, the whole consisting of a mass of variable richness.

This silicide is also found perfectly crystallised in regular tetrahedra, and the following figures show the composition of some I obtained at the factory at Bozel (Savoy) of the Compagnie-Générale d'Electro-Chimie.

		Theory.
Fe	68·37	66·67
Si	30·08	33·33
C	1·41	—

These crystals sometimes contain a little calcium, sulphur, and phosphorus. The following is a typical complete analysis:—

Iron	67·17
Silicon	29·41
Carbon	1·230
Sulphur	0·012
Phosphorus	0·116
Calcium	1·840

In these commercial ferro-silicons we frequently find 0·7 to 3·0 per cent of carbon.

The compound FeSi can be obtained in a state of purity by taking a rich ferro-silicon and melting it with silica which combines with the carbon. The crystals which are separated give the following figures:—

Si	33·10	33·21
Fe	66·86	66·74

The Silicide $FeSi_2$.—The existence of this compound, obtained by M. Chalmot, is somewhat doubtful. I have never been able to isolate it directly from any commercial ferro-silicon.

I have used a silicide obtained by the direct union of silicon and iron in the proportion of about 55 per cent Si. This silicide, on slow cooling, allowed the compound FeSi (33·3 per cent Si) to separate out, a much richer ferro-silicon forming the rest of the mass.

On the other hand, an alloy of 41 per cent Si was treated according to M. Chalmot's method by hydrofluoric acid; a residue was obtained with a crystalline appearance which answered roughly to the formula $FeSi_2$. Four analyses gave:—Si = 54·28, 48·76, 51·01, and 44·94; theory for $FeSi_2$ requires 50·0 per cent Si.

Under the microscope, these crystals were very slightly characteristic, irregular, and non-homogeneous.

The same products, treated with a hot concentrated solution of soda, lost silicon and left a powder of a crystalline appearance, containing Si = 30·47, 31·28, 30·98, and 32·16; theory for $FeSi_2$ requires 33·33 per cent Si.

It therefore appears as if this product, $FeSi_2$, is nothing more than a simple alloy or mixture of FeSi and Si.

The result of what has been stated above seems to show that commercial ferro-silicons contain the silicon in the form of mixtures of the two definite compounds Fe_2Si and FeSi, with variable proportions of iron or of silicon.

The compounds Fe_3Si_2 and Fe_5Si_2 have not been obtained in a distinct crystalline form; their existence is very doubtful and quite hypothetical.

In conclusion, I would remark that the alloys used by me were obtained by the direct reduction of silica by carbon, as was also the silicon used for the direct formation of the products containing proportions near to 50 per cent.

The factory at Bozel (Savoy), where these products were made, has since our research made a speciality of the manufacture of ferro-silicons, no longer as laboratory experiments, but at the rate of several tons a day of products rich in silicon.

Remarks on the presence of Carbon in Ferro-silicons.—It has been shown that crystallised ferro-silicons similar to FeSi contain carbon. The following are a few analyses:—

Fe ..	69·68	69·09	69·33	67·48	67·89
Si ..	28·02	29·11	28·61	31·82	31·11
	(28·02)	(29·05)	(28·63)	(31·77)	(31·05)
C ..	2·28	1·84	2·02	0·67	0·98

We know that 12 of carbon corresponds to 28 of silicon. If we transform the carbon into silicon in this proportion, and subtract this value in silicon of the carbon from the theoretical figure, 33·33 per cent, we obtain the figures given in brackets, which are remarkably close to those found.

The carbon thus appears to enter into the constitution of the crystals, substituting itself for the silicon. It, however, still remains to be determined in what state it really exists.—*Bull. Soc. Chim.*, Series 3, vol. xxv., No. 6.

LONDON WATER SUPPLY.

REPORT ON THE COMPOSITION AND QUALITY OF DAILY SAMPLES OF THE WATER SUPPLIED TO LONDON FOR THE MONTH ENDING MARCH 30TH, 1901.

By SIR WILLIAM CROOKES, F.R.S., and PROFESSOR DEWAR, F.R.S.

To CHARLES PERRIN, Esq., M.Inst.C.E., *Water Examiner, Metropolis Water Act*, 1871.

London, April 10th, 1901.

SIR,—We submit herewith, at the request of the Directors, the results of our analyses of the 208 samples of water collected by us during the past month, at the several places and on the several days indicated, from the mains of the London Water Companies taking their supply from the Thames and Lea.

In Table I. we have recorded the analyses in detail of samples, one taken daily, from March 1st to March 30th inclusive. The purity of the water, in respect to organic matter, has been determined by the Oxygen and Combustion processes; and the results of our analyses by these methods are stated in Columns XIV. to XVIII.

We have recorded in Table II. the tint of the several samples of water, as determined by the colour-meter described in previous reports.

In Table III. we have recorded the oxygen required to oxidise the organic matter in all the samples submitted to analysis.

Of the 208 samples examined by us during the month, all were found to be clear, bright, and well filtered.

The rainfall at Oxford during the month has been 1·44 inches; the average fall for the last thirty-five years is 1·47 inches; this leaves a deficit of 0·03 inch, making the total deficit for the year 1·56 inches, or 29·1 per cent on the thirty-five years' average.

Our bacteriological examinations of 545 samples have given the results recorded in the following table; we

have also examined 38 other samples, from special standpipes, &c., making a total of 583 samples in all:—

	Microbes per c.c.
New River, unfiltered (mean of 26 samples) ..	593
New River, filtered (mean of 131 samples) ..	10
Thames, unfiltered (mean of 26 samples) ..	2303
Thames-derived water, from the clear-water wells of eight Thames-derived supplies (mean of 295 samples)	27
Ditto ditto .. .. highest	448
Ditto ditto .. .. lowest	0
River Lea, unfiltered (mean of 26 samples) ..	315
River Lea, from the East London Company's clear-water wells (mean of 41 samples) ..	43

Of the 467 samples of impounded and filtered water supplied to London, examined bacteriologically during the past month, twenty samples, or 4·2 per cent, were sterile. Only ten samples out of the total number examined contained more than 150 microbes, and twenty-nine samples, or 6·2 per cent, contained more than 100 microbes per c.c. The mean of the microbes in the excess samples was 162, as against a corresponding mean last month of 151.

Nearly the whole of the excess results occurred during the early part of the month, when the climatic conditions were unusually exceptional.

We are, Sir,
Your obedient Servants,
William Crookes.
James Dewar.

SOME PRINCIPLES AND METHODS OF ROCK ANALYSIS.*

By W. F. HILLEBRAND.

(Continued from p. 178).

XII. *Titanium* (continued).

Gooch's Gravimetric Method.

When titanium is present in excess of 4 to 5 per cent, and whenever for any reason it is desired to employ a gravimetric method, among the few that have been thoroughly tested that of Dr. Gooch (*Proc. Am. Acad. Arts Sci.*, New Series, vol. xii., p. 435; *Bull. U. S. Geol. Survey*, 1886, No. 27, p. 16; Chemical News, 1885, vol. lii., pp. 55 and 68), is unequalled. With one or two minor modifications introduced by Dr. T. M. Chatard (*Am. Chem. Journ.*, 1891, vol. xiii., p. 106; *Bull. U. S. Geol. Survey*, No. 78, p. 87; Chemical News, 1891, vol. lxiii., p. 267), it is as follows:—

Any solution of the rock freed from silica can be used, and the first step is to remove the iron. This is best done, after adding tartaric acid, and reducing the iron by means of hydrogen sulphide to the ferrous condition, by rendering the solution ammoniacal, and introducing more hydrogen sulphide. If the iron is not thus reduced before precipitation, titanium will be in part thrown down also (Cathrein, *Zeit. für Kryst.*, 1882, vol. vi., p. 243; 1883, vol. vii., p. 250). The amount of tartaric acid is to be gauged according to the combined weights of the oxides to be held by it in solution, and three times this weight is ample. After removing the iron sulphide by filtration—little washing suffices, because of the relatively small amount of titanium commonly present—the tartaric acid is destroyed as follows:—

Potassium permanganate to the extent of two and one-half times the weight of the tartaric acid used is made into a strong solution, and to the ammoniacal filtrate from the iron sulphide enough sulphuric acid is introduced to leave some excess after all the permanganate has been reduced. After expulsion of hydrogen sulphide by boiling, the permanganate is added gradually to the hot solution contained in a large beaker or flask. A vigorous reaction ensues. When a permanent brown precipitate of manganic hydrate appears the tartaric acid has been fully broken up, and the precipitated manganese is to be re-dissolved by a few drops of ammonium bisulphite or of sulphurous acid solution.

Ammonia is then added in slight excess, followed at once by acetic acid in considerable excess, and the boiling is continued for a few minutes. Thereby the titanium is freed from most of the alumina, and from lime and magnesia if they had not been earlier removed, also from most of the manganese introduced. The precipitate is filtered and washed with water containing acetic and sulphurous acids, then ignited, fused thoroughly with sodium carbonate, and leached with water to remove phosphoric acid and most of the remaining alumina. The residue is again ignited and fused with sodium carbonate. To the cooled melt in the crucible strong sulphuric acid is to be added, wherein it dissolves readily by aid of gentle heat. This solution is to be poured into a small volume of cold water, and the platinum it contains precipitated by hydrogen sulphide at or near boiling temperature. After filtering and cooling, ammonia is added till the titanium is just precipitated, and a measured volume, containing a known weight of absolute sulphuric acid, is then added—just enough to re-dissolve the precipitate. The solution is then made up with acetic acid in such amount that the final bulk shall contain from 7 to 11 per cent of absolute acid, and then enough solid sodium acetate is stirred in to more than take up the sulphuric acid introduced. Upon rapidly bringing the liquid to ebullition the titanium is precipitated in flocculent and easily filterable condition, and the precipitation is complete after a minute's boiling, provided all the prescribed conditions have been followed and zirconium is absent.

The precipitate is washed first with acetic acid of 7 per cent strength, and then with hot water. After fifteen to twenty minutes' ignition over a good burner it is in condition for weighing, and will lose no more weight over the blast-lamp. For large amounts of titanium a repetition of the sodium carbonate fusion, &c., should be made. The actual carrying out of all these operations, when once the method is understood, requires much less time than the detailed description would indicate.

Gooch's Method not Directly Applicable to Rocks containing Zirconium.

Prior to the adoption of the colorimetric method, Dr. Gooch's was invariably used in this laboratory. Occasional inability to secure clean and complete precipitation by it was experienced, especially with a certain series of rocks rather poor in titanium. Long research showed the difficulty to be due to the presence of zirconium, which acts as a marked preventive of the precipitation of titanium by boiling in an acetic acid solution under the conditions of the Gooch method.

The above rocks were found to contain up to 0·2 per cent of ZrO_2, and this amount was able to prevent precipitation of 0·3 per cent of TiO_2. The titanium which came down in excess of this amount did not settle out in flocculent condition, as happens when zirconium is not present, and it was difficult to filter. After the removal of the zirconium in the manner hereafter described (p. 185), however, no difficulty was experienced in precipitating all the titanium with the usual ease.

Superiority of the Colorimetric and Gooch Methods over the Older ones.

In view of the good results obtainable by the colorimeter method in all cases and by the Gooch method in the absence of zirconium, it is incomprehensible that the old method of precipitation by many hours' boiling in a nearly neutral sulphate solution in presence of sulphurous acid should still find adherents in any part of the world.

Attention has been directed (p. 165) to the error resulting

* *Bulletin of the United States Geological Survey*, No. 176.

from attempting to separate aluminum from titanium by either fused or dissolved sodium hydroxide.

Baskerville's Method.

Baskerville (*Journ. Am. Chem. Soc.*, 1894, vol. xvi., p. 427) has proposed the separation of titanium from iron and aluminum by boiling the neutralised solution of the chlorides for a few minutes in presence of sulphurous acid. The test separations as given by him are sharp, and a single precipitation is said to suffice, the titanium being free from iron and easily filterable. This last statement and the ready precipitability are fully confirmed by the experiments of the writer on titaniferous iron ores, but, although the titanium is completely thrown out, it carries with it a little iron, for instance, about 0·25 per cent Fe_2O_3 with 8 to 10 per cent TiO_2. Zirconium would probably be likewise precipitated (see p. 186), and phosphorus perhaps also, but this last point has not been investigated, neither has the applicability of the method to aluminous rocks been tested.

XIII. *Barium (Zirconium, Total Sulphur).*

Reasons for Estimating Barium in a Separate Portion of Rock Powder.—It has been said above (p. 166) that only in very exceptional cases will barium be found with the calcium and strontium after two, or possibly three, precipitations of the latter as oxalate, since it passes into the filtrates with the magnesium, whence it may be obtained as sulphate after removal of ammoniacal salts. Addition of some alcohol insures also the recovery of traces of strontium if the rocks are very rich in it. But it is unsafe to regard the amount thus separated from the magnesium as representing the total amount of barium in the rock. It will almost always be found lower than the truth, probably for the reason that there are opportunities during the analysis for slight losses. It is best to estimate it in a separate 2 grm. portion, which may also serve with advantage for the estimation of zirconium and total sulphur.

Modes of Attack and Subsequent Treatment.—If zirconium and sulphur are not to be looked for, the simplest procedure is to decompose the powder by sulphuric and hydrofluoric acids (see p. 178, under "Titanium"), and to complete the purification of the barium sulphate thus obtained in the manner described in the third paragraph below.

If zirconium and sulphur are both to be likewise determined, decomposition is effected by fusing over the Bunsen flame, and then over the blast with sulphur-free sodium carbonate and insufficient nitre to injure the crucible, first fitting the latter snugly into a hole in asbestos board (Lunge) to prevent access of sulphur from the gas flame. In case sulphur is not to be regarded, the nitre and asbestos board are omitted. After thorough disintegration of the melt in water, to which a drop or two of methyl or ethyl alcohol has been added for the purpose of reducing manganese, the solution is filtered, and the residue washed with a very dilute solution of sodium carbonate free from bicarbonate. This is to prevent turbid washings. A yellow colour in the filtrate indicates chromium.

For the further treatment of the filtrate see "Sulphur," and "Chromium—Colorimetric Method" (*prox.*).

The residue is dissolved in quite dilute warm sulphuric acid (stronger acid may be used if barium only is sought), and filtered through the original filter. This, with its contents, is ignited, evaporated with hydrofluoric and sulphuric acid, and taken up with hot dilute sulphuric acid. The filtrate, added to the former one, now contains all the zirconium (see under "Zirconium" for its further treatment). The residue contains all the barium, besides some of the strontium, and perhaps a good deal of calcium. It is fused with sodium carbonate, leached with water, the residue dissolved off the filter by a few drops of hydrochloric acid, from which solution the barium is thrown out by a large excess of sulphuric acid. A single solution of the barium sulphate in concentrated sulphuric acid and re-precipitation by water suffices to remove traces of calcium which might contaminate it if the rock was one rich in calcium, and even strontium is seldom retained by it in quantity sufficient to give concern. Should this be the case, however, which will occur when the SrO and BaO are together in the rock in, roughly speaking, 0·2 and 0·4 per cent, respectively, the only satisfactory way is to convert the sulphates into chlorides, and to apply to the mixture the ammonium chromate method of separation (p. 166).

Barium and strontium sulphates can be brought into a condition for testing spectroscopically by reducing for a very few moments the whole or part of the precipitate on a platinum wire in the luminous tip of a Bunsen burner, and then moistening with hydrochloric acid. This should be known to everyone, but probably is not.

The procedure outlined in the foregoing paragraphs for the estimation of calcium, strontium, and barium in silicate rocks is the one which long experience has shown to be best adapted for securing the most satisfactory results with a minimum expenditure of time. (For details consult W. F. Hillebrand, *Journ. Am. Chem. Soc.*, 1894, vol. xvi., p. 83; CHEMICAL NEWS, 1894, vol. lxix., p. 147). Even where no attempt is made to separate contaminating traces of SrO and BaO one from the other, the error is usually of no great consequence, for an absolute error of 25 per cent, even, in a substance constituting only one or two tenths per cent of a rock is ordinarily of small moment compared with the ability to certify to its presence with approximate correctness.

With such small amounts of barium as are usually found in rocks it is doubtful if Mar's (*Am. Journ. Sci.*, 1892, 3rd Ser., xliii., p. 521), method for the separation of barium from calcium and magnesium by the solvent action of concentrated hydrochloric acid mixed with 10 per cent of ether on the chlorides, could be conveniently applied here, although for larger amounts the method would seem to be accurate and easily executed. Moreover, it would probably not entirely remove contaminating strontium, and hence offers no advantage.

XIV. *Zirconium.*

This element is rarely looked for by chemists, though shown by the microscope to be one of the most constant rock constituents, usually in the form of zircon, in which occurrence its amount can be approximately judged of and a chemical test rendered almost unnecessary; but sometimes it occurs in other minerals, and is then unrecognisable under the microscope. It may rarely be present up to a few tenths of 1 per cent of the rock.

Author's Method.

For its detection and estimation in such cases, or whenever a search for it seems called for, the following procedure, based on a method by G. H. Bailey (*Journ. Chem. Soc.*, 1886, vol. xlix., pp. 149, 481), has been devised which serves, when carried out with care, to detect with certainty the merest trace—0·02 per cent, for instance—in 1 grm.

The preliminary treatment of the rock powder has been fully given under "Barium," where the separation from barium has been described, and also the concentration of the zirconia in a small amount of very dilute sulphuric solution. This should probably not contain much above 1 per cent of sulphuric acid, though the actually permissible limit has not been established. To the solution, which should be in a small flask, is now added hydrogen peroxide to oxidise the titanium, and then a few drops of a soluble orthophosphate solution. The flask is set aside in the cold for twenty-four to forty-eight hours. If the colour bleaches after a time, more hydrogen peroxide should be added. Under these circumstances the zirconium is thrown out as phosphate, and collects as a flocculent precipitate, which at this stage is not always pure. No matter how small or in-

significant, it is collected on a filter, ignited, fused with sodium carbonate, leached with water, the filter again ignited, fused with very little acid potassium sulphate, brought into solution in hot water with a few drops of dilute sulphuric acid, poured into a flask of about 20 c.m.^{3} capacity, a few drops of hydrogen peroxide and of sodium phosphate added, and the flask set aside. Titanium is now almost never present, and the zirconium appears after a time as a white flocculent precipitate, which can be collected and weighed as phosphate. For the small amounts usually met with it is safe to assume that it contains 50 per cent of ZrO_2 (51·8 by theory). If the amount is rather large, it may be fused with sodium carbonate, leached, ignited, fused with acid potassium sulphate, re-precipitated by ammonia, and weighed as ZrO_2. Certainty as to its identity can be had by again bringing it into solution, precipitating by ammonia, dissolving in hydrochloric acid, evaporating to a drop or two, and testing with turmeric paper or by a microchemical reaction. With the very smallest amounts no colour can be obtained by this turmeric-paper test, which, however, responds readily to as little as 1 m.grm. of dioxide, and with proper care for as small an amount as 0·3 m.grm. (Dr. H. N. Stokes). No element other than thorium is ever likely to contaminate the zirconium thus precipitated.

In Bailey's experiments the precipitation was not made by addition of a phosphate, but is said to be due solely to the hydrogen peroxide, the precipitate being a hydrated peroxide, Zr_2O_5, or ZrO_3 (Bailey, Chemical News, 1889, vol. lx., p. 6). My own efforts to secure a precipitate in acid solutions of zirconium sulphate by hydrogen peroxide alone were unsuccessful, perhaps for lack of a sufficiently strong peroxide. The ability to obtain the zirconium free from phosphoric acid would certainly be a great improvement on the method described above.

Were it not for the necessity of working in a weakly acid solution, the separation of zirconium could be made in the same portion in which the titanium is colorimetrically determined.

Other Methods of Separating Zirconium.

Streit and Franz (*Journ. für Prakt. Chemie*, 1869, vol. cviii., p. 65), claim to secure complete separation of titanium from iron and zirconium by boiling the neutralised solutions of the sulphates with a large excess (50 per cent) of acetic acid. The method has been from time to time recommended, but without any data showing its value. The single separation made by Streit and Franz was far from perfect.

Davis (*Am. Chem. Journ.*, 1889, vol. xi., p. 27) separated zirconium sharply from aluminum, but not from iron, by precipitation as an oxyiodate in a boiling neutralised solution of chlorides, but the method is hardly applicable for rock analysis.

Baskerville (*Journ. Am. Chem. Soc.*, 1894, vol. xvi., p. 475; Chemical News, 1894, vol. lxx., p. 57), has proposed a method for the separation of zirconium from iron and aluminum similar to his method for the separation of titanium from those elements (p. 185). It is based on the precipitability of ZrO_2 by boiling the neutralised chloride solution for two minutes in presence of sulphurous acid, and seems to be excellent. As titanium is always present and is presumably quantitatively thrown down also, the two would have to be separated by hydrogen peroxide. No tests as to the availability of the method for separating the small amounts met with in rock analysis have been made.

XV. *Rare Earths other than Zirconia.*

For the few cases in which it may be necessary to look for rare earths other than zirconia, the following procedure is suggested as likely to prove satisfactory:—

The rock powder is thoroughly decomposed by several partial evaporations with hydrofluoric acid, the fluorides of all earth metals except zirconium are collected on a platinum cone, washed with water acidulated by hydrofluoric acid, and the precipitate washed back into the dish or crucible, and evaporated with enough sulphuric acid to expel all fluorine. The filter is burned and added. By careful heating the excess of sulphuric acid is removed and the sulphates are taken up by dilute hydrochloric acid. The rare earths, with perhaps some alumina, are then separated by ammonia, washed, re-dissolved in hydrochloric acid, and evaporated to dryness, then taken up with water and a drop of hydrochloric acid, and only enough ammonium acetate to neutralise the latter added, followed by oxalic acid (not ammonium oxalate, which would fail to precipitate thorium). In this way as little as 0·03 per cent of rare earths have been found when working on not more than 2 grms. of materials.

This method eliminates at once most of the aluminum, all the iron, phosphorus, titanium, and zirconium, and has the further advantage of collecting with the earthy fluorides, as UF_4, any uranous uranium that the rock might have held.

An alternative method would be to fuse with sodium carbonate, leach with water to get rid of phosphorus as far as possible, dissolve the residue in hydrochloric acid, separate silica as usual, precipitate alumina, &c., by ammonia, dissolve the precipitate again in hydrochloric acid, evaporate, and proceed as by the former method, which in most cases would undoubtedly give better results than this one.

XVI. *Phosphorus.*

It is sometimes possible to extract all phosphorus from a rock by simple digestion with nitric acid, but quite as often, if not oftener, this fails; hence the necessity for resorting to one of the longer methods of extraction detailed below.

Procedure when Material is Ample.

When material is ample it is best to use one portion for phosphorus only, and to proceed as follows:—

Fuse with sodium carbonate, separate silica by a single evaporation with nitric acid, treat the ignited silica with hydrofluoric and a drop or two of sulphuric acids, evaporate to expel hydrofluoric acid, bring the small residue into solution by boiling with nitric acid, and add it to the main portion, in which, after addition of considerable ammonium nitrate, precipitate the phosphorus by molybdate solution.

The turbidity often observed on dissolving the precipitated and washed phospho-molybdate in ammonia is due to a compound of phosphorus. If the addition of a small fragment of a crystal of citric or tartaric acid fails to dissolve it, this should always be re-fused with sodium carbonate, extracted with water, and the filtrate otherwise treated as above, in order to secure the phosphorus in it.

According to Gooch and Austin (*Am. Journ. Sci.*, 1899, Fourth Series, vol. vii., p. 187; *Zeit. für Anorg. Chemie*, 1899, vol. xx., p. 121; Chemical News, 1899, vol. lxxix., pp. 233, 244, 255), in order to secure a magnesium-ammonium phosphate of normal composition, the procedure at this point should be as follows:—To the phosphate solution containing not more than 5 to 10 per cent of ammonium chloride, and a slight excess of magnesia mixture, a little ammonia is added, and the precipitate is washed in due time with weak ammonia water. In general, however, as these conditions can seldom be fulfilled, they recommend to decant the supernatant liquid through the filter which is later to receive the precipitate, to dissolve this in as little hydrochloric acid as possible, to re-precipitate by dilute ammonia without further addition of magnesia mixture, and to wash finally with weakly ammoniacal water. Excess of ammonia, of ammonium salts, and of precipitant are all objectionable. In rock analysis the second precipitation will seldom be necessary. For ignition, &c., of the precipitate, see this subject under "Magnesium" (p. 176).

Procedure when Material is Scanty.

The following procedure admits of determining in the same portion, besides phosphorus, barium, iron, vanadium,

chromium, and titanium, the last two either colorimetrically or gravimetrically, and is in large part extracted from a paper by Dr. T. M. Chatard (*Am. Chem. Journ.*, 1891, vol. xiii., p. 106; *Bull. U. S. Geol. Survey*, No. 78, p. 87; Chemical News, 1891, vol. lxiii., p. 267).

Silica is removed by hydrofluoric and sulphuric acids, excess of fluorine expelled, the residue brought into solution as far as possible with sulphuric or hydrochloric acid and hot water, filtered, the residue ignited, fused with sodium carbonate, dissolved in hydrochloric acid, and the solution, after precipitation of barium, added to the main one, which is now precipitated by ammonia to get rid of the magnesium salts usually present, and thus ensure a cleaner subsequent fusion with sodium carbonate.

The precipitated Al_2O_3, P_2O_5, Cr_2O_3, Fe_2O_3, and TiO_2 is dissolved in hot hydrochloric acid, and filtered into a large platinum crucible, the filter burned and added, the solution evaporated to pastiness, a little water added to dissolve the salts, and dry sodium carbonate added in portions, and stirred in thoroughly to prevent lumpiness in the fusion to follow, which is continued for half-an-hour. Addition of sodium nitrate is not necessary.

The fused mass is boiled out with water, and washed with very dilute sodium-carbonate solution. In the residue iron and titanium can be determined by the methods already described. In the filtrate chromium can be determined colorimetrically if present in sufficient amount to give a pronounced colour (see "Chromium—Colorimetric Method," *prox.*). Afterwards, or immediately if the chromium is not to be thus estimated, enough ammonium nitrate is added to react with all the carbonate, and the solution is digested on the bath till most of the ammonium carbonate is gone. Nearly, if not quite all alumina is thus thrown out, carrying with it all phosphorus. The precipitate is washed with dilute ammonium-nitrate solution till the yellow colour wholly disappears, after which it is dissolved in nitric acid, and the phosphorus thrown out by molybdate solution. The filtrate, containing chromium and vanadium, can be treated as detailed in the next following sections.

(To be continued).

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Ordinary Meeting, March 21st, 1901.

Professor Thorpe, C.B., F.R.S., President, in the Chair.

Messrs. G. D. Lander, H. W. Kinnersley, and E. F. Linstead were formally admitted Fellows of the Society.

The following certificates were read for the first time:—William Henry Duckworth, 87, New Bank Road, Blackburn; Samuel Philip Eastick, 25, Woodville Road, Ealing; Ernest Allred Lewis, 310, Dudley Road, Birmingham; Alexander McKenzie, Jenner Institute, S.W.; Edgar Neuman, 10, Randolph Crescent, Maida Vale, London; William Oldershaw, Market Place, Nottingham; Samuel Slefrig, 18, Waterloo Road, Shepton Mallet, Som.; James Smith, 14, Mersey Road, Aigburth, Liverpool.

Reply to the Address to the King.

The Secretary read the following reply which His Majesty the King has been graciously pleased to cause to be made to the Address of the President, Council, and Fellows of the Society:—

Marlborough House,
Pall Mall, S.W.
23rd February, 1901.

The Private Secretary is commanded by the King to thank the President, Council, and Fellows of the Chemical Society, for the kind expression of their sympathy with His Majesty, on the occasion of the lamented death of Her late Majesty the Queen, and for the loyal and dutiful sentiments conveyed in their Address to the King.

Day and Hour of Meeting.

The following is the report of the Committee appointed by the Council to examine the cards returned by Fellows in reply to the question as to the suggested change in the Day and Hour of the Ordinary Meetings to Wednesday, at 5.30 p.m.:—

"Nineteen hundred cards were issued to Fellows, and 1000 answers were returned. Of these, 581 were unreservedly in favour of the change, namely, 256 London Fellows, and 325 Country Fellows. 118 Fellows, whilst not voting unreservedly for the change, said they offered no objection to it. 172 Fellows were unreservedly opposed to the change. Of the 129 Fellows remaining, 85 expressed no objection to the change of day, but offered suggestions as to change of hour. 3 suggested meeting at 3, 1 at 4, 1 at 4.30, 12 at 5, 12 at 6, 9 at 6.30, 10 at 7, 5 at 7.30, 15 at 8, and 2 at 8.30. 11 suggested a later hour than 5.30 without particularising it, and 4 alternately 5.30 and 8. 24 Fellows suggested meeting on some other day than Wednesday or Thursday, namely, 2 on Monday at 5.30, 1 on Tuesday at 8, 14 on Friday, 10 of whom preferred 5.30; of the remaining 4, 2 indicated no preference as to hour, 1 suggested 8, and 1 suggested 8.30. 7 Fellows suggested various hours on Saturday afternoon or evening. 16 Fellows preferred Thursday, but suggested some other hour than 8, 11 suggested 5.30. 1 preferred 6, and 3 preferred 7. 1 suggested 8.30. 4 Fellows deprecated the change on the ground that it clashed with the present arrangements of the Society of Public Analysts.

"Analysing the replies of those Fellows who have contributed papers to the Society, 266 of whom have responded, 188 have voted for the change, and 78 against it."

Of the following papers, those marked * were read:—

*40. "*Researches on Morphine.*" Part II. By S. B. Schryver and F. H. Lees.

The authors have shown (*Trans.*, 1900, lxxvii., 1024), that bromomorphide, $C_{17}H_{18}O_2NBr$, is decomposed by water in accordance with the equation—

$$C_{17}H_{18}O_2NBr + H_2O = C_{17}H_{19}O_3N,HBr,$$

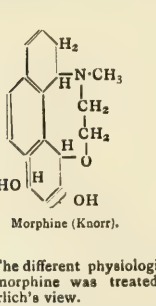
and from the reaction product a new base, isomeric with morphine, and designated *isomorphine*, was isolated and described. The authors have since isolated from the product of the above reaction another new base, *β-isomorphine*, $C_{17}H_{19}O_3N$, which is formed only in relatively small amount. It crystallises from alcohol in double pyramids of the formula $2C_{17}H_{19}O_3N,C_2H_6O$, which, after drying at 120° melt at 182°, and for which $[\alpha]_D$ 17° = −216·2°. Chloromorphide, when decomposed by water, also yields *β-isomorphine*, together with another base which has not yet been further examined. In view of the non-narcotic action of *iso*morphine as compared with morphine, experiments were carried out to determine the chemical relationship between the two isomerides. *iso*Morphine yields a *diacetyl* *isomorphine methiodide*, $C_{17}H_{17}(O{\cdot}CH_3CO)_2ONCH_3I$, as needles melting at 242° with decomposition. Phosphorus tribromide reacts with *iso*morphine, giving bromomorphide (m. p. 170°) identical with that obtained from morphine by the same reaction. Phosphorus trichloride, on the other hand, reacts with *iso*morphine, yielding no definite product, whereas chloromorphide results from the same reaction with morphine. iso*Codeine methiodide*, $C_{17}H_{18}O_2(OCH_3)NCH_3I$, forms leaflets melting at 265° with decomposition, and for it $[\alpha]_D$ 17° = −102·1°. It was prepared by the three following methods: (*a*) by the action of silver sulphate and barium hydroxide on *iso*morphine methoidide, with subsequent interaction of the resulting methydroxide and methyl iodide; (*b*) by the action of excess of methyl iodide on the sodium derivative of *iso*morphine; (*c*) from codeine by the following steps: *bromocodeide*, $C_{17}H_{17}O(OCH_3)N{\cdot}Br$, prepared by the action of phos-

phorus tribromide on codeine, forms pearly scales melting at 162°, for which $[\alpha]_D\ 20° = +56{\cdot}7°$; *isocodeine*, $C_{17}H_{18}O_2(OCH_3)N$, from the action of water on bromocodeide, which forms needles melting at 144°, for which $[\alpha]_D\ 13° = -169°$. The methiodide was then readily prepared from *iso*codeine.

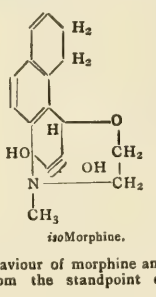
The formation of *iso*codeine methiodide by the above methods confirms the phenolbetaine constitution,—

$$C_{16}H_{15}O_2\overset{O}{\underset{N(CH_3)_2}{<}},$$

for *iso*morphine methydroxide, which was provisionally assigned to this substance by the authors in their previous paper. Sodium hydroxide reacts with *iso*codeine methiodide, yielding the base *methi*-iso*morphimethin*, $C_{16}H_{14}O_2(OCH_3)\cdot N(CH_3)_2$, which forms tables melting at 167°, and having $[\alpha]_D\ 20° = +64{\cdot}6°$. *Methi*-iso*morphimethin methiodide*, $C_{16}H_{14}O_2(OCH_3)\cdot N(CH_3)_3I$, forms needles melting at 265°, and for which $[\alpha]_D\ 17° = +34{\cdot}7°$. *Methi*-iso*morphimethin methydroxide* is split up by the action of heat, and yields morphenol methyl ether, $C_{15}H_{10}O_2$, m. p. 65°, which is identical with the phenol obtained by Knorr (*Ber.*, 1889, xxii., 183), from codeine methiodide, the morphine derivative, by analogous reactions to the above. These results indicate the presence in *iso*morphine of exactly the same groups as occur in morphine, and the authors suggest that the relationship between these two bases is, in all probability, similar to that represented by the two following formulæ:—



Morphine (Knorr).



*iso*Morphine.

The different physiological behaviour of morphine and *iso*morphine was treated of from the standpoint of Ehrlich's view.

"41. "*The Constitution of Pilocarpine.*" Part II. By H. A. D. Jowett, D.Sc.

When bromine acts on *iso*pilocarpine in acetic acid solution, dibromo*iso*pilocarpine perbromide is formed as the chief product of the reaction, but small quantities of monobromo*iso*pilocarpine and *iso*pilocarpinic acid are also produced. *Dibromoisopilocarpine perbromide*, $C_{11}H_{14}O_2N_2Br_2\cdot HBr_3$, crystallises in needles melting at 165°. Treated with ammonia, *dibromoisopilocarpine*, $C_{11}H_{14}O_2N_2Br_2$, is formed, crystallising in rectangular prisms melting at 135°. It is optically inactive, and is only feebly basic, being precipitated from its solution in strong acids by water; it does not react with methyl iodide. On reduction, it is converted into *iso*pilocarpine. *Monobromoisopilocarpine*, $C_{11}H_{15}O_2N_2Br$, forms needles melting at 164°. Iso*pilocarpinic acid*, $C_{11}H_{16}O_4N_2$, was only obtained as an oil. It yields a microcrystalline barium salt $(C_{11}H_{15}O_4N_2)_2Ba$, and is therefore monobasic.

Dibromo*iso*pilocarpine, on oxidation with permanganate, yields hydrobromic acid, ammonia, methylamine, a new acid termed *pilopinic acid*, $C_8H_{11}O_4N$, and the acid, $C_7H_{10}O_4$, previously described, and which is now called pilopic acid.

Pilopinic acid, $C_8H_{11}O_4N$, is crystallised with difficulty, forming pearly plates melting at 98°. It is lævorotatory $[\alpha]_D = -13{\cdot}6°$. It is a monobasic lactonic acid. The monoethyl ester boils at 262° at 10 m.m. On oxidation it yields ammonia and pilopic acid.

When bromine acts on *iso*pilocarpine in aqueous solution at 100° in a sealed tube, the following products are formed: — Dibromo*iso*pilocarpinic, monobromo*iso*pilocarpinic, bromopilopinic, and bromopilopic acids, ammonia and methylamine, the two first-named acids being the chief products formed in about equal quantities.

Dibromoisopilocarpinic acid, $C_{11}H_{14}O_4N_2Br_2$, forms rectangular crystals melting at 235°. The acid is dextrorotatory $[\alpha]_D = +24{\cdot}4°$, and is monobasic.

Monobromoisopilocarpinic acid, $C_{11}H_{15}O_4N_2Br$, has only been obtained as a syrup.

When dibromo*iso*pilocarpinic acid is treated with sodium amalgam in alcoholic solution, pilopic acid is formed. This acid, previously described as an oil, has now been obtained in crystals melting at 103°. Both mono- and dibromo-*iso*pilocarpinic acids, on reduction with zinc and glacial acetic acid, yield a new crystalline lactone, *isopilocarpinolactone*, $C_{11}H_{14}O_4N_2,H_2O$, which forms rectangular prisms which melt at 83°. It is lævorotatory, $[\alpha]_D = -51{\cdot}9°$, and is a neutral substance which reacts with strong alkalis, forming salts of hydroxy*iso*pilocarpinic acid, $C_{11}H_{16}O_5N_2$, which are stable. It does not unite with methyl iodide, even when heated in alcoholic solution at 100°.

Dibromopilocarpine, $C_{11}H_{14}O_2N_2Br_2$, first prepared by Pinner and Kohlhammer (*Ber.*, 1900, xxxiii., 1424), has been further studied; it melts at 95° when pure, and not at 79° as stated by these authors. It is dextrorotatory $[\alpha]_D = +43{\cdot}6°$, and, like its isomeride dibromo*iso*pilocarpine, is very feebly basic, and does not unite with methyl iodide. On reduction, it is converted quantitatively into pilocarpine.

Efforts to prepare bromocarpinic acid, first described by the above authors, have been unsuccessful, and results have been obtained which indicate that the first action of bromine on pilocarpine at 100° under pressure is analogous to that on *iso*pilocarpine. The bromopilocarpinic acids on reduction, however, yield pilocarpinic acid, $C_{11}H_{16}O_4N_2$, thus differing from the bromo*iso*pilocarpinic acids.

Experiments on the oxidation and attempted reduction of *iso*pilocarpine were also described.

"42. "*The Chemical Action of Bacillus Coli Communis and Similar Organisms on Carbohydrates and Allied Compounds.*" By A. Harden.

Bacillus coli communis ferments glucose with production of a quantity of lactic acid corresponding to rather less than half the sugar, and of alcohol and acetic acid in approximately equivalent amounts, each representing about one-sixth of the carbon of the sugar. Small amounts of succinic and formic acids are also produced, and carbon dioxide and hydrogen evolved. The carbon dioxide amounts to 12—18 per cent of the sugar, whilst the volume of hydrogen is slightly greater. The lactic acid formed was found to be a mixture of inactive acid (25—5 per cent), with *l*-lactic acid (75—95 per cent). *B. typhosus* produces the same products from glucose, except that it yields a large amount of formic acid (17 per cent) and no gas. Some of the abnormal forms of *B. coli communis* act in a similar manner on glucose, others produce the same substances but in entirely different proportions. *d*-Fructose yields the same products of fermentation by *B. coli communis* as glucose, and *l*-arabinose and *d*-galactose also yield *l*-lactic acid. Mannitol yields a much larger proportion of alcohol, 26—29 per cent, and a much smaller amount of lactic and acetic acids. The production of alcohol by this organism therefore appears to depend on the presence of the group $CH_2(OH)\cdot CH\cdot OH$ in the compound to be fermented; glycerol, which also contains this group, yields nearly half its weight of alcohol when fermented by the same organism.

Formic acid is decomposed into carbon dioxide and hydrogen (Pakes and Jollyman), but lactic acid is not attacked, and hence the active lactic acid is probably not

produced by the selective decomposition of previously formed inactive acid.

When asparaginic acid is the sole nitrogenous nourishment, glucose and mannitol are fermented as usual by this organism, but a large proportion of the hydrogen is absorbed, and reduces the asparaginic acid to ammonium succinate.

DISCUSSION.

Mr. PAKES remarked with regard to the fact that Dr. Harden's experiments were made under anaerobic conditions, that quite different decompositions took place when the conditions were altered; for example, when nitrates were present with *d*-glucose, nitrogen was evolved instead of hydrogen; the yield of lactic and acetic acids was quite altered if the medium containing *d* glucose had abundant oxygen either free or in the form of nitrates. Again, out of 84 strains of typical *B. coli communis* under observation at the present time, about two-thirds inverted sucrose and subsequently fermented it, the remainder failing to invert it, did not ferment it; a similar selective power was noticed in the case of glycerin. Some, again, did not appear to be able to start the fermentation of glycerin under anaerobic conditions, but if the process were started, it would then continue anaerobically. He had observed a similar reaction with the *B. fluorescens liquefacians* in media containing nitrates; the bacilus would not begin to grow in this medium under anaerobic conditions, but if the growth were started by the introduction of a few cubic centimetres of oxygen, the decomposition of the nitrate would continue under strictly anaerobic conditions.

Dr. HARDEN, in reply, stated that the products of fermentation, in the presence and absence of oxygen, had frequently been found to be different. Anaerobic conditions seemed likely to furnish the most interesting results. The reduction of nitrates by this organism in presence of glucose appeared to be a secondary reaction of the same order as the reduction of asparaginic acid. The variability of the action of the organism on cane-sugar had been previously observed by Cushing, who, however, had not investigated the interesting question as to the inversion of the sugar by this organism.

*43. "*Action of Dry Silver Oxide and Ethyl Iodide on Benzoylacetic Ester, Deoxybenzoin, and Benzyl Cyanide.*" By G. D. LANDER, D.Sc.

The author has studied the action of silver oxide and ethyl iodide on benzoylacetic ester, deoxybenzoin and benzyl cyanide, as further examples of compounds analogous to acetoacetic ester (*Trans.*, 1900, lxxvii. 729).

With benzoylacetic ester either at the temperature of the steam-bath or in the cold, the course of the reaction is entirely similar to that of acetoacetic ester, the alkylated product consisting almost entirely of C-ethyl homologue, mixed, however, with minute quantities of β-ethoxycinnamic ester (Claisen, *Ber*, 1896, xxix., 1006). These substances were identified by dilute alkali hydrolysis, when phenyl propyl ketone, giving an oxime, m. p. 55—56° (*N* = 8·94 instead of 8·59 per cent), was obtained. The alkaline hydrolysis liquid yielded small quantities of β-ethoxycinnamic acid, separating by slow crystallisation from dilute alcohol in prisms, by more rapid re-crystallisation in leaflets melting at 160·5° with energetic evolution of gas, Claisen (*loc. cit.*) gives m. p. 162°; the isomeric ethylbenzoylacetic acid melts at 116°.

Only oxidation products were obtained from deoxybenzoin and benzyl cyanide.

After boiling deoxybenzoin for eight hours with silver oxide and ethyl iodide an unchanged substance and a minute quantity of a compound (m. p. 245°), sparingly soluble in alcohol, alone resulted. This latter compound was evidently bidesyl (m. p. 255°).

By the action of silver oxide on benzyl cyanide, either in the presence of ethyl iodide on the steam-bath, or in the absence of iodide in the cold, profound decomposition ensued. By rapidly heating the thick tarry product in a vacuum small distillates of dicyanostilbene were obtained (m. p. 158—159°), which gave the characteristic fluorescent green prisms of diphenylmaleic anhydride (m. p. 155°) on hydrolysis with alcoholic potash.

*44. "*Alkylation of Acylarylamines.*" By G. D. LANDER, D.Sc.

The alkylation of various acylarylamines, containing the aceto-, benzo-, oxalyl-, and oxal-residues, by means of dry silver oxide and alkyl iodides has been studied.

By means of oxide and ethyl iodide, O- or imino-ethers alone result, whereas when methyl iodide is employed the alkylation usually gives a mixture of N-, or acylalkylamine, and O- or imino-homologues. Apparently the methylation of acet-*p*-toluide yields N-ether alone. A partial explanation of this anomalous action of methyl iodide is afforded by the observation that simple heating serves to convert N phenylacetiminomethyl ether, $C_6H_5N\,C(OCH_3)CH_3$, into the N-substituted isomer.

The imino-ethers corresponding to acylarylamines are readily distinguished from the isomeric N-substituted compounds; by their liquidity at the ordinary temperature; by their boiling-points, which are from 30—50° lower than those of the acylalkylamines; by the characteristic behaviour on heating of their hydrochlorides when obtainable), regenerating acylarylamine by loss of alkyl chloride, and by their very ready hydrolysis by dilute hydrochloric acid into the original amine, acid, and alcohol. The presence of a methyl group in the ortho-position in the N-*o*-tolyl imino-ethers, however, inhibits this characteristic hydrolysis, it being possible to prepare platinichlorides of these ethers from aqueous solutions. N-α-Naphthylacetimino-ethyl ether seems also to possess greater relative stability than the β-naphthylisomer.

The following compounds have been obtained:—From acetylarylamines: N-*phenylacetiminomethyl ether* (with N-isomer), b. p. 197°; N-*o-tolylacetiminoethyl ether*, b. p. 222°, *hydrochloride*, m. p. 90—91° (with regeneration of acetotoluide), *platinichloride*, m. p. 171°; N-*o-tolylacetiminomethyl ether* (along with N-isomer), b. p. 212° (atmos.), *hydrochloride*, m. p. 79—80°, *platinichloride*, m. p. 169°; N-*p-tolylacetiminoethyl ether*, b. p. 232° (hydrochloride unstable); N-*α-naphthylacetiminoethyl ether*, b. p. 175° (12 m.m.), *hydrochloride*, m. p. 111°; N-*β-naphthylacetiminoethyl ether*, b. p. 176·5° (12 m.m.). From benzanilide: N-*phenylbenziminoethyl ether*, formerly prepared by Lossen (*Ann.*, 1891, cclxv., 138), b. p. 176° (12 m.m. From oxanilic ester, *semi-N-phenylimino-oxalic diethyl ether*, $C_6H_5N{:}C(OC_2H_5){\cdot}CO_2C_2H_5$. The dimethyl ether has been described by Anschütz and Stiepel (*Ber.*, 1895, xxviii., 61). The diethyl ether is a liquid, b. p. 152—155° (12 m.m.), decomposed by dry hydrochloric acid apparently into a mixture of oxanilic ester and anhydrous oxanilic acid; with aniline at 100° it gives *diphenylamidinooxalic ester*,—

$$C_6H_5N{:}C_6H_5NH{\cdot}C{\cdot}CO_2C_2H_5,$$

m. p. 73—74·5°, a base giving a stable platinichloride, and passing by warming with aniline at 160—170° into *diphenylamidino-oxalanilide*, melting when rapidly heating at 140—142°, softening at 134°.

From oxanilide: *di-N-phenylimino-oxalic diethyl ether*, $\{C_6H_5N{:}C(OC_2H_5)\}_2$, a viscid, brown, rather unstable oil, b. p. 205° (12 m.m.).

*45. "*The Preparation of Aliphatic Imino-ethers from Amides.*" By G. D. LANDER, D.Sc.

The synthesis of imino-ethers from acid amides has only been found possible hitherto with certain aromatic amides which give stable silver salts (Tafel and Enoch, *Ber.*, 1890, xxiii., 103). The same authors, in a later paper (*loc. cit.*, 1550), describe unsuccessful attempts to effect the analogous synthesis from some aliphatic amides.

The author has examined the possibility of accomplishing this by the aid of dry silver oxide and ethyl iodide.

Semi-imino-oxalic diethyl ether, $NH{:}C(OEt){\cdot}CO_2Et$ (compare Nef, *Ann.*, 1895, cclxxxvii., 288), boiling at

75—77° at about 20 m.m., can be readily prepared from ethyl oxamate by means of silver oxide and ethyl iodide at 100°. When urethane is warmed with ethyl iodide and silver oxide, there occurs a vigorous reaction, a liquid boiling from 90—200°, along with small quantities of triethyl isocyanurate, m. p. 93—94°, being obtained. The liquid is probably a mixture of ethyl iminocarbonate, unchanged urethane, and triethyl cyanurate.

The formation of imino-carbonic diethyl ether can be demonstrated by carrying out the reaction in the cold, separating the imino-ether from unaltered urethane by distillation below 85° (20 m.m.), purification by means of potassium hydroxide and conversion by hypobromite into brominocarbonic diethyl ether m. p. 40—42°, 0·4 grm. being thus obtained from 18 grms. of urethane.

The results of several experiments with acetamide, silver oxide, and ethyl iodide, carried out either at 100° or in the cold, unfortunately still leave the question of the formation of acetiminoethyl ether by this process open. The production of a liquid base of "imino" odour, volatile between 70° and 100°, from which, however, so far, only an oily hydrochloride has been prepared, nevertheless inclines the author to suppose that acetiminoethyl ether is actually one of the products of the reaction.

46. "*Note on the Latent Heats of Evaporation of Liquids.*" By H. Crompton.

Imagine a saturated vapour in so attenuated a state that the gas law $PV = RT$ applies to it. Assume that it were possible at constant temperature and by compression alone to reduce the volume of the vapour V_0 to the volume which the liquid it forms would normally occupy v_0, *without any change in state occurring, and the substance during this compression continuing to obey the gas law.* The work done in bringing about this change in volume would be—

$$\int_{v_0}^{V_0} p\,dv = \int_{v_0}^{V_0} \frac{RT}{v}\,dv = RT \log_e V_0/v_0;$$

and, as no change in temperature occurs, heat equivalent to this work will be given out during compression.

The vapour now occupies the volume of the liquid, but it is not yet liquid. It is by assumption a gas under high pressure, and if the pressure is now reduced to its original amount, the gas would expand to its original volume. To form the liquid the substance must be brought to such a state that it would be possible to reduce the pressure to the normal vapour-pressure of the liquid, without any corresponding change in volume. Assuming that no change in molecular aggregation occurs, the substance must then be deprived of the potential energy of expansion of the gas; that is, of the energy that would enable the molecules of the substance to occupy their original volume on a return to the original pressure. This energy is equal to that expended in compressing the material, namely, $RT \log_e V_0/v_0$. If this is removed in the form of heat, the total heat given out during the production of the liquid from the vapour is $2RT \log_e V_0/v_0$, and this is the latent heat of evaporation.

If, in the above, V_0 and v_0 apply to the grm.-molecule, R would have the value 1·976 calories, and $2RT \log_e V_0/v_0$ would be the molecular heat of evaporation. Dividing this by the molecular weight M, the latent heat of evaporation would be obtained in the ordinary units.

The observations of Cailletet and Mathias, with carbon dioxide, nitrous oxide, and sulphur dioxide, allow the above formula to be tested for fairly wide variations in temperature and pressure. D_0 is the density of the vapour, d_0 the density of the liquid, l the latent heat of evaporation. The calculated values are obtained by the method described. (See Table, next column).

In calculating the latent heats of evaporation at the ordinary boiling-points of liquids, we have approximately $V_0/v_0 = 22320 T d_0/273 M$, if d_0 is the density of the liquid at its boiling-point. In general, the calculated values are found to be about 5 to 10 per cent higher than the observed. This may be attributed to the fact that the saturated vapour at the boiling-point is not a perfect gas, and has usually a slightly higher density than that corresponding to the normal molecular weight M. With a few associating liquids, notably the alkyl alcohols, the calculated values are somewhat lower than the observed. Here, in addition to the changes described and accounted for, the production of molecular aggregates occurs on liquefaction, doubtless involving the evolution of heat. Hence the observed latent heat is higher than the calculated by this amount.

From the equation $l = 2RT(\log_e V_0 - \log_e v_0)/M$ we get $Ml/T = 2R(\log_e V_0 - \log_e v_0)$. According to the law of Trouton, Ml/T is approximately constant for liquids at their normal boiling-points, and has an average value of about 21. It will be found that for most liquids V_0/v_0 varies from 300 to 400. This gives a value varying from 22·8 to 23·9 for Ml/T. As, strictly speaking, in Trouton's formula M is double the vapour-density and not merely the theoretical molecular weight, slight abnormalities in the densities of the saturated vapours may account for the difference. As is well known, the boiling-points are approximately comparable points in the case of liquids. If liquids were truly comparable at the boiling-point, the ratio V_0/v_0 would be the same for all liquids at this point. Trouton's law according to the above expression would then hold absolutely.

(To be continued).

NOTICES OF BOOKS.

Traité Général des Applications de la Chimie. Par Jules Garcon. Tome premier, *Métalloïdes et composés Métalliques.* Paris: Dunod, Editeur. 1901. Pp. xxxviii.—747. Roy. 8vo.

This comprehensive treatise on the applications of chemistry reflects the tireless energy of the author previously shown in his three volume work on Dyeing ("La Pratique du Teinturier," 1893—97), and in his profound studies in bibliography ("Les Sources Bibliographiques des Sciences Chimiques," 1899, and "La Bibliographie Industrielles," 1901). The author's familiarity with cataloguing and indexing has enabled him to supply the work with bibliographical helps of importance and utility; this is shown in the arrangement of the volume, which contains a systematic table of contents, an alphabetical subject-index, a list of authorities consulted, besides a very full chapter on the sources of chemical bibliography (pages 1—29). It is gratifying to residents of the United States of America to notice that their country is foremost in the production of general and special bibliographies of chemistry.

Preliminary to the main subject three sections are devoted to important matters bearing on industrial chemistry:—First, the laws relating to patents in France; second, the laws of France concerning the conduct of manufactories using or producing dangerous and unsanitary bodies; this chapter has a table giving in alphabetical order the substances and the operations in the several classes under legal control; and thirdly, the laws of France regulating the transportation by railway, &c., of combustibles, explosives, infectious and other dangerous commodities.

The fifteen chapters of this volume assume knowledge of elementary facts and principles, and give under each of the non-metallic substances its uses in pharmacy, photography, dyeing, and technology. Under each non-metal is grouped the compounds of that body with metals instead of the reverse and more common way. This brings the potashes of commerce under carbon monoxide, the sulphides of arsenic, and of antimony under sulphur, and the use of dichromates in dyeing and printing under compounds of oxygen, in place of derivatives of chromium; this arrangement is, however, made clear by the alphabetical index.

We notice with regret rather favourable comments on the absurd claim of an American to the discovery of a method for transmuting silver into gold (p. 4), and a record of Fittica's conversion of phosphorus into arsenic (p. 633). We call attention also to the suggestive bibliography of water from the industrial point of view on pages 384 to 399.

The succeeding volumes will be awaited with interest, and if the elaborate programme of Vol. I. is carried out they will contain an immense amount of information not readily found elsewhere. Vol. I. has approximately the enormous number of 373,000 words. H. C. B.

CORRESPONDENCE.

ESTIMATION OF CARBOLIC ACID IN SOAP.

To the Editor of the Chemical News.

SIR,—Having frequently to estimate the carbolic acid in soap, and finding the following gives good results (compared with other methods), I venture to suggest that it may be useful to other analysts:—

20 grms. of the soap are boiled with 150 c.c. water and sufficient caustic soda to effect solution of soap. Excess of salt is then added, and the resulting lye poured on a filter. The soap is washed again with 75 c.c. saturated solution of brine, and the whole put on the filter. The filtrate is then treated in the usual manner with concentrated H_2SO_4. Two grms. stearic acid are then added to the hot filtrate. This melts and mixes with the carbolic acid. Cool, and remove the solid cake, which consists of stearic acid, plus carbolic acid. Weigh, and the weight less 2 grms. equals carbolic acid present in 20 grms. soap.

The cake will have a little moisture adhering to it, but may be removed with filter-paper.—I am, &c.,

J. J. PICKTHALL.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. cxxxii., No. 12, March 25, 1901.

Electro-chemical Relations between the Allotropic Forms of Metals, particularly Silver.—M. Berthelot.—Owing to the evolution of sensible quantities of heat during the transformation of metals from one allotropic form to another, the author puts forward the theory of the possibility of developing an electric current between the two forms. This possibility was proved to be true in the case of silver, by using electrodes made of two of the allotropic forms of this metal, immersed in a solution of silver nitrate at a constant temperature, communication between the electrodes being made by means of a pure silver thread through a very sensitive Arsonval galvanometer. A current is immediately produced, the surface of the two specimens of silver tending to become identical.

Secondary Radio-activity.—Henri Becquerel.—Secondary radio-activity consists of (1) a portion not deviable by a magnetic field and easily absorbed; (2) a portion deviable by a magnet, which is apparently identical with cathode rays; and (3) a portion not deviable by a magnetic field and very penetrating. The present paper gives an account of researches on these three varieties of secondary radiation, to find whether they all give further secondary rays and whether the nature of these depends on that of the exciting rays. The experiments on these various points do not give a complete solution of the questions, but bring to light a number of interesting facts.

New Derivatives of Dimethylamidobenzoylbenzoic Acid.—A. Haller and A. Guyot.—When dimethylamidobenzoylbenzoic acid undergoes nitration by means of potassium nitrate and strong sulphuric acid, nitro-dimethylamidobenzoylbenzoic acid results:—

$$C_6H_4\begin{matrix}COC_6H_3\\CO\ OH\end{matrix}\!\!<\!\!\begin{matrix}N(CH_3)_2\\NO_2\end{matrix}+H_2O$$

From this is prepared the methylic ether and various other derivatives.

Specific Heat of a Gaseous Mixture of Bodies in Chemical Equilibrium.—A. Ponsot.—The system whose formation increases the volume of the mixture, and which displaces the other when the volume increases, is also that which tends to make up the gaseous mixture when the temperature rises beyond the limit, if the pressure remains constant or the volume is invariable. This formation increases the specific heat of the mixture and the increase is greater under constant pressure than under constant volume.

Induced Radio-activity in Gases due to Radium.—P. Curie and A. Debierne.—The authors have previously announced that induced radio-activity is not produced by direct rays from a radium salt, but that it is communicated by the air from molecule to molecule from the radium salt to the body which is exited. The present paper contains an account of researches on the precise part played by the gas in this phenomenon.

Method of Determination of Atomic Weights Founded on the Laws of the Transparence of Matter to X-Rays. Atomic Weight of Indium.—L. Benoist.—The specific opacity of a simple body, or that which practically represents this, its definite equivalent of transparence, constitutes a physico-chemical constant more closely allied to the atomic weight than specific heat, since it is independent of everything that makes the latter vary. The transparence of indium to X-rays, with all the variation in characteristics which accompany it, assigns to this simple body the atomic weight 113·4, to the formal exclusion of the value 75·6.

Action of Hydrogen on Realgar and the Inverse Reaction. Influence of Pressure and Temperature.—H. Pélabon.—When hydrogen acts on excess of realgar in a sealed tube, in presence of variable quantities of arsenic, it is observed that when the mass of this latter substance is above a certain limit, the proportion of sulphuretted hydrogen produced only depends on the temperature and remains constant, for the same temperature, if the relative proportions of realgar and arsenic are varied. The pressure of the gas exerts no influence on the limiting composition of the gaseous system.

Heat of Formation of Acetals compared with that of their Isomeric Compounds.—Marcel Delépine.—A comparison of the heats of formation of acetals with that of compounds isomeric in constitution and of different function leads to some interesting observations. It shows,

in a high degree, the thermic difference which exista between a body derived from a single carbon chain and s body derived from several carbon chains, re-united by oxygen and susceptible in general of decomposing by fixation of water. The present paper gives examples of ordinary ether compared with isobutylic alcohol and methyl formic ether compared with acetic acid, anisol, and *p*-cresylol.

Acidimetric Value of Mono-substituted Benzoic Acids.—G. Massol.—The author studies thermometrically the three oxybenzoic acids, the three nitrobenzoic acids, ortho-, chloro-, and iodo-benzoic acids, and *o*- and *p*-bromo-benzoic acids. For each of these he determines the heat of neutralisation by soda, the heat of solution of the anhydrous soda salt, and, for some acids, the heat of solution in water (at 15° when the solubility is great enough). In general, however, these acids are very slightly soluble in water. From these numbers he calculates the heats of formation of the anhydrous and solid soda salt direct from the solid elements. All the determinations are made under the same conditions of temperature and dilution; the heats of formation obtained compared with that of benzoate of soda. From these can be found the influence of an atom of chlorine, bromine, iodine, or of the substituted group OH or NO_2, and a thermometric measurement made of the increase in acidity of the molecule.

Passage of Anethol to Anisic Acid by Five successive Oxidations.—J. Bougault.—The table given below shows the various stages of the regular oxidation from anethol to anisic acid:—

Anethol	$CH_3O—C_6H_4—CH=CH—CH_3$.
By HgO and I ..	$CH_3O—C_6H_4—CH<^{CHO}_{CH_3}$.
By alkaline Ag_2O ..	$CH_3O—C_6H_4—CH<^{CO_2H}_{CH_3}$.
By chromo-sulphuric mixture	$CH_3O—C_6H_4—CO—CH_3$.
By alkaline MnO_4K	$CH_3O—C_6H_4—CO—CO_2H$.
By acid MnO_4K ..	$CH_3O—C_6H_4—CO_2H$ (anisic acid).

Naphthylol-naphthyl-oxy-naphthylmethane,—

$$OH—C_{10}H_6—CH<^{C_{10}H_6}_{C_{10}H_6}>O.$$

—R. Fosse.

Action of Zinc on the Dibromide and Di-iodide of Tetramethylene.—J. Hamonet.

MEETINGS FOR THE WEEK.

MONDAY, 22nd.—Society of Arts, 8. (Cantor Lectures). "Alloys," by Sir William Chandler Roberts-Austen, K.C.B., F.R.S.

TUESDAY, 23rd.—Royal Institution, 3. "On Cellular Physiology, with special reference to Enzymes and Ferments," by Allan Macfadyen, M.D., B.Sc.

WEDNESDAY, 24th.—Society of Arts, 8. "Patent Law Reform," by Alexander Siemens.

THURSDAY, 25th.—Royal Institution, 3. "Naturalism in Italian Painting," by Roger Fry.

FRIDAY, 26th.—Royal Institution, 9. "Colour in the Amphibia," by Hans Gadow, Ph.D., M.A., F.R.S.

—— Society of Arts, 8. (Howard Lectures). "Polyphase Electric Working," by Alfred C. Eborall, M.I.E.E.

—— Physical, 5. "On the Thermodynamical Correction of the Gas Thermometer," by Prof. Callendar, F.R.S. "On the Production of a Bright-line Spectrum by Anomalous Dispersion and its Application to the Flash Spectrum," by Prof. R. W. Wood.

SATURDAY, 27th.—Royal Institution, 3. "Climate, its Causes and Effects," by John Young Buchanan, M.A., F.R.S.

LONDON HOSPITAL MEDICAL COLLEGE.

The SUMMER SESSION commences on MAY 1st.

The Hospital is the largest in the Kingdom; nearly 800 beds are in constant use, and no beds are closed. Being the only general Hospital for East London—*i.e.*, for a million and a half people—the practice is immense. In-patients last year 13,234; out-patients, 189,638; accidents, 17,871; major operations, 2508.

APPOINTMENTS.—Owing to the enormous number of patients, more appointments are open to students than at any other hospital. Sixty qualified appointments are made annually, and more than 150 Dressers, Clinical Clerks, &c., appointed every three months. All are free to Students of the College. Holders of resident appointments have free board.

SCHOLARSHIPS AND PRIZES.—Twenty-seven Scholarships and Prizes are given annually. Students entering in May can compete for Five Entrance Scholarships in September.

Special arrangements have been made to enable Students entering in May to present themselves for examination in Chemistry, &c., in July.

SPECIAL CLASSES are held for the University of London and other higher Examinations. Special entries for Medical and Surgical Practice can be made. Qualified practitioners will find excellent opportunities for studying the rarest diseases.

A reduction of 15 guineas is made to the sons of members of the profession.

ENLARGEMENT OF THE COLLEGE.—New laboratories and class-rooms for Bacteriology, Public Health, Operative Surgery, Chemistry, Biology, &c., have now been added, with all modern improvements.

The Club's Union Athletic Ground is within easy reach of the Hospital. The Metropolitan and other railways have stations close to the Hospital and College.

For Prospectus and information as to residence, &c., apply personally, or by letter, to—

NOTE ON THE DETECTION AND ESTIMATION OF NITRIC ACID IN COMBINATION WITH THE ALKALI METALS.

By E. P. PERMAN, D.Sc.

THE author has observed, but has not seen anywhere recorded, that the nitrates of the alkali metals are decomposed if heated gently with the sulphate of any metal except those of the alkalis. The sulphate of the heavy metal is formed, and red fumes of nitrogen peroxide are evolved. This reaction may be used as a convenient dry test for a nitrate of the alkali metals; the substance is mixed with lead sulphate for example, or with ordinary alum (anhydrous), and heated, when red fumes will show the presence of the nitrate.

This method may also be applied quantitatively; the nitrate is heated with anhydrous potash alum, at first very gently, and finally to a low red heat for one or two minutes. If heated by the full flame of the Bunsen burner for any length of time, the aluminium sulphate will decompose, but the complete decomposition of the nitrate is effected before this takes place. The sulphate of the alkali metal remains together with alumina and the excess of the alum, and nitrogen peroxide and oxygen are expelled. From the loss of weight, which may be calculated as N_2O_5, the percentage of nitric acid in combination can be calculated. The author has obtained the following results: —

Percentage of NO_3 *in* KNO_3.

Found.	Calculated.
61·5	
61·2	61·4
61·3	

It is best to put the alum in the crucible first, and upon this the nitrate; the two need not be mixed if the quantity of nitrate is small (0·2 g. to 0·3 g.). The operation takes about ten minutes only, and the residue does not stick to the crucible.

Unfortunately the method is of no very general application, as the presence of a chloride causes the formation of the volatile aluminium chloride.

THE ACTION OF WATER ON PENTACHLORIDE OF MOLYBDENUM.

By MARCEL GUICHARD.

WE will first set forth a few of the properties of the solution obtained by dissolving binoxide of molybdenum in hydrochloric acid; that is to say, the solution of the hydrated tetrachloride.

This solution is red when concentrated, and yellow when diluted; when very acid it is green, the addition of chloride of lime to the red solution changes it into a green solution; on the other hand, the green solution, diluted until it becomes red, changes to green when heated, and then becomes red again on cooling. Potash added to this solution of tetrachloride gives a red precipitate of hydrated binoxide. The variations of colour point to the existence of several hydrates of the pentachloride.

Finally, if we dilute a solution of the tetrachloride with water, it gradually becomes blue when exposed to the air.

We will now show what has been observed with regard to the action of water on pentachloride of molybdenum prepared by the direct combination of chlorine and molybdenum.

If we drop some anhydrous pentachloride of molybdenum into water a great deal of heat is given off, so that the solution appears to boil, though no gas is actually evolved. The solution obtained is red, and after dilution turns blue when exposed to the air. With the alkalis it gives a red precipitate of binoxide, and molybdic acid remains in solution. When hydrochloric acid or chloride of calcium are added the solution becomes green. In fact, the liquid resulting from the action of water on the pentachloride has all the characteristics of a solution of the tetrachloride. Berzelius (*Pogg. Ann.*, vi., p. 341), and Blomstrand (*Journ. f. Prakt. Chem.*, lxxi., p. 449; lxxvii., p. 88), found the formula $MoCl_4$ for the anhydrous chloride resulting from the action of chlorine on the metal: but since the research of Debray (*Comptes Rendus*, lxvi., p. 722), and those of Liecht and Kempe (*Liebig's Ann.*, clxi., p. 344), it is well-established that this compound is the pentachloride $MoCl_5$. It must be therefore admitted that the action of water on the pentachloride transforms it into the tetrachloride.

We have endeavoured to find out how this transformation is effected. In the first place, when it takes place there should be liberation of chlorine, but we have observed that the chlorine oxidises the tetrachloride, giving molybdic acid; the solution resulting from the action of water on pentachloride of molybdenum should therefore contain hydrated tetrachloride, hydrochloric acid, and free molybdic acid. The most simple equation by which this reaction can be represented is the following:—

$$2MoCl_5 + 3H_2O = MoCl_4 + MoO_3 + 6HCl.$$

We have confirmed this equation; in the first place, the solution is very acid, it gives a lively effervescence with marble; further, on the addition of an alkali it gives a precipitate of binoxide (by its action on the tetrachloride), only after a certain quantity has been added which corresponds precisely to the presence of free acids.

Again, if we react with the pentachloride, not on water, but on very concentrated hydrochloric acid, the reaction is the same, but the hydrochloric acid formed during the reaction is unable to dissolve, and is therefore given off in the gaseous state.

We have endeavoured to confirm this reaction quantitatively by titrating the free acids. To the fresh solution of the pentachloride in water we gradually added a titrated solution of potash. This potash first saturates the hydrochloric acid and the free molybdic acid, and then acts on the tetrachloride, giving a precipitate of hydrated binoxide. The appearance of the precipitate indicates the end of the saturation of the free acids. There is, however, some uncertainty as to the commencement of the precipitation; we therefore only give the following figures as being approximately correct.

0·1 grm. of $MoCl_5$ dissolved in water gave an acid solution which required, according to the above equation, 9·5 c.c. of the alkaline liquor used to bring about the commencement of the precipitation (found, 8·3 c.c., 8·0 c.c. 9·3 c.c.). The weights of pentachloride were calculated from the weight of the total molybdenum. The action of water on the pentachloride does not appear to be limited; it is complete immediately, and even with water saturated with hydrochloric acid gas it still takes place, since in this case we observe the disengagement of gas, and the formation of dissolved tetrachloride, which is green on account of the excess of oxide.

Thus the action of water on pentachloride of molybdenum gives rise to a mixture, in solution, of tetrachloride, molybdic acid, and hydrochloric acid.

We will now describe our research on the change undergone by this solution of pentachloride in water, when it is diluted. We must first remark that the solution only becomes blue on exposure to the air; titrations with permanganate show that the proportion of oxygen to metal

increases in a solution which becomes blue, a dilute solution obtained by the action of water on the pentachloride gives:—Mo, 70·05; O, 29·94. Calculated for Mo_2O_5, Mo, 70·58; and O, 29·41.

This solution after having turned blue on contact with the air gave:—Mo, 67·74: O, 32·26. Calculated for $MoO_2.4MoO_3$, Mo, 68·18 and O, 31·81.

There is thus an oxidation taking place, and this oxidation evidently forms $MoO_2.4MoO_3$; that is to say, the blue oxide. We can even demonstrate that the completely oxidised solution is nothing else than a solution of the pure blue oxide.

If we evaporate down a solution which has become blue after dilution and oxidation, we obtain a blue residue which is analogous to the molybdate from the binoxide, but it contains a little chlorine; if we re-dissolve it in water it gives a deep blue solution, which, when again evaporated down on the water-bath, still contains a little chlorine. After several successive evaporations and re-solutions, we eventually obtain a blue substance which does not contain a trace of chlorine, and which on analysis gives results very close to those required by the formula $MoO_2.4MoO_3$. Mo in the supposed anhydrous oxide = 67·52, 67·35, 67·63; calculated 68·18.

These figures are, as a matter of fact, too low, as the blue oxide is itself slowly oxidisable. If we turn to what we pointed out in our research on the blue oxide (*Bull. Soc. Chim.*, 1901), we are able to explain the mechanism of the change which takes place in a solution obtained by the action of water on the pentachloride.

We have said that this solution, at the moment of being made, contains one molecule of molybdic acid for one molecule of binoxide in the form of tetrachloride; it cannot therefore form the blue oxide which contains four molecules of molybdic acid for one of binoxide except by becoming oxidised. By oxidation a part of the binoxide it contains is transformed into molybdic acid, and, if the solution is diluted with water, this molybdic acid displaces the hydrochloric acid, as we have shown, when the acidity becomes sufficiently low to permit the existence of the blue molybdate.

After several evaporations the whole of the hydrochloric acid set free has disappeared. A concentrated solution will never become blue, as it is too acid.

The transformation of the red solution into the solution of blue oxide thus takes place in two phases:—1. Oxidation of a part of the binoxide it contains. 2. Displacement of the hydrochloric acid by the molybdic acid formed.

To sum up, after examining the action of water on the pentachloride of molybdenum we have come to the conclusion that this chloride cannot exist in solution; it is decomposed and transformed into tetrachloride, molybdic acid, and hydrochloric acid. Finally, the solution obtained is transformed by the oxidising action of the air into the blue oxide, and this reaction would afford a means of preparing the blue oxide, if this compound were not itself slowly oxidisable.—*Bull. Soc. Chim.*, Series 3, vol. xxv., No. 4.

Northern Polytechnic Institute.—The Governors of this Institution have appointed Mr. R. T. Smith, B.A. (Cantab.), as Principal of the Institute, in succession to Dr. Dunn, who is leaving to take up practice as an Analytical and Consulting Chemist in the North of England. Mr. Smith was 34th Wrangler in his year, and afterwards took a Second Class in Part II. of the Natural Science Tripos. He organised and equipped the South African College at Cape Town, and acted as Professor of Mathematics and Physics in the College for some years. Returning to England he took up work with Messrs. Vickers, Son, and Maxim, and was also appointed Lecturer in Mathematics and Physics in the Goldsmiths' Institute, New Cross. The new Principal will undertake the teaching of Mathematics in the Northern Polytechnic Institute.

THE MOLECULAR WEIGHT OF ALUMINIUM COMPOUNDS.*

By ELMER P. KOHLER.

THE molecular weight of aluminium compounds has been the subject of investigations by—

Deville and Troost	*Ann. Chim. Phys.*, [3], lviii., 257.
Odling and Buckton	*Phil. Mag.*, [4], xxix., 316.
V. Meyer and C. Meyer ..	*Ber. d. Deut. Chem. Gesell.*, xii., 1199.
Nilson and Pettersson ..	*Zeit. Phys. Chem.*, i., 456.
Friedel and Crafts	*Comptes Rendus*, cvi., 73; cvi., 602; cvii., 600.
Roux and Louise	*Comptes Rendus*, cvi., 1764.
Combes..	*Comptes Rendus*, cviii., 405.
Werner and Schmujlow ..	*Zeit. Anorg. Chem.*, xv., 24.

All of the earlier results, obtained by applying vapour-density methods to aluminium halides, lead to the general formula Al_2X_6 for these salts. All the later results—obtained partly by vapour-density and partly by newer methods—lead to the general formula AlX_3 for all classes of aluminium compounds. The last two investigations, in particular, have appeared so conclusive that the double formulæ have been more or less reluctantly abandoned. Combes determined the vapour-density of aluminium acetylacetone and obtained results that agree perfectly with the formula $Al(C_5H_7O_2)_3$, showing that in compounds of this type aluminium is unquestionably trivalent. Werner and Schmujlow determined the molecular weight of aluminium chloride by the boiling-point method, using pyridine as solvent. Their results agree closely with the formula $AlCl_3$.

The investigation described in this paper was undertaken as the result of some observations made while studying the mechanism of organic reactions that are induced by aluminium halides. The aim was the determination of the molecular weight of aluminium halides, as well as that of their addition- and reaction-products, as nearly as possible under the same conditions as those under which they are used and formed in organic reactions; namely, dissolved in some low-boiling, indifferent medium.

The substances studied were:—

I. Organic compounds, like aluminium acetylacetone.
II. Aluminium halides.
III. Compounds formed by the addition of aluminium halides to a number of different classes of organic and inorganic compounds.

Nearly all the determinations were made by the boiling-point method, with carbon disulphide as solvent; but at the end of the paper some experiments are described in which nitrobenzene was used as solvent for determinations by the freezing-point method. These were made to determine the behaviour of the addition-products above referred to in the presence of a large excess of one of the components. They show the relation between the results described in this paper and those obtained by Werner and Schmujlow.

These determinations presented no difficulties, and the results, as expected, fully confirm those of Combes.

II. ALUMINIUM HALIDES.

Aluminium chloride is insoluble in carbon disulphide, hence its molecular weight could not be determined directly. An indirect determination is given under the addition-products.

Aluminium bromide was made by Mallet's method (*Trans. Roy. Soc.*, 1880, 1003; and *Am. Chem. Journ.*, iii., 77), from pure bromine and metallic aluminium. To avoid the troublesome distillations necessary to free it from bromides of carbon, silicon, and iron, the following method of purification was adopted:—A piece of Jena glass tubing 3 metres long was constricted at three points, and bent, at the constrictions, into a flattened W. One of the ends was drawn into a capillary and connected with a phosphorus pentoxide drying-tube, which, in turn, was connected with a pump. Aluminium wire that had been heated to a low red heat in a current of hydrogen was placed in the limb next to the other end, that connected with the retort in which the bromide had been prepared, and the latter distilled into the tube. This end of the tube was then sealed off. The limb holding the bromide and wire was wrapped with thin asbestos paper and placed in a furnace in such a position that the second limb served as a reflux condenser. The bromide was boiled until colourless, when the other end of the tube was sealed off, the position of the tube changed, and the bromide distilled from the first into the second limb. The first limb was then sealed off at the constriction, the position of the tube changed, and the distillation repeated, &c. The second distillation left a slight residue of oxybromide; the third, no residue at all. The bromide was thus obtained sealed up in the fourth limb. To get it into convenient form for use, it was melted into a layer of uniform thickness throughout the length of the tube. By hitting the tube sharply with a block of wood, the layer could be readily broken up into lumps of any desired size. In this way there is no difficulty either in preparing or manipulating the bromide.

The principal difficulty met with in this part of the work consisted in getting and keeping carbon disulphide sufficiently free from water. After a most careful purification it was repeatedly distilled from phosphorus pentoxide; but though used immediately after distillation, enough water was invariably present to cause errors of from 50 to 100 in the molecular weight. The difficulty which has been experienced by others (Rosenheim and Woge, *Zeit. Anorg. Chem.*, xv., 283) working with such sensitive substances, is due to the adsorption of water by the apparatus. To remove this water, the weighed molecular-weight apparatus was filled with dry carbon disulphide, and a considerable quantity of the latter distilled off, the vapour sweeping freely through the condenser. The condenser was then capped with phosphorus pentoxide tubes that were ground on, the apparatus closed with a ground-glass stopper, and weighed with the thermometer in place.

Pure dry carbon disulphide dissolves aluminium bromide without any indication of chemical action. The solution is clear and colourless; its boiling-point remains constant during protracted boiling; and, if the disulphide is allowed to evaporate at ordinary temperatures, the pure bromide crystallises out in large lustrous rhombohedra. These are far less sensitive to atmospheric moisture than the lumps of the fused salt. An analysis of the crystals gave 10·02 per cent aluminium and 89·72 per cent bromine, instead of the calculated 10·15 per cent aluminium and 89·85 per cent bromine.

Molecular Weight of Aluminium Bromide.

(To be continued).

SOME PRINCIPLES AND METHODS OF ROCK ANALYSIS.*

By W. F. HILLEBRAND.

(Continued from p. 187).

XVII. *Chromium.*

IF vanadium is absent, or nearly so, as is apt to be the case in those highly magnesian rocks (peridotites) usually carrying a good deal of chromium, the following separation and gravimetric method for chromium gives good and concordant results, but in presence of vanadium, and it is best generally to assume its presence, the colorimetric method should always be adopted.

Gravimetric Method.

Having obtained chromium in solution as chromate and free from all else but a little alumina, as at the conclusion of the preceding section on phosphorus, proceed as follows:

Concentrate if necessary, and add fresh ammonium sulphide, or introduce hydrogen sulphide. The chromium is reduced and appears as a precipitate of sesquioxide mixed with the rest of the alumina. This precipitate is now treated according to Baubigny (*Bull. Soc. Chim.*, New Series, 1884, vol. xlii., p. 291; CHEMICAL NEWS, 1885, vol. l., p. 18), by dissolving in nitric acid, evaporating to near dryness, and heating with strong nitric acid and potassium chlorate, finally evaporating to dryness to get rid of the acid. Oxidation is complete and very speedy. On dilution with cold water, acid sodium carbonate is added in slight excess, and after two or three hours the precipitated alumina is filtered off. From the filtrate the chromium is then thrown out by fresh ammonium sulphide, re-dissolved and re-precipitated to free from alkali, and weighed.

The separation of aluminum from chromium by hydrogen peroxide in ammoniacal solution, as recommended by Jannasch and Cloedt (*Zeit. fur Anorg. Chemie*, 1895, vol. x., p. 402), has been shown by Friedheim and

* *Bulletin of the United States Geological Survey*, No. 176.

Brühl (*Zeit. fur Anal. Chemie*, 1899, vol. xxxviii., p. 681), together with most of the other separations of Jannasch based on the use of hydrogen peroxide, and from which so much was hoped, to be valueless.

Colorimetric Method.

For this very accurate and by far the quickest method* for determining chromium in rocks and ores where the amount does not exceed a few per cent, there is needed the aqueous extract of a sodium-carbonate fusion of the rock (as obtained, for instance, under "Phosphorus," p. 186), in order to compare its colour with that of a standard solution.

Preparation and Strength of Standard Solution.—This standard solution is made by dissolving 0·25525 grm. or double that amount of pure potassium monochromate in one litre of water made alkaline by a little sodium carbonate. Each cubic centimetre then corresponds to one-tenth m.grm. or two-tenths m.grm. of chromic oxide (Cr_2O_3), in which condition chromium is usually reported in rocks and ores. It is probably inadmissible to increase the strength of the standard much above the figure given.

Preparation of the Test Solution.—Before filtering the aqueous extract of the sodium-carbonate fusion a few drops of alcohol (ethyl or methyl) are added to destroy the colour of sodium manganate. If the yellow colour of the filtrate is very faint, concentration by evaporation will strengthen it, and less than 2 m.grms. of chromic oxide in 1 grm. of rock can then be exactly measured. For smaller amounts it is best to employ from 3 to 5 grms. of powder, and then to concentrate the chromium by precipitation by mercurous nitrate, as detailed in the next section under "Vanadium" (see *prox.*); otherwise it may be difficult or impossible, because of the large amount of alkali carbonate present, to obtain a filtrate of sufficiently small bulk to show a decided colour.

If nitre has been used in the fusion and the crucible has been at all attacked by it, a yellow colouration of the filtrate may be due to dissolved platinum, but neither the proportion of nitre nor the temperature of the blast should ever be high enough to permit the crucible to be attacked.

Comparison of Colours.—The final solution is transferred to a graduated flask of such size that its colour shall be weaker than that of the standard chromium solution. Definite amounts of the latter are then diluted with water from a burette until of the same strength as the test solution, exactly as described on page 177 for the colorimetric estimation of titanium. For very minute amounts it is necessary to use Nessler tubes, as in ammonia estimations, instead of the glasses and apparatus described and depicted under "Titanium" (p. 177).

As with colorimetric methods in general, this one gives better results with small than with large percentages of chromium, yet it can be applied in the latter cases with satisfactory results by making a larger number of consecutive comparisons with the same solution.

A few Comparative Data.

A few comparisons between colorimetric and gravimetric determinations of chromium are here given to show the order of agreement, the former having been made several months and even years after the latter.

TABLE IV.

* W. F. Hillebrand (*Journ. Am. Chem. Soc.*, 1898, vol. xx., p. 454; CHEMICAL NEWS, 1898, vol. lxxviii., pp. 227, 239; *Bull. U. S. Geol. Survey*, No. 167, p. 37). First applied by L. de Koningh ("Nederl. Tyds. voor Pharm. Chem. and Tox., 1889"), for the estimation of chromium in foodstuffs.

The outcome was somewhat surprising, for it was hardly to be expected that the long and laborious quantitative separations should have resulted so well as they are shown to have done. It should be mentioned that for the gravimetric tests but 1 or 2 grms. at most were used, which accounts for the reported absence of chromium in two instances, this report being based on the lack of colour in the aqueous extract of the alkali fusion after removal of manganese.

(To be continued).

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Ordinary Meeting, March 21st, 1901.

Professor THORPE, C.B., F.R.S., President, in the Chair.

(Concluded from p. 190).

47. "*On the Atomic Weight of Lanthanum, and on the Error of the 'Sulphate Method' for the Determination of the 'Equivalent' of the Rare Earths.*" By BOHUSLAV BRAUNER and F. PAVLÍČEK.

Lanthanum material was prepared from crude cerite material and purified, first by repeated re-crystallisation of the double ammonium nitrate. The nitrate was then further purified by fusion with potassium sodium nitrate, traces of cerium, praseodymium, and yttrium being thus removed, after which the material was further fractionated by this process of fusion. The purest lanthanum nitrate was next subjected to a series of fractional precipitations with potassium hydroxide so that about 7/8 of the earth was precipitated, and the most "positive" fraction contained in the filtrate was converted into the pure oxalate and designated as La 1. In the same way, fractions La 2—La 7 were obtained, La 7 being most "negative" of the series. After this followed the still more negative fractions A1—A6, obtained by fusion with nitre.

For the determination of the atomic weight the oxide (from the oxalate) was converted into the sulphate, and the conditions accompanying its formation were carefully investigated. On heating the sulphate to a constant temperature of 450° and repeatedly weighing, a gradual decrease of weight was observed until at last an approximately constant weight was obtained corresponding to an atomic weight of about La=138. On heating the salt in an atmosphere of ammonium carbonate, further loss of sulphuric acid takes place, and an atomic weight of La=138·2 (O=16) was obtained with the purest material (La 1), a number which, owing to the condordant determinations of Brauner, Cleve, and Bettendorf, has hitherto been regarded as the true atomic weight of lanthanum. This number is, however, incorrect, a careful investigation having shown that the sulphate so obtained contains some of Wyrouboff's *acid sulphate*. This acid sulphate is so stable that even at temperatures above 500° some of it remains undecomposed, whilst another part of the sulphate, in the same crucible, may have undergone a partial decomposition into the basic sulphate. An aqueous solution of a sulphate so prepared shows, with ethyl orange as indicator, a strongly acid reaction, whereas the true normal sulphate obtained by repeated re-crystallisation is perfectly neutral towards ethyl orange. Every sulphate obtained in this way was therefore dissolved in water, tested with ethyl orange, and a *N*/20 solution of sodium hydroxide added until the red colour of the indicator was converted into the yellow tint shown by the normal neutral lanthanum sulphate solution containing ethyl orange. The error of the atomic weight of lanthanum due to the presence of sulphuric acid in the form of an acid sulphate may amount to −0·8 of a unit.

All "equivalent" determinations of the rare earths made

by the "sulphate method" during the 19th century are vitiated by this error. This error is largest with the most positive lanthanum, and diminishes as the basicity of the earth decreases.

After the determination and application of the above correction the single fractions of lanthanum gave the following atomic weights (means of several determinations):

La 1.	La 2.	La 3.	La 4.	La 5.	La 6.	La 7.	A 5+6.
138·78	138·80	138·88	138·97	138·98	139·07	139·10	139·25

The sulphate is very hygroscopic, and absorbs moisture during weighing. After excluding this error completely by means of a novel cooling and weighing arrangement, it was found that a correction of +0·2 to +0·3 must be applied to the whole series so that the atomic weight of the most positive fraction becomes La=139·0.

Lanthanum is a complex of two earth metals consisting, however, chiefly of the true lanthanum with the atomic weight La=139·0. Gibbs' and Shapleigh's results confirm this, for they found for the *mixture* the atomic weight 139·7.

48. "*On the Atomic Weight of Praseodymium.*" By B. Brauner.

The atomic weight of this element was determined by four methods. (1). By the analysis of the anhydrous sulphate. The oxide of the approximate formula, Pr_4O_7, remaining after strong calcination of the sulphate was analysed by Bunsen's iodometric method, and the weight of the pure Pr_2O_3 was determined; this series gave Pr=140·95. (2). By the analysis of the oxalate. The amount of pure Pr_2O_3 contained in the oxide Pr_4O_7, which remains after calcination, was determined as in (1), and the oxalic radicle was determined by a novel gravi-volumetric method with permanganate. A series of fractions was obtained by fusion of praseodymium nitrate with nitre, but all gave the same number, Pr=140·95, so that no decomposition into different earths took place. (3). By synthesis of the sulphate. A known quantity of the oxalate containing a known quantity of the oxide, Pr_2O_3, as determined in (1) and (2) was converted into the sulphate by the usual method. Different fractions did not show any sign of decomposition, but the atomic weight deduced in this way was lower than in (1) and (2), being only Pr=140·78. As in the case of lanthanum it was found that praseodymium sulphate also does not part completely with the slight excess of free sulphuric acid (acid sulphate of Wyrouboff) on heating, and therefore shows an acid reaction. Using a normal sulphate tinted with ethyl orange as indicator as the standard of comparison, this excess of sulphuric acid was determined with *N*/20 sodium hydroxide. The result of series (4), in which the error due to the hygroscopic nature of the oxide and of the anhydrous sulphate was eliminated, gave the atomic weight Pr=140·93. Excluding series (2) as it was vitiated by an error which became known only at a later period, and which caused Jones and v. Scheele to obtain the incorrect number Pr=140·4—140·5, the mean result is Pr=140·94.

The above results only prove that the equivalent of praseodymium is 47, so that the atomic weight is either $Pr^{I}=47$ or $Pr^{II}=94$, $Pr^{III}=141$, $Pr^{IV}=188$, or $Pr^{V}=235$. In order to solve this question the molecular weight of the anhydrous chloride was determined by the ebullioscopic method, absolute alcohol being used as the solvent. Several determinations gave numbers for the molecular weight approaching 247·4 (this corresponds to $PrCl_3$); so that this fact, together with the analogies pointed out three years ago (*Proc.*, 1898, xiv., 71), proves definitely that the true atomic weight of praseodymium is Pr=140·94.

49. "*On Praseodymium Tetroxide and Peroxide.*" By B. Brauner.

When the author published his preliminary note (*Proc.*, 1898, xiv., 71), he left unsolved many of the problems connected with the black higher oxide which he was the first to prove possessed the formula Pr_2O_4. This oxide was subjected to a new and careful investigation. The only method for obtaining this oxide pure is by fusion of the nitrate with nitre, the combustion of the oxalate employed by v. Scheele giving a very impure compound. The pure praseodymium tetroxide has a sp. gr. of 5·978 (at 20°/4° and in a vacuum); the pure trioxide, Pr_2O_3, has a sp. gr. of 7·068. The molecular volume of $Pr_2O_4=57·9$, that of $Pr_2O_3=46·7$, hence the volume of the active (the fourth) oxygen atom is +11·2, an unusually large number for the volume of 1 atom of active oxygen. Hence we can understand the great instability of the salts of the type PrX_4. The oxides, Pr_2O_4 and Pr_2O_3 combine to form a complex oxide of the approximate composition Pr_4O_7, or more correctly $Pr_{10}O_{18}$, of sp. gr. 6·704, showing that slight contraction has taken place. The *pure* praseodymium tetroxide does not give the hydrogen peroxide reaction, and is a purely *ozonic* oxide. It gives free chlorine with hydrochloric acid, ozonised oxygen with oxy-acids; in acid solution, it oxidises cerous salts to ceric salts, manganous salts to permanganic acid, and gives the characteristic violet colouration with a solution of strychnine in sulphuric acid. It "catalyses" with hydrogen peroxide in acid solution,

Praseodymium nitrate yields with hydrogen peroxide, with sodium peroxide and an alkali, the hydrated real peroxide, Pr_2O_5, belonging to the *antozonic* oxides. To the same type belongs the acetate the composition of which may be represented by the formula—

$$Ac_2{:}Pr^{III}{\cdot}O{\cdot}O{\cdot}O{\cdot}Pr^{III}{:}(OH)Ac+H_2O.$$

The maximum valency of praseodymium is tetrad, like that of cerium. The corresponding oxides have a smaller volume (greater density) than those of cerium, which it resembles most of all elements, but no place has been found in the periodic system for an element possessing the physical and chemical properties of praseodymium and its compounds.

50. "*Note on Neodymium.*" By B. Brauner.

Applying the "sulphate method" for the determination of the atomic weight of neodymium as in the case of lanthanum and praseodymium, the neodymium material, purified with sodium sulphate, gave the atomic weight Nd=143·80, the correction due to the presence of the acid sulphate being determined experimentally. Neodymium forms (in the dry way) a higher oxide, Nd_2O_4, with such an extremely feeble tension (potential) of the active (fourth) oxygen atom that on liberation with acids this oxygen passes through ferrous salt solutions without oxidising them. Many other rare earths will probably form higher oxides of the same type, but their preparation and investigation offer great difficulties. These acids seem to represent the extreme limit of *ozonic* oxides.

In addition to this, neodymium yields purely *antozonic* compounds of the type R_2O_5, like the hydrated peroxide and the peculiar acetate,—

$$Ac{:}Nd^{III}{\cdot}O{\cdot}O{\cdot}O{\cdot}Nd^{III}{:}(OH){\cdot}Ac+H_2O,$$

strictly analogous to the corresponding praseodymium compounds.

The difficulties of finding a place for neodymium in the periodic system are even greater than in the case of praseodymium.

51. "*Contribution to the Chemistry of Thorium.*" By B. Brauner.

The results obtained on studying the behaviour on hydrolysis of the salt, $Th(C_2O_4{\cdot}NH_4)_4+7H_2O$ (*Trans.*, 1898, lxxiii., 951), were applied to the fractionation and purification of commercial thorium compounds. In this way, at the one end of the series the most basic positive fractions were obtained, that is, those which are most easily hydrolysed and termed Th_α, and at the other the most acid negative fractions which are most easily hydrolysed, and which are called Th_β.

After removing the trivalent rare earths by methods indicated (*loc. cit.*), the atomic weight of thorium contained

in the most basic (positive) fractions was determined, and the numbers $Th_\alpha = 233{\cdot}5$ (by the oxalate method) and $Th_\alpha = 233{\cdot}3 - 233{\cdot}7$ (by the sulphate method) were found.

The most negative ($Th\beta$) fractions gave at first the atomic weight $Th\beta = 232{\cdot}5$, and this by further purification of the material decreased to $Th\beta = 232{\cdot}0$ and $231{\cdot}9$. By working up a much larger quantity of material and trying to determine the atomic weight by the oxalate method, abnormal results were obtained owing to the easy formation of basic salts by the $Th\beta$ material, a property not possessed by the ordinary thorium salts. An extremely careful set of analyses by the oxalate method gave $R^{IV} = 236{\cdot}3$, whereas an analysis of the sulphate precipitated by alcohol from an aqueous solution which must be strongly hydrolysed gave $R^{IV} = 280{\cdot}7$. Ordinary thorium sulphate, owing to only partial hydrolysis of the sulphate in the aqueous solution, gives under the same conditions of precipitation $R^{IV} = 234{\cdot}6$, that is, only a slightly basic salt.

On further fractionation of the most negative ($Th\beta$) fraction, a material was obtained which, after conversion into the normal sulphate and its analysis, gave $Th\beta = 220$. This decrease of the atomic weight from 232 to 220 is accompanied by a decrease in the density of the oxide from 10·2 to 9·6 along with the property of the β-fractions of easily forming basic salts—a property exhibited by no known earth, with the exception of zirconium, which, however, cannot be present, may be regarded as proving the complex nature of thorium. These thoroughly established facts have been known to the author for years, but he abstains from further conclusions, especially as the study of the very complicated spectral phenomena connected with the above research proceeds but slowly.

52. "*Pheno-α-ketoheptamethylene and its Derivatives.*" By F. S. Kipping and A. E. Hunter.

The authors have continued the investigation of the ketone obtained by the action of aluminium chloride on phenylvaliric chloride (Kipping and Hall, *Proc.*, 1899, xv., 173), and have proved that it contains a seven carbon atom ring condensed with benzene in the ortho-position, as on oxidation with dilute nitric acid it yields *o*-phthalic acid.

Pheno-α-ketoheptamethylene oxime crystallises from dilute alcohol in lustrous needles melting at 108—109°; the corresponding phenylhydrazone and *p*-bromophenylhydrazone do not crystallise readily, and are oxidised on exposure to the air.

Pheno-α-aminoheptamethylene,—

is obtained when the oxime is reduced with sodium amalgam in acetic acid solution; it is a strongly basic, colourless liquid which absorbs carbon dioxide on exposure to the air.

The *hydrochloride*, $C_{11}H_{15}N,HCl$, is only moderately soluble in cold water, and crystallises in small prisms which do not melt at temperatures below 250°.

The *platinichloride*, $(C_{11}H_{15}N)_2,H_2PtCl_6$, forms orange needles. The *picrate* crystallises well, and is only sparingly soluble. The *sulphate* forms thin, transparent plates, and melts at about 229°; like the *oxalate*, it is only moderately soluble in water.

The *benzoyl* derivative crystallises in felted masses of needles melting at 171—172°.

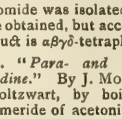
53. "*Note on Diphenyldinitroethylene.*" By J. J. Sudborough.

In the last number of the *Berichte* (1901, xxxiv., 619), Julius Schmidt describes two stereoisomeric *s*-diphenyldinitroethylenes, $NO_2{\cdot}CPh{:}CPh{\cdot}NO_2$, the one melting at 186—187°, and the other at 105—107°. Both compounds were obtained by the direct addition of nitrogen peroxide to tolane. The compound melting at 105—107° was prepared by the author several years ago (*Diss.*, 1893; *Trans.*, 1897, lxxi., 223; Richter's *Lexicon II.*, 1422), by the addition of nitrogen peroxide to monochlorostilbene, and the subsequent elimination of hydrogen chloride. The melting point was given as 104—105°, and it crystallised in sulphur-yellow prisms and pyramids resembling those described by Schmidt. The molecular weight was determined and the action of bromine investigated, but no dibromide was isolated, and no definite reduction products were obtained, but according to Schmidt the chief reduction product is $\alpha\beta\gamma\delta$-tetraphenyl piperazine.

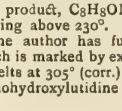
54. "*Para- and Ortho-cyanohydroxy-derivatives of Pyridine.*" By J. Moir, M.A., B.Sc.

Holtzwart, by boiling an aqueous solution of the polymeride of acetonitrile, $C_4H_6N_2$, obtained a condensation product, $C_8H_8ON_2$, which he described merely as melting above 230°.

The author has further investigated this substance, which is marked by extraordinary stability, and finds that it melts at 305° (corr.) and that it is, in all probability, a cyanohydroxylutidine of the constitution—



isomeric with the compound—



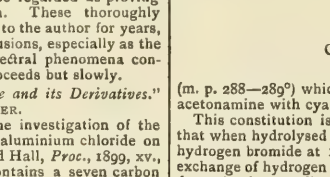
(m. p. 288—289°) which Guareschi obtained from acetylacetonamine with cyanoacetic ester.

This constitution is based on the fact, among others, that when hydrolysed by heating with strong solution of hydrogen bromide at 170°, it yields pseudolutidostyril, by exchange of hydrogen for cyanogen. All attempts to produce the intermediate carboxy-acid have failed. This acid has been obtained by Collie by an analogous reaction. Attempts to synthesise the cyano-compound from Collie's acid and ester have also been without result, owing to the stability of the compounds in question.

The mechanism of the condensation is evidently as follows:—

(1). $CH_3{\cdot}C(NH_2){:}CH{\cdot}CN + H_2O \rightarrow CH_3{\cdot}C(OH){:}CH{\cdot}CN$ (cyanoacetone).

(2).



The author has also found that the supposed third isomeride of $C_8H_8ON_2$, prepared by von Meyer from a compound, $C_8H_9N_3$, by the action of nitrous acid, is in reality identical with Holtzwart's isomeride. It follows that $C_8H_9N_3$ is 3-cyano-2:4-dimethyl-6-aminopyridine.

A careful physical and chemical comparison of Holtzwart's and Guareschi's isomerides has been made, and, although they resemble one another very closely, they were found to be different.

Both compounds form white, sparingly soluble needles of a very bitter taste; they are not basic, but form soluble derivatives with the alkali-metals, and cannot be directly methylated. Both resist hydrolysis with strong alkalis and acids, but give pseudolutidostyril with hydrogen bromide. They differ in their action on polarised light, and when mixed the melting-point is depressed. Different

compounds are obtained from each by bromination and nitration. The bromo-derivative of Holtzwart's isomeride melts at 307—308°; that of Guareschi's compound at 260—262°. The nitro-compound of Holtzwart's isomeride melts at 262° and forms yellow salts; that of Guareschi's compound melts at 271°, and forms white salts which give yellow solutions. This agrees well with the formulæ assigned to them, the former having the nitro-group in the ortho-position relatively to the hydroxyl, while in the latter case it is in the para-position.

Again, Guareschi's isomeride can be hydrolysed by warm fuming sulphuric acid, or by fusion with potash, whereas Holtzwart's isomeride cannot.

On reducing the two nitro-compounds, characteristic differences are obtained in the reactions of the amino-derivatives; while that from Guareschi's isomeride gives no colour with ferric chloride, and in alkaline solution has a strong blue fluorescence, the amino-derivative of Holtzwart's isomeride gives an indigo-colour with ferric chloride, and becomes cherry-red in presence of ammonia. These reactions are also given by Collie's acid after nitration and reduction, whence it follows that they have the same configuration.

The author failed to obtain, by the action of phosphorus pentachloride on his compound, the substance $C_8H_6N_2$, described by Holtzwart.

From the pseudolutidostyril obtained in these experiments, the following derivatives were obtained:—

(1). 3 : 5-*Dibromo-ψ-lutidostyril*, melting at 253° (corr.).
(2). 5-*Nitro-ψ-lutidostyril*, melting at 254° (corr.).
(3). 3-*Nitro-ψ-lutidostyril*, melting at 196° (corr.).

ANNIVERSARY MEETING, *March 28th*, 1901.

Professor THORPE, C.B., F.R.S., President, in the Chair.

DR. JOWETT and Mr. WERNER were appointed scrutators, and a ballot was opened for the election of Officers and Council for the ensuing year, the ballot being closed at the conclusion of the President's Address.

The PRESIDENT, in beginning his Address, said that the Chemical Society was founded about four years after the accession to the throne of the Gracious Lady whose recent loss they deplored, and the memory of whose virtues and worth as a woman and as a monarch would for ever abide with them. He was proud to think that this Society, in so far as it had ministered to the progress of chemistry, may have contributed in some measure to the lustre of a reign so pre-eminently associated with the development and spread of science in this country, and with the extension of those arts which rest upon chemistry. The Society was not unmindful of what the science owed to the Royal Family, and in particular to the late Prince Consort, whose appreciative interest in the fortunes of the Royal College of Chemistry, of which he was the President, and whose friendship for the eminent man who made it the first organised school of chemical research in this country, had directly ministered to its own activity, welfare, and usefulness. The Society had sought to give utterance to these sentiments in an Address which it ventured to submit to His Majesty on his accession to the Throne, and in respectfully tendering its congratulations, and in offering its homage, it expressed the hope that his reign would be marked by discoveries in the science it represented not less brilliant than those which characterised the reign of his illustrious mother.

The following Fellows have died:—Edmund Atkinson, John Borland, Alfred Hunter Boylan, Wm. Harcourt Branscombe, Sir John Conroy, Henry Howard Crawley, Thomas Flower Ellis, Frank W. Harris, Herbert A. Hotblack, Sir John Bennet Lawes, Stevenson Macadam, Frederick Alfred Manning, William McConnell, William Parsons, Richard Reynolds, Saville Shaw, George Smith, C. J. H. Warden, Augustus A. Wood, Thomas M. Wyatt.

The numerical strength of the Society was as follows:—

Number of Fellows, March 29th, 1900		2292
" " since elected		117
" " reinstated by Council		5
		2414
Removed on account of non-payment of two annual subscriptions	28	
Withdrawn	31	
Deaths	20	
	—	79
Number of Fellows, March 28th, 1901		2335
Foreign Members		33

The President offered on behalf of the Society its warm congratulations to its former President and Treasurer, Dr. Russell, on the attainment this year of his jubilee as a Fellow of the Society. Mr. Nevil Story Maskelyne, a former President of the Society; Sir David Gamble, C.B.; and Mr. Edward Riley were also congratulated on reaching this anniversary.

During the year, the Society had joined in the commemoration of the fortieth year of the doctorate of Professor Markownikoff of Moscow, one of its distinguished Foreign Members.

Since the last Anniversary, 182 communications had been made to the Society, a number greater than in any preceding year. In character, variety, and importance they compared not unfavourably with the contributions of any former period. Abstracts of all these had appeared in the *Proceedings*, while 106 have already been published in the *Transactions*. The volume of *Transactions* for 1900 contained 127 memoirs, occupying 1334 pages; in the preceding year 120 papers were published, occupying 1166 pages. The President drew particular attention to the desirability of brevity in the papers communicated to the Society.

The volumes for 1900 contains 3758 abstracts of papers, published mainly in continental journals, occupying 1492 pages, arranged as follows:—

	Pages.	No. of Abstracts.
PART I.		
Organic Chemistry	712	1355
PART II.		
General and Physical Chemistry		467
Inorganic Chemistry		383
Mineralogical Chemistry		174
Physiological Chemistry		336
Chemistry of Vegetable Physiology and Agriculture		368
Analytical Chemistry		675
	780	2403
Total in Parts I. and II. ..	1492	3758

The number of abstracts dealt with in 1900 is 141 more than in the preceding year, though occupying 304 pages less.

The volume for 1900 contained no less than four Memorial Lectures, giving an account of the life-work of Victor Meyer, Bunsen, Friedel, and Nilson. The Council had determined to issue those Memorial Lectures which had appeared up to the end of 1900 in a separate form. The President in this connection paid a special tribute to the late Prof. FitzGerald, who had delivered the Helmholtz Memorial Lecture, one of the most weighty of the series.

A special reference was made to the bearing of the Copyright Bill upon the Society as a publishing agency.

As regards the Library, 810 books had been borrowed, as against 790 last year; and 95 books, 327 volumes of periodicals, and 30 pamphlets had been added, as against 114 books, 397 volumes of periodicals, and 27 pamphlets in the preceding year.

A number of books and periodicals not bearing in any way on the work of the Society had been removed from the library. Some proportion of these had been offered to and accepted by the British Museum; the remainder will be disposed of either by presentation to kindred societies or otherwise. The need of shelf room was pressing in view of the fact that the present accommodation would be exhausted in two years. The Library Catalogue was within sight of completion; it included 6300 author entries and nearly as many subject entries. An estimate for printing was in preparation.

The President, referring to the result of the voting on the question of the day and hour of meeting, said the Committee had reported to the Council that the returns, however, analysed, showed such a large majority in favour of the proposed change, that the Council had decided that it should be provisionally tried during the coming session. The Ordinary Meetings of next session would therefore be held on the first and third Wednesdays of the month at 5.30 p.m.

A reference was made to the movement for a uniform system of atomic weights, and it was announced that the Atomic Weights Committee had decided to recommend—(1) That O = 16 be taken as the basis of calculation of atomic weights; (2) that in assigning a number as the atomic weight of any element only so many figures should be employed that the last may be regarded as accurately known to one unit in that figure.

Grants amounting to £160 had been made from the Research Fund in aid of chemical investigation.

Dr. Armstrong proposed a vote of thanks to the President, coupled with the request that he would allow his Address to be printed in the *Transactions*.

Prof. Smithells seconded the motion, which was carried by acclamation.

The President having returned thanks,

Prof. Tilden, F.R.S., the Treasurer, in giving an account of the balance sheet, which he laid before the Society, duly audited, said:—

The receipts had been:—By admission fees and subscriptions, £4290; by sale of Journal and advertisements, £880 12s. 9d.; and by dividends on invested capital, £464 14s. 4d. The total receipts from all sources amounted to £5668 19s. 8d. The expenses had been:—On account of the Journal, £3512 9s. 11d.; on account of the Proceedings, £250 15s.; on account of the preparation of a new Catalogue, £51 16s. 4d.; on account of the Library, £238 15s. 11d.; House expenses, £210 9s. 11d. The total expenditure being £4832 3s. 9d.

The Treasurer, in concluding, proposed a vote of thanks to the auditors, which was acknowledged by Mr. Page.

Prof. Emerson Reynolds, F.R.S., proposed a vote of thanks to the Officers and Council.

Prof. Collie, F.R.S., seconded the motion, which was unanimously adopted.

Prof. Dunstan, F.R.S., responded.

The scrutators having presented their report to the President, he declared that the following had been duly elected:—

President—J. Emerson Reynolds, D.Sc., M.D., F.R.S.

Vice-Presidents who have filled the office of President—Sir F. A. Abel, Bart., G.C.V.O., K.C.B., D.C.L., F.R.S.; H. E. Armstrong, Ph.D., LL.D., F.R.S.; A. Crum Brown, D.Sc., LL.D., F.R.S.; Sir W. Crookes, F.R.S.; James Dewar, M.A., LL.D., F.R.S.; Sir J. H. Gilbert, Ph.D., LL.D., F.R.S.; J. H. Gladstone, Ph.D., D.Sc., F.R.S.; A. Vernon Harcourt, M.A., D.C.L., F.R.S.; H. Müller, Ph.D., LL.D., F.R.S.; W. Odling, M.B., F.R.S.; W. H. Perkin, LL.D., Ph.D., F.R.S.; Sir H. E. Roscoe, D.C.L., LL.D., F.R.S.; W. J. Russell, Ph.D., F.R.S.; T. E. Thorpe, C.B., Ph.D., D.Sc., LL.D., For.Sec.R.S.; A. W. Williamson, LL.D., F.R.S.

Vice-Presidents—E. Divers, M.D., D.Sc., F.R.S.; C. E. Groves, F.R.S.; Prof. Herbert McLeod, F.R.S.; Prof. H. A. Miers, M.A., F.R.S.; T. Purdie, Ph.D., F.R.S.; T. Stevenson, M.D.

Secretaries—Wyndham R. Dunstan, M.A., F.R.S.; A. Scott, M.A., D.Sc., F.R.S.

Foreign Secretary—Raphael Meldola, F.R.S.

Treasurer—William A. Tilden, D.Sc., F.R.S.

Other Members of Council—H. Brereton Baker, M.A.; F. D. Chattaway, Ph.D., D.Sc.; Frank Clowes, D.Sc.; A. W. Crossley, Ph.D., D.Sc.; A. E. Dixon, M.D.; Prof. J. J. Dobbie, M.A., D.Sc.; H. J. H. Fenton, M.A., F.R.S.; M. O. Forster, Ph.D., D.Sc.; D. Howard; S. U. Pickering, M.A., F.R.S.; W. J. Pope; James Walker, D.Sc.

Anniversary Dinner.

The Anniversary Dinner of the Society took place at the Whitehall Rooms, on Wednesday, March 27th, at 7 p.m.

In proposing the loyal toasts, The President, while paying the Society's tribute to the late Queen, said they could have no manner of doubt that the King would worthily follow in her footsteps. That the King would long rule over the splendid heritage to which he had succeeded, and that his reign might be marked with the same full measure of prosperity, intellectually and morally which had graced the reign of Victoria, was their constant hope and confident anticipation.

The Treasurer, Professor Tilden, in proposing the toast of the Houses of Legislature, said they did not seek the honour of the presence of so many members of both Houses at their Dinner that evening solely for the purpose of enjoying their society. The fact was the Chemical Society, old and respectable as it was, had to give a sort of account of itself in the face of the world, and nowhere was it so important that the objects of the Society, and the benefits they thought it conferred upon the community, should be recognised as in the Houses of Legislature. Some of them were rather anxious as to the part which science had to play and the position which science was to occupy in the national programme. Science demanded a much more influential place in the councils of the nation than had hitherto been granted it.

The Lord Chancellor, in responding for the House of Lords, said he had feared from the Treasurer's speech that they were about to be subjected to a quantitative and qualitative analysis, but was glad to see it pass off into a homily upon the importance of infusing into Parliament a more scientific spirit. He was always glad to use the phrase Parliament, because although, for obvious purposes, it was desirable that it should be divided into two Chambers, he always liked to regard that great instrument of human enlightenment and freedom as being one, and he would lament anything which interfered with the working of that great constitutional machine. He believed that the House of Commons had that day been distinguishing itself in its energy to procure chemically pure beer. (Laughter). He, unfortunately, had no such claim to make for the House for which for the moment he had the honour to respond. He did not believe they had been dealing either with beer or science during this Session, except so far as military science might be supposed to demand public attention. He accepted with the most perfect good faith the exhortation which he had received from the proposer of the toast, and so far as he could influence either public opinion or the action of the House of Lords, he would never forget what they owed to science. He had heard it whispered—he would not say by unkind friends—that their work in manufacturing Acts of Parliament was not absolutely perfect, but the more they advanced in the science of language, in perfecting precision in organising human thought and reasoning, the plainer they would make to the popular understanding the meaning of an Act of Parliament. Nothing could more induce to the making of clear laws than a scientific education, which would bring about an assiduity of reasoning and clearness of thought.

Sir Herbert Maxwell, Bart., M.P., in responding for the House of Commons, said though much had been said in condemnation of that House he submitted that its present Members were not worse than those who had gone before. Though they might conduct their business in a way which would disgrace a self-respecting company, they were not so indifferent to the work of scientists as they appear to be. They would, for instance, as soon condemn a witch to be burnt as discuss a subject of a scientific nature, such as that which had occupied them that afternoon, without taking the advice of the experts of the question. He asked that they would rather judge of the result of their labours than the way in which that result was attained. He took the opportunity of specially thanking the Chemical Society for the aid and hospitality it had recently afforded the Committee on Food Preservatives, of which he was Chairman.

Lord Kelvin, in proposing the toast of The Chemical Society, said he was perfectly appalled at the magnitude of the work he was asked to commend to their notice. When he thought of all that had been done in chemistry during the last century, he was convinced he would in no way be exaggerating when he said that chemistry was the first and last science of the nineteenth century. It only began to exist as a science at the close of the eighteenth century. He was a physicist, and he could assure them that physicists had to go to chemistry all through their work. The physicist wanted to measure everything, and now in particular they wanted to know the weight of an atom of hydrogen and the number of molecules in a litre of hydrogen. They were, he was glad to say, in a fair way of learning it, thanks to the labours of chemists. Chemists must stick to dynamics. The chemist had to do with the forces between particles of matter from the hundred-millionth of a grm. in weight to the thousand-millionth, and had to look to the forces between them, and tell the number of their particles in a litre of water or beer, and say how many of those atoms were arsenic, and how many atoms of arsenic might be allowed. They had learned within the month that some amount of arsenic might be allowed—that without arsenic man could not exist, that an essential in the composition of the human body was the seventeen-hundredth of a grm. of arsenic in the thyroid gland. Chemistry was the first and the last science of the nineteenth century, and only recently had given them what ancient chemists would have been glad to have seen—namely, liquid air and liquid hydrogen. He referred eloquently to the work of the great chemists of the past, especially of the first President of the Society, Professor Graham, and to that of Lord Rayleigh and Professors Ramsay and Dewar. To their labours the physicist owed much, and there was no reason whatever why chemistry and physics should not go hand in hand, helping one another, and working cordially together for the advancement of knowledge. Some of the work of the physicist was looked upon as drudgery. Chemists knew a great deal about drudgery, too, and did not shrink from it. Lord Rayleigh devoted himself to working painfully and laboriously at an object which looked trivial, the finding of the density of atmospheric nitrogen, and he discovered that it contained a gas that had never even been suspected before. That was a triumph for drudgery. In looking back to the early history of the Chemical Society he took some pride in thinking that Glasgow took its part, in that it provided the first President, and that Dr. Thorpe had been Professor of Chemistry at the Andersonian Institute there. The Chemical Society though but young, only 61 years old, had a glorious past, and he believed a splendid and prosperous future before it.

The President, in reply, said no matter how they regarded the Society, whether from the point of view of its numerical strength or from the character of its scientific output, or from the lower ground of its financial condition, he thought there was no constitutional infirmity about it. This happy result was largely to be attributed to that constant accession of strength they gained in the increase of membership. There was no English chemist of note who was not proud of being a member of their body, whilst they had in their ranks almost every foreign chemist of prominence. The honorary membership of their Society was a distinction as highly prized as any mark of recognition which a body of scientific workers could bestow. There were signs of many changes in the chemical world, but whatever the future might have in store for them, he who occupied the presidential chair in the 2001, and who in ushering in the new century sought to know what was being done when the preceding century was dying, would, he was convinced, do them the justice to recognise that they who collectively made up that body corporate were, according to their several rights and within the measure of their individual powers, doing what within them lay to further the true object of their calling as men of science, the attainment of the truth for the sake of the truth.

Professor Dewar, in proposing the toast of the Learned and Scientific Societies, said that whenever any body of men had associated themselves for the purpose of discovery, invention, or the verification of truth, then the Chemical Society was most desirous of recognising the advantage of their labours on behalf of the community and of chemistry especially. Chemists were particularly desirous of recognising the great benefits which accrued from the corporate action of so many minds in the multitudinous departments of scientific work. He spoke of the dangers of exaggerating the importance of personality in matters of scientific research, as scientific work was always based on the labours of the past.

Mr. A B. Kempe, Treasurer of the Royal Society, in reply, said there was one point on which the progress of their Society was not so satisfactory as he could wish it to be. That was in the matter of financial support. It was true they had much to thank private beneficence for, and he thought it was a matter of congratulation that His Majesty's Government had in the person of Mr. Balfour recognised the value of pure science. As Treasurer of a scientific society, however, he felt, and he was sure treasurers of other societies felt the same, that they might promote the interests of mankind rather more than they did at present, if they had a little more money to devote to the work.

Professor S. P. Thompson, F.R.S., referred particularly to the great work chemists had done in the matter of artificial illumination. He trusted the century now opening would see still greater advances, and that the scientific bodies wherever their work seemed to cross or coincide would work hand in hand for the good of all.

Professor Emerson Reynolds, President-Elect, proposed the toast of the Guests, which was responded to by Sir W. S. Church and Sir Francis Mowatt.

Sir Henry Roscoe proposed the health of the Chairman.

NOTICES OF BOOKS.

A Manual of Laboratory Physics. By H. M. Tory and F. H. Pitcher. New York: John Wiley and Sons. London; Chapman and Hall, Ltd. 1901. Pp. x.—288. 8vo., Ill.

The authors of this Manual have embodied in its pages their experience in teaching large classes at McGill University, Montreal; the course comprises experimental studies in Sound, Light, Heat, Magnetism, and Electricity. The method of presentation is distinctly practical; each exercise begins with a list of references to standard text-books of physics, a list of the apparatus required, and then follows the theory of experiment, practical directions, and lastly an example of the method of reporting results, which includes a blank to be filled in by students. The mathematical knowledge required to follow the course is only moderate, the calculus is not used; diagrams illus-

trate the experiments wherever necessary; in short, the book is well arranged and carefully adapted to its purpose. The proof reading seems to be accurate, but on p. 40, for RO read PO. There is an index. H.C.B.

CORRESPONDENCE.

AMERICAN *v.* ENGLISH SPELLING.

To the Editor of the Chemical News.

SIR,—In the CHEMICAL NEWS of March 22nd (vol. lxxxiii., p. 141), there appeared a letter from Dr. H. Carrington Bolton, of Washington, in regard to the American spelling of chemical words, defending the use of such forms as *oxid, sulfur*, &c. I am not an American citizen myself, but have lived in the United States the larger part of my life, and hence may be allowed to remark that the statement of Dr. Bolton, "the American authors use a definite system, endorsed by high authorities in the United States," is rather an *over*-statement. The rules for the spelling and pronunciation of chemical terms which are referred to as prepared by a Committee of the Chemical Section of the American Association for the Advancement of Science were adopted by a very small number of the chemists of the United States at a meeting in Washington in 1891, and are acted upon by but a small number of "reformers."

It is proverbially useless to dispute about matters of taste, and I have never taken any part in argument with those whose taste leads them to print a scientific book on paper so that it looks like a bad specimen of the so-called "dialect story"; but as regards the single reason given by Dr. Bolton in his letter for a change of English spelling in the case of the word sulphur, I am inclined to think that his philological argument is not sound. He says, "I wish to point out that the word 'sulphur,' spelled as if derived from Greek, is etymologically incorrect, and is being replaced by 'sulfur' on this side of the Atlantic." The word in question is found in Latin works in the three forms—sulfur, sulphur, and sulpur; and of these the last named is, I believe, the most ancient—it appears in the oldest manuscripts of Lucretius. It is easy to see how "sulpur" may have received an "h," originally as a mere aspirate of the second vowel, and after the "p" and "h" had acquired the blended sound like that of, though not derived from, the Greek ϕ. This sound came in later times to be represented by "f," but the reverse order of change seems inadmissible. Not being entitled to write as an expert on this point I should be glad to see it discussed by good classical scholars.—I am, &c.,

J. W. MALLET.

University of Virginia, U.S.A.,

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. cxxxii., No. 13, April 1, 1901.

Some Osmyloxalates.—L. Wintrebert.—During a previous research, the author determined the constitution of potassium osmyloxalate, $OsO_2(C_2O_4)K_2.2H_2O$, and proved the existence of corresponding silver and sodium salts. Since then, he has determined the conditions under which the two latter bodies can be easily obtained, and also prepared certain other osmyloxalates:—Sodium osmyloxalate, $OsO_2(C_2O_4)_2Na_2.2H_2O$; ammonium osmyloxalate, $OsO_2(C_2O_4)_2(NH_4)_2.2H_2O$; silver osmyloxalate, $OsO_2(C_2O_4)_2Ag_2$; barium osmyloxalate, $OsO_2(C_2O_4)_2Ba.4H_2O$; abnormal barium osmyloxalate, $OsO_2(C_2O_4)_3Ba_2.6H_2O$; strontium osmyloxalate, $OsO_2(C_2O_4)_2Sr.4H_2O$; and calcium osmyloxalate, $OsO_2(C_2O_4)_2Ca.2H_2O$.

Reducing Properties of Magnesium and Aluminium.—A. Dubois.—Magnesium and aluminium reduce nearly all oxides; evidently those in which the metal, when combining with oxygen, evolves more heat than hydrogen when it combines with oxygen to form water. It is apparent, then, that these two metals ought to act energetically on water. The author shows this to be the case by two brilliant experiments. He finds that if 4 atoms of aluminium are mixed with a molecule of alumina and a light applied, they react with great vigour, giving the oxide Al_2O. He also effects a number of reductions in hydrogen.

Cinchonine.—E. Jungfleisch and E. Léger.—In this research, the authors endeavour to find the proportion of cinchonine in hydrocinchonine, to show that the properties attributed to cinchonine correspond in reality to a mixture, and, indeed, to find what are the properties of pure cinchonine.

Some Iodo-derivatives of Phenol.—P. Brenans.—In a previous research, the author examined the action of a solution of iodine in iodide of potassium on phenol in alkaline solution. He now investigates certain unexpected results obtained by means of the same reagents, but under different experimental conditions. He obtains, under the conditions adopted, di-iodophenol, $OH—C_6H_3—I_2.1.2.4$, accompanied by tri-iodophenol, $OH—C_6H_2—I_3.1.2.4.6$, and, under slightly varying conditions, the tri-iodophenol alone.

Action of the Ethers of Bibasic Acids on the Organo-metallic Compounds.—Amand Valeur.—The action of the organo-metallic derivatives of zinc or magnesium on an ether-salt results in the transformation of the group $R—CO_2C_2H_5$ into $R—C\begin{matrix}R'\\R'\end{matrix}OH$. With the ether derivatives of the bibasic acids the author obtains twice this reaction, and so arrives at the bi-tertiary glycols.

The Organo-metallic Compounds of Magnesium.—MM. Tissier and Grignard.—It has already been shown that magnesium reacts with great facility on the halogen derivatives of the alcohols when in ether solution, giving the compound $C_nH_{2n+1}—Mg—(M')$; where M' denotes an atom of Cl, Br, I, which is capable, in the same manner as zinc methyl, of reacting on various organic compounds. At the same time a secondary reaction takes place which gives rise to saturated carbides by the splitting off of two monovalent groups, C_nH_{2n+1} and formation of $Mg(M')_2$: $2[C_nH_{2n+1}(M')] + Mg = Mg(M')_2 + C_nH_{2n+1}—C_nH_{2n+1}$. Magnesium behaves in this case in an analogous fashion to the alkaline metals. The influence of this secondary reaction increases with the accumulation of the carbon atoms in the molecule of the halogen derivative, being less noticeable in the lower terms of the series, and ending by being equal to the principal reaction in terms of C_6.

New Reactions of Organo-magnesium Compounds.—Ch. Moureu.—The action of magnesium ethyl iodide on amyl nitrite and on nitromethane forms, in both cases, diethylhydroxylamine. These two reactions may be generalised. These precise facts, and certain experiments which the author mentions, establish clearly that the oxygen compounds of nitrogen and of sulphur react on organo-magnesium derivatives. Doubtless the acid-oxygen compounds of other elements react in a similar manner, and the author intends to further investigate this matter.

Ethero-organo-magnesium Derivatives.—E. E. Blaise.—The author's experiments show that when an alcoholic halogen derivative reacts on magnesium in pre-

sence of anhydrous ether, an ether derivative is obtained, of remarkable stability and possessing the composition $RMgX(C_2H_5)_2O$. Under these conditions, ether is not a mere solvent, it enters into the reaction itself, and the stability of the product obtained shows that it is intimately united to the rest of the molecule. If ether is replaced by another solvent, the other conditions of the experiment being identical, the reaction does not take place.

New Synthesis of Aniline.—George F. Jaubert.—The author effects the synthesis of the aromatic amines according to the equation $C_6H_6+NH_2.OH=C_6H_5NH_2+H_2O$. He uses zinc chloride, sulphuric anhydride, and aluminium chloride to effect condensation.

Bulletin de la Société Chimique de Paris.
Series 3, Vol. xxiii., No. 24.

Estimation of Oxygen in Commercial Copper.—Maurice Lucas.—Oxygen is generally estimated in copper by two methods, viz., reduction by hydrogen and measuring the loss of weight, which represents the oxygen and the volatile metals; or by treatment with nitrate of silver and estimation of the copper in the residue. The author has devised a third method, which consists of melting the copper with tin in the electric furnace in a current of carbonic oxide; the carbonic acid formed is then collected and weighed. The copper and the quantity of pure tin necessary to form a 20 per cent alloy are placed in a tared porcelain boat in the cool part of a porcelain tube, and the carbonic oxide gas passed over it for a quarter of an hour; then fix on the potash and sulphuric bulbs, previously weighed full of air. The porcelain tube is then gradually moved until the boat is in the hot part; the temperature is maintained at 900° for an hour. The bulbs are then disconnected and weighed again full of air. The boat is allowed to cool by moving the porcelain tube back to its original position, and the boat is weighed. In this manner we get—(1) The weight of CO_2 formed, which multiplied by 0·364 gives the oxygen set free; (2) the loss of weight, which represents the oxygen and the volatile bodies (As, Sb, &c.). This method has been tried with pure suboxide of copper and with known mixtures of Cu_2O+Sn, $Cu_2O+Sn+Cu$, &c., and the effect of impurities was determined by the addition of salts, such as arseniate, phosphate, &c., of copper, to the boat containing the pure copper and tin. This method can be generalised and applied to all metals whose oxides are reduced by carbonic oxide.

The Composition of a Calcic Sulphate Water from Lautaret (Hautes-Alpes).—J. A. Muller.—The temperature of the principal spring, taken repeatedly during the months of August, September, and October, averaged 25·3°, the greatest variations being 25·0° and 25·5°; its flow is about 2000 litres per hour. The complete analysis of this water has given the following results:—

	Weight per kilogrm. Grms.
Carbonate of calcium	0·893
Sulphate of calcium	0·715
Tricalcic phosphate	0·002
Sulphate of magnesium	0·667
Sulphate of sodium	1·429
Sulphate of potassium	0·083
Chloride of sodium	1·379
Silica	0·044
Ferric oxide	0·004
Total	5·216
Residue at 180°	5·167

There was also a slight trace of fluorine met with. The deposit formed round the mouth of the spring was also analysed, and gave the following results:—

Moisture at 115°	0·83
Insoluble in dilute nitric acid (dried at 115°)	0·22
Silica	0·46
Oxide of copper	0·03
Ferric oxide	1·60
Carbonate of lime	91·12
Sulphate of lime	2·95
Phosphate of lime	0·31
Fluoride of lime	Traces
Carbonate of magnesium	0·65
Sulphate of sodium	1·30
Chloride of sodium	0·09
	99·56

The αβ-Dimethylglutolactonic Acids.—E. E. Blaise.—Already noticed.

Acetals of Monovalent Alcohols; Thermo-chemistry.—Marcel Delépine.—Already noticed.

Acetals of Plurivalent Alcohols.—Marcel Delépine.—Already noticed.

The Estimation of Arsenic, and its Determination in the form of Ammonio-magnesian Arseniate.—O. Ducru.—Already noticed.

MISCELLANEOUS.

City and Guilds of London Institute.—His Majesty the King has graciously consented to become Patron of the City and Guilds of London Institute, of which as Prince of Wales he has been President since 1881.

New Method for obtaining Non-saturated Hydrocarbides.—L. A. Tchougaef.—This process is founded on the decomposition undergone by some xanthogenic compounds by dry distillation; this decomposition has been in the first place thoroughly examined for the particular case of the transformation of menthol into menthene. Mentholate of soda, by fixing the elements of CS_2, gives menthylxanthogenate of soda, which, when warmed with iodide of methyl in ethereal solution, gives crystallised methylic ether, $C_{10}H_{19}O—CS—SCH_3$, fusible at 38—39°, boiling at 153° under 15 m.m. pressure, with decided decomposition. It is insoluble in water, but soluble in ether, benzene, and chloroform. When heated to over 160° this substance melts and decomposes according to the following formula:—

$$C_{10}H_{19}O—CS—SCH_3=C_{10}H_{18}+CH_3—HS+CSO.$$

In a well-cooled recipient, menthane and methylic mercaptan condense. By evaporation of the volatile products and repeated distillation over sodium we obtain menthene, boiling at 167—168°; the return is 70 per cent of theory. Menthene thus obtained has very definite properties, $d_0^0=0·8132$; $[\alpha]_D=+114·77°$ to 116·06° (such a high rotatory power has not yet been observed for menthene). The author is of the opinion that this method of preparing menthene is the only one up to the present time which does not give rise to isomerisations. Identical results are to be obtained with other menthylxanthogenic ethers (ethylic, benzylic), and also with dimenthyldixanthogenic ether, $C_{10}H_{19}O—CS—S—S—CS—OC_{10}H_{19}$. This latter is obtained by the action of iodine on menthylxanthogenate of soda, and occurs in beautiful crystals, fusible at 90—91°. By dry distillation it decomposes principally according to the following equation:—

$$C_{10}H_{19}O—CS_2—S_2C—OC_{10}H_{19}=$$
$$=C_{10}H_{18}+C_{10}H_{19}OH+S+CS_2+COS.$$

By fractionation of this product over sodium we obtain

menthene, boiling at 167—168°, $[\alpha]_D = +90{\cdot}97°$. The author has prepared, by this method and using borneol, a crystallised camphene, and with octylic alcohol a caprylene boiling at 122—123°. He is now engaged in the study of how far the method can be generalised. According to his results the superiority of this process is due to the facility with which the xanthogenic compounds are decomposed, and to the fact that the reaction takes place without the intervention of any energetic reagents, such as acids, capable of producing isomerisation.—*Journ. Soc. Phys. Chim. R.*, vol. xxxi., p. 959.

MEETINGS FOR THE WEEK.

MONDAY, 29th.—Society of Arts, 8. (Cantor Lectures). "Alloys," by Sir William Chandler Roberts-Austen, K.C.B., F.R.S.

TUESDAY, 30th.—Royal Institution, 3. "On Cellular Physiology, with special reference to Enzymes and Ferments," by Allan Macfadyen, M.D., B.Sc.

—— Society of Arts, 4.30. "The British West Indies," by Sir Nevile Lubbock, K.C.M.G.

WEDNESDAY, May 1st.—Society of Public Analysts, 8. "Alkaline Waters from the Chalk," by W. W. Fisher, M.A., F.I.C. "Citron Oil," by Herbert E. Burgess. "Arsenic in Coal and Coke," by Alfred C. Chapman, F.I.C.

—— Society of Arts, 8. "Thames Steamboat Service," by Arnold F. Hills.

—— Royal Institution, 5. (Annual General Meeting).

THURSDAY, 2nd—Chemical, 8. Ballot for the election of Fellows. "The Synthetical formation of Bridged-rings—Part I., Some Derivatives of Bicyclopentane," by W. H. Perkin, jun., F.R.S., and Dr. J. F. Thorpe

—— Royal Institution, 3. "Arthur Sullivan" (with Vocal and Instrumental Illustrations), by Sir Alex. Campbell Mackenzie, Mus.Doc.

FRIDAY, 3rd.—Royal Institution, 9. "Memory," by Charles Mercier, M.B., F.R.C.S., M.R.C.P.

—— Society of Arts, 8. (Howard Lectures). "Polyphase Electric Working," by Alfred C. Eborall, M.I.E.E.

SATURDAY, 4th.—Royal Institution, 3. "Climate, its Causes and its Effects," by John Young Buchanan, M.A., F.R.S.

TO CORRESPONDENTS.

Rev. E. Rattenbury Hodges.—The spectroscope shows nothing but lime.

BIRKBECK INSTITUTION,

VITRIFIED QUARTZ.*

By W. A. SHENSTONE, F.R.S.

In spite of the great improvements introduced into the art of glass making by Abbe and Schott, which have led to marked advances in microscopy, in thermometry, and in other directions during the last quarter of a century, glass is still unsuitable for many of the purposes to which we put it, and there remains a real need for some plastic material, more infusible, more insoluble, more fully transparent, more elastic, and more stable under changes of temperature than glass.

Such a substance exists in the form of vitrified quartz, or vitrified silica as I shall prefer to call it.

Vitrified silica was first made in 1839 (*Comptes Rendus*, viii., 678, 711), by M. Gaudin, who spun threads of it by hand and noticed their flexibility; made small, very hard pellets of it by dropping fused quartz into cold water, and observed that in this form it was inactive to polarised light.† It was re-discovered in 1869 by M. Gautier (*Comptes Rendus*, cxxx., 816), who made capillary tubes and spirals of vitreous silica, and exhibited them at the Paris Exhibition in 1878; but who failed to obtain larger objects even with the aid of the electric furnace. Finally, it was yet once again independently discovered, in 1889, by Professor C. V. Boys, who used the torsion of "quartz fibres" for measuring small forces, and produced fine tubes and small bulbs of the same material; and who was the first to really recognise the great value of this remarkable substance.

As all who are here to-night are not chemists, I may remind you that quartz, or rock crystal, has for some time past been used by spectacle makers, and in the construction of optical instruments; and that it is a form of oxide of silicon,‡ which is very familiar to us all in the forms of sand and flint. Quartz is occasionally found in magnificent masses, but our chief source of supply is Brazil, where it occurs in large fragments like those on the table.

Quartz itself exhibits many of the desirable qualities enumerated above. It is hard, transparent to the ultra-violet rays, difficult to melt, a good insulator, and insoluble in most solvents, but it bears sudden changes of temperature very badly, and therefore it is very difficult to manipulate quartz at high temperatures. When it has been vitrified by heat, however, it becomes much more tractable, and in the vitrified state (vitrified silica) it is not very difficult to deal with.

It is about this "vitrified silica," how to prepare it and fashion it into apparatus when plastic, and about its properties and uses, that I am about to address you to-night.

The first obstacle met by those who wish to obtain vitrified silica is caused by the tendency of quartz to splinter. It will not bear contact with a flame. As you see, when a piece of quartz is thrust into a flame it cracks and falls to pieces, and the fragments again break up when similarly treated. Consequently it was very difficult for the pioneer workers to soften it in the flame. It is true that if the quartz be broken small and heated to redness in a crucible it becomes more easy to manage; but even then it gives trouble, and I should not like to say how much my first silica tube, which held about 5 c.c., had cost for oxygen and labour when it was finished.

Fortunately we have found that we can overcome the splintering of quartz by heating it in small fragments to about 1000° C., and throwing it quickly into cold water. As you see, it then becomes white and enamel like, and after the treatment has been repeated the product, though still in masses, may be thrust suddenly into the hottest part of an oxy-hydrogen flame without splintering to the slightest extent. The preparation of this non-splintering silica constitutes the first stage of the process we are about to show you.

Another difficulty is connected with the oxy-gas burner. Vitrified silica only becomes sufficiently plastic for our purpose when it is above the melting-point of platinum; and it cannot be heated sufficiently in all parts of an oxy-gas flame. What is wanted is not so much a very large flame as one which presents a very hot spot (this is situated just beyond the inner blue cone of the flame). After trying all sorts of burners, I have concluded that the "mixed gas" jets give the best results, and the injector burner of Mr. Jackson, of Manchester, is decidedly the best I have met with.

The first step in the process of converting the white enamel-like non-splintering silica into tubes and other vessels consists in pressing together the heated ends of two small fragments of it, held in platinum forceps, till they adhere, and adding a third lump, then a fourth, and so on, until a rough rod has been made. This rod is afterwards re-heated, and drawn out into finer rods, about 1 m.m. in diameter; care being taken to heat each fresh mass of material slowly, and from below upward in order that there may be as few bubbles as possible in the product.

A few of the fine rods of silica are bound round a stout platinum wire, or twisted into a spiral whilst soft (Boys and Dufour's method), and heated in the flame till their sides adhere. The uncouth tube thus produced is re-heated, drawn out, and closed at one end. A bulb is blown on the closed end in the usual manner, and this, when again drawn out, gives us a fine and fairly regular tube, which can be lengthened by adding silica to one end of it, blowing a new bulb from this, and drawing it out as before.

The enlargement of the small bulbs was rather difficult at first. My earliest attempts consisted in adding small lumps of silica to one end of a bulb, softening them in the flame, and expanding the bulb by blowing. It is not impossible to succeed in this way, though the vessels so produced are apt to be uncouth in appearance. But the process is unsatisfactory owing to the fact that often the thinner parts of the bulb immediately surrounding the mass to be expanded become hotter and softer than the latter. When this happens the bulb bursts, and as it can only be repaired by the addition of fresh lumps of silica the process is apt to be tedious and expensive. After many failures, it occurred to me that I might develop the bulbs by applying thin rings of silica as shown in Fig. 1,

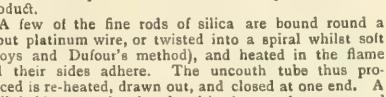

Fig. 1.

heating them until the silica begins to spread, and then expanding them by blowing. This method gave satisfactory results at once. By it we can produce long tubes, and other apparatus like those exhibited to-night, if not at a very quick rate or very low cost, yet with certainty and very much more quickly than before.

When a silica tube has been made it can be worked in the flame as easily, though not as inexpensively, as glass. Such a tube can be thickened readily by adding fresh rings of silica; it can be drawn out to various degrees of fineness and sealed hermetically, whilst all kinds of joints can be made easily. In one respect silica is easier to work than glass. It never breaks when thrust suddenly into the flame and finished apparatus needs no annealing,

* A Discourse delivered before the Members of the Royal Institution, Friday, March 8, 1901.

† A more recent observation made by Professor S. P. Thompson confirms this.

‡ Silicon was discovered by Berzelius in 1823.

One precaution must be taken. The eyes must be protected by black spectacles. The glass of which these are made must be very dark; so dark that white-hot silica does not look very bright when viewed through it.

I have spoken of silica as being easy to work. I do not mean you to understand, however, that it is easy to do what you see Mr. Lacell doing to-night. It is not easy to perform any operation of this sort with his wonderful precision, and especially it is not easy to work under the conditions enforced upon him now; for he can see nothing of the effects he produces, and must adapt his manipulations to my remarks, although he can hear the latter only very imperfectly.

The Properties and Applications of Silica.

Vitrified quartz is harder than felspar, but less hard than chalcedony. When cut with a file it breaks like glass. Its conducting power for heat is about equal to that of glass. Mr. Boys has shown that even in an atmosphere saturated with moisture it is a very good insulator. Its density (2·21)* is decidedly less than that of quarts (2·66), and almost identical with that of amorphous silica. Its optical properties have not yet been fully studied, but its approximate index of refraction has been determined by Professor S. P. Thompson by means of a small prism cut for the purpose by Mr. Hilger. It is decidedly less than that of quartz.

The melting-point of silica is not known, and it is plastic over a considerable range of temperature. When a platinum wire embedded in a thick tube of silica is heated from outside by means of an oxy-gas flame the platinum melts, and runs at a temperature at which the silica retains its shape.

Its rate of expansion has been studied first by H. Le Chatelier (*Comptes Rendus*, cxxx., 1703), and more recently by Professor Callendar. The former finds its mean coefficient of expansion between 0° and 1000° to be 0·0000007, but from the manner in which his material was prepared I think it probable that it was not quite pure. Professor Callendar has, within the last few days, examined the behaviour of a rod of pure vitrified silica prepared by my method. He finds its mean coefficient of expansion to be only 0·00000059, which is only 1/17 as great as that of platinum, and much smaller than that of any similar substance that has hitherto been studied. He finds also that the expansion of vitrified silica is exceedingly regular up to 1000°, and that if not heated above 1000° the rod returns very exactly to its original length when cold. Beyond 1000° he found a slight permanent elongation, although the rod was under compression. Professor Callendar was able to carry his experiments up to 1500°, which is very satisfactory, for it shows that vitrified silica remains solid, or practically solid, at this very high temperature. This is an important observation, as less carefully conducted experiments made by others had led me to fear that it became slightly plastic even at as low a temperature as 1000°. Above 1000° the rate of expansion diminishes rapidly, changing to a contraction at about 1200°.† On cooling from 1500° to 1200° it expands.

Fine rods of silica, and also quartz fibres, are apt to become rather brittle after being heated to redness. But we have not at present detected this defect in the case of thick tubes or rod.

The transparency of vitrified silica to ultra-violet rays has been carefully examined by Dr. A. Wynter Blyth, to whom I am greatly indebted.

A good illustration of his experiments is to be found in the results obtained by photographing the spectrum of the light produced by electric discharge between electrodes of an alloy of zinc, tin, cadmium, and mercury, using quartz prisms and lenses. When the light was made to pass through a plate of vitrified silica 3 m.m. thick, it was quite possible to photograph bands up to the cadmium line λ 2264, while the interposition of a similar plate of soda-glass completely cut off all radiations beyond the mercury line at λ 3125, and a plate of flint-glass was found to be still more opaque.

The advantage of quartz over glass for the spectroscopic examination of the light given out by gases in vacuum tubes is apparent from a consideration of this result.

The most remarkable property of vitreous silica is its behaviour under sudden changes of temperature. We have seen already that tubes of it may be plunged suddenly into an oxy-gas flame without injury, and I have mentioned the fact that apparatus made of silica needs no annealing. But this is not all; we may drop water on a rod of white-hot vitrified silica, or plunge a white-hot silica tube into cold water, or even, by Professor Dewar's kind aid, into liquid air, without injuring it in any way whatever; indeed, experiments seem to show that the material gains very distinctly in regard to its elasticity when it is thus treated. I need hardly point out how convenient tubes of such a material will be to chemists, or how many spoilt lecture experiments may be avoided in future by those who possess a silica tube.

This last property of silica and the splintering of quartz find an explanation in the results obtained by H. Le Chatelier (*Comptes Rendus*, cxxx., 1703), and by Callendar. These, as already explained (Fig. 2), show that its rate of expansion is exceedingly low, and, moreover, that at temperatures much above 1000° it contracts when heated. Under these circumstances it follows first that the strains set up in silica when it is suddenly heated or cooled are comparatively small in amount; and, secondly, that if, for example, vitrified silica be suddenly cooled, say from 1500° to temperatures below 1000°, the strains set up at the earlier stages of the cooling process will tend to neutralise those produced subsequently. These facts enabled Le Chatelier to predict the indifference of vitrified silica to sudden change of temperature (*loc. cit.*). But the phenomena had been observed previously and exhibited in this country.

The behaviour of quartz under changes of temperature is also very peculiar. This was studied by Le Chatelier in 1889 (*Comptes Rendus*, cviii., 1046). From his curves, which are given in Fig. 2, it may be seen that this form

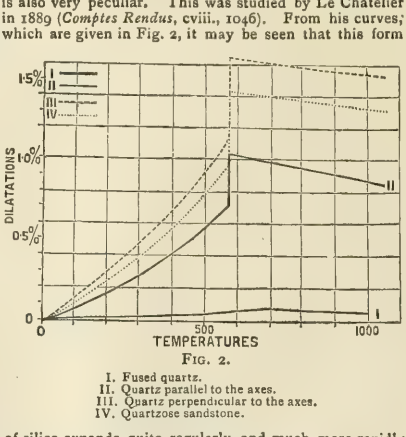

Fig. 2.

I. Fused quartz.
II. Quartz parallel to the axes.
III. Quartz perpendicular to the axes.
IV. Quartzose sandstone.

of silica expands quite regularly, and much more rapidly than vitreous silica up to 570°, but that at this temperature a sudden expansion takes place which is followed by a steady contraction on further heating.

One of the most important fields in which vitrified silica is likely to be useful is that of thermometry.

* This was determined by my pupil, Mr. T. Pears; the silica used contained a few minute bubbles.

† H. Le Chatelier's curve (Fig. 2), shows a similar contraction, but commencing at a somewhat lower temperature.

Owing to the small coefficient of expansion of vitrified silica, the degrees of silica-mercury thermometers will be of greater length in proportion to the volumes of their bulbs than those of mercury-glass instruments. Owing to its high melting-point it should be possible to employ it with advantage for measuring high temperatures by replacing the mercury by tin or other metal as has been done already by M. Dufour (*Comptes Rendus*, cxxx., 775). And whilst the great elasticity of vitrified silica suggests that the zero points of silica-mercury thermometers will be much more stable than those of glass instruments, the impunity with which it may be suddenly cooled from high temperatures promises obvious advantages.

Finally, the high melting-point of silica should make it very valuable for use in platinum thermometers, and I exhibit such a thermometer to-night which has been fitted up for me by Professor R. T. Glazebrook. As the applications of vitreous silica in thermometry are still under investigation I will not dwell on this part of the subject, except to add that, as glass reservoirs for air thermometers have proved disappointing, I am not without hopes that the new material may prove helpful in that department also.

We have not yet had time to examine the behaviour of silica with solvents, but if it acts like other forms of the same compound it may be expected to replace platinum for some purposes, as, for example, for condensers for the preparation of pure water; and vessels of silica probably would be much more suitable for use in exact experiments on the freezing-points and boiling-points of many dilute solutions than the glass-tubes now often used for such work, but of course silica vessels will be very susceptible to the action of alkalis. Finally, vitrified silica may be expected to prove superior to glass for use in researches on pure gases, owing to the qualities of its surface; and for use in experiments concerning the behaviour of gases at high temperatures. We have already one small application of silica to research in this latter field to put upon record.

It is well known that nitrogen and oxygen enter into combination under the influence of the silent discharge, and Sir William Crookes (CHEMICAL NEWS, lxv., 301), has shown that oxides of nitrogen are present in considerable quantities in the flames which accompany the electric discharges of large induction coils. But although various observers have reported indications of the presence of nitrous fumes in the neighbourhood of flames, the forming of an oxide of nitrogen from nitrogen and oxygen alone, and without the intervention of electricity has not, so far as I am aware, been unmistakably established. Therefore it is interesting to record the fact, first observed by my colleague, Mr. Lacell, that nitric peroxide may be produced by heating a mixture of oxygen and nitrogen above the melting-point of platinum in tubes of silica. It is easy to obtain a gas showing a distinctly yellow colour, and exhibiting the reactions of nitric peroxide in this way.

Of course vitreous silica is not entirely without defects. Unfortunately it becomes slightly permeable to hydrogen, as platinum does, though to a less extent, at about 1000° (Villard, *Comptes Rendus*, cxxx., 1752). It is attacked when hot by alkaline oxides. It may be heated to about 960° in contact with copper oxide without injury, but at higher temperatures it is affected. It may be heated more strongly with ferric oxide, but quicklime attacks it at a bright red heat. It is evident that caution must be exercised when it is in contact with basic oxides or alkaline solutions. When one first fashions vessels of silica before the flame the vessels exhibit to a greater or less extent a phenomenon resembling devitrification. They become covered with a white opaque crust. This is easily removed by re-heating, provided that the tube has been kept scrupulously free from dust and dirt during the process of making it. If this precaution has not been taken, the appearance of the vessel may be spoilt permanently. The earlier observers attributed this phenomenon to the volatility of silica. My impression is that it is connected with the minute traces of alkaline metals present in most Brazil pebble, which are usually burnt off in the processes I have described.

From what I have told you to-night you will see that in several respects vitrified silica is as much superior to the best glass as Jena glass is superior to more ordinary specimens, and that the progress made during the last few years will make it possible for investigators to employ vitreous silica much more widely in the future than has been possible in the past. At the same time it is evident that the method of producing it is still in its infancy, that there is much more to be done, and that further progress can only be made at considerable expense.

In concluding my remarks I wish to express the great obligation I am under to my friend and colleague Mr. H. G. Lacell. You will have discovered for yourselves that the chief burden has been upon his shoulders to-night, and that without the illumination provided by his precise and beautiful manipulations my discourse would have been but a dry affair. Also I must add that the cost of the work at its later stages has been aided by a subsidy from the Government Grant Fund of the Royal Society.

THE TITRATION OF A SOLUTION OF HYPOSULPHITE.

By M. PERRIN.

THE exact titration of a solution of hyposulphite by means of a known weight of pure iodine is a complicated and inconvenient method. It is necessary first to sublime the iodine several times, and then to admit that it is absolutely pure; at the same time it must be remembered that the weighing of such a volatile body is itself a very delicate operation.

A much more practical method of titrating hyposulphite consists of using a titrated solution of sulphuric acid, such as is to be found in every laboratory, or even a titrated solution of any acid.

We well know that most acids react on a mixture of iodate and iodide of potassium according to the equation $5KI+IO_3K+3SO_4H_2=3SO_4K_2+3H_2O+I_6$. So that 49 of SO_4H_2 correspond to 127 of iodine.

Method of Operating.

Suppose we wish to make a N/20 solution hyposulphite, we place in a 250 c.c. flask, having a ground glass stopper, about 2 grms. of accurately neutralised iodide of potassium, 50 c.c. of distilled water, and a pinch of pure iodate of potassium; we then add 10 c.c. of an exactly decinormal solution of sulphuric acid. After a few moments we add, drop by drop, the hyposulphite solution to be titrated until all the iodine is transformed; this can be determined by the disappearance of the yellow colour, or by using starch emulsion. In the case where we have used 10 c.c. of decinormal acid we ought to add 20 c.c. of hyposulphite if the latter is N/20.

The only important condition to remember is to use only absolutely neutral iodide of potassium and hyposulphite, but the method would appear to be inapplicable when we have need of an alkaline solution of hyposulphite, for keeping for example.

To overcome this difficulty all we need do after having determined, on the neutral solution of hyposulphite, the quantity of liquid necessary to bring the latter to the desired strength, is to add the difference between the volume of the alkaline solution to be used and that found by calculation.

Let us suppose, for example, that after a preliminary trial, effected on the still neutral solution of hyposulphite, we calculated that it was necessary to add 150 c.c. to obtain a N/20 solution; if, on the other hand, this ought to contain, when once adjusted, 200 c.c. of an alkaline solution, we should only add 130 c.c. of distilled water, and

calculate, if necessary, the number of c.c. and tenths of c.c. which would be required by 10 c.c. of N/10 SO_4H_2 when operating on the solution thus diluted. If the figure previously determined is obtained, nothing remains but to add the alkaline solution.—*Moniteur Scientifique*, April, 1901, p. 244.

ACTION OF PEROXIDE OF HYDROGEN ON THE BLOOD. EASY MEANS OF DISTINGUISHING HUMAN BLOOD FROM THAT OF ANIMALS.

By S. COTTON.

THE well-known property possessed by blood of whatever origin of decomposing peroxide of hydrogen has not yet been examined, so far as I am aware, from the point of view of the volume of oxygen set at liberty. This is what I have now undertaken.

Experimental Method.

The blood is strongly squeezed in a linen bag until nothing remains but the fibrine; we thus get the serum and the corpuscles free from fibrine. After having well stirred the liquid to make it homogeneous I measured out 1 c.c. in a small wide-mouthed flask.

At the same time I placed 250 c.c. of commercial peroxide of hydrogen at 12 vols. in a litre flask.

On account of the necessity of pouring from one flask to another the peroxide is reduced to about 11 vols. Care must be taken, that no bubbles of gas are given off,

The flask containing the blood is then gently dropped into the larger flask and the cork immediately inserted.

The gas is rapidly given off and collected under water, and measured. The operation takes less than an hour.

Results Obtained (Means).

	One c.c. of blood gave:—	
	Maximum.	Minimum.
	C.c.	C c.
Man	610	580
Horse	350	320
Pig	350	320
Bullock	170	165
Guinea-pig	125	115
Sheep	65	60

There is a slight difference in favour of females and the young. This difference would be still more pronounced if we take account of the number of the corpuscles. This is a proof that the quality has more influence than the quantity, since, according to different writers, the blood of the male is richer in corpuscles than that of the female.

To get the most sensitive reaction it is preferable not to operate on more than 1 c.c. of blood, as the first volumes of oxygen are given off more easily than the others; the strength of each variety of corpuscle can be measured with greater distinctness. Further, when reduced to such simplicity the method may be used clinically.

Doubtless, in fact, the above figures would be notably modified by serious illnesses, especially by those in which a micro-organism attacks the corpuscles, such as in malaria, anthrax, or in leucocythenia.

The addition of water rapidly decreases the decomposing power; 7 vols. of water added to 1 vol. of blood reduced the gas given off by human blood from 600 to 65 c.c. This should make an interesting subject of research.

Theoretically, also, we might expect to find greater variations with peroxide of hydrogen of higher tension. This decomposing property goes on increasing in the case of human blood during the first six hours of its exposure to air, as if the corpuscles required to be supersaturated with oxygen. It then remains stationary for twelve or fourteen hours according to the temperature, that is so long as the temperature does not vary. It then decreases, without, however, reaching zero. The blood of animals shows this in a much more rapid and less durable manner.

Peroxide of hydrogen acts on the blood, not as on permanganates, which are only incompletely reduced, but rather in the same manner as on iodic acid; the reduction is complete, the corpuscle is entirely destroyed and decolourised. It loses the whole of its oxygen, while the peroxide loses only a portion.

We can also compare this action to that which it exerts on ferments and microbes.

The albumin of the serum has no action. The fibrine, in spite of what has been said, only acts very slightly when it has been really freed from hæmoglobin.

The deductions to be drawn from these observations are the following.—

1. Human blood has a much stronger decomposing action on peroxide of hydrogen than that of animals. The volume of gas given off is more than four times the amount than in the case of bullock's blood, and ten times greater than with sheep's blood.

2. It should on this account be extremely easy to distinguish between human blood and that of animals.

3. The blood of animals transfused to a man would asphyxiate the latter. The same would occur between animals of different species. This may be looked upon as a new line of distinction as important as the one already recognised by Cuvier.

4. Microbes which are pathogenic to man, in whom they reach their maximum development when transferred to the blood of animals, where the vital conditions are so different, become weakened themselves through partial asphyxia, and lose a part of their activity; that is to say, their virulence. This is the secret of attenuated serums and viruses.—*Bull. Soc. Chim.*, Series 3, vol. xxv., No. 5.

THE MOLECULAR WEIGHT OF ALUMINIUM COMPOUNDS.*

By ELMER P. KOHLER.

(Concluded from p. 195).

III. ADDITION PRODUCTS.

ALUMINIUM bromide, like aluminium chloride, combines directly with acid chlorides, ketones, esters, nitro-compounds, and tertiary amines. The compounds obtained with the bromide are invariably more easily soluble in carbon disulphide than those obtained with the chloride. It is therefore easier to get them in a form in which it is possible to use them for molecular weight work. They are, at best, extremely difficult to manipulate, and only very few gave satisfactory results. With these, however, it was possible to prove that, for the purpose of this investigation, it is not at all necessary to isolate the substances. They can just as well be made in the apparatus in which their molecular weight is to be determined.

Benzene Sulphonchloride and Aluminium Bromide.

Slightly more than two molecules of pure benzene sulphonchloride were added to one molecule of aluminium bromide dissolved in a large amount of carbon disulphide. The flask was closed with a phosphorus pentoxide tube, and the disulphide allowed to evaporate slowly through the tube. In the course of a week the product began to separate in large colourless tables. The solution was removed in a current of dry air, the crystals washed with dry disulphide, dried in a current of dry air, and used without further purification. A halogen determination gave the following results:—

I. 0·3245 grm. substance gave 0·5152 grm. silver halide.
II. 0·4105 „ „ 0·6530 „ „

* From the *American Chemical Journal*, xxiv., No. 5.

Nitrobenzene and Aluminium Bromide.

Gatterman (*Ber. d. Deut. Chem. Ges.*, xii., 2719) found that aluminium chloride combines with nitrobenzene to form a crystalline addition-product of the composition $AlCl_3.C_6H_5NO_2$. The corresponding aluminium bromide compound crystallises well at low temperatures, forming large yellow prisms considerably less sensitive to atmospheric moisture than the analogous addition-products with acid chlorides. The substance was washed with dry carbon disulphide and dried in a current of air.

Molecular Weight of $(AlBr_3.C_6H_5NO_2)_x$.

Solvent: Carbon disulphide. K = 2370.

	Solvent. Grms.	Substance. Grms.	Rise in boiling-point.	Molecular weight.
1.	40·2020	0·8510	0 064	784
2.	40·2020	1·8200	0·135	794
3.	40·2020	2·3840	0·178	789
4.	40·2020	2·9630	0·220	794
	Mean			790·25
	Calculated for $Al_2Br_6.2C_6H_5NO_2$ ..			780·14

According to these results, one molecule of aluminium bromide combines with two molecules of other substances to form one molecule of product:—

$$Al_2Br_6+2C_6H_5SO_2Cl=Al_2Br_6.2C_6H_5SO_2Cl,$$
$$Al_2Br_6+2C_6H_5NO_2=Al_2Br_6.2C_6H_5NO_2.$$

If these equations are correct, then the addition of sulphonchloride or nitro-compound to a solution of aluminium bromide of known boiling-point should not affect the boiling-point so long as the bromide is in excess; while the addition of the bromide to a solution of benzene sulphonchloride or nitrobenzene should immediately lower the boiling-point, and the lowering should be proportional to the grm.-molecular amounts of bromide added. The experimental results are as follows:—

Effect of Adding Benzene Sulphonchloride to a Solution of Aluminium Bromide.

Solvent: Carbon disulphide. K = 2370.

	Solvent. Grms.	Bromide. Grms.	Sulphonchloride. Grms.	Boiling-point.	Change in boiling-point.
1.	39·7150	—	—	2·572	—
2.	39·7150	1·7730	—	2·770	0·198
3.	39·7150	1·7730	0·2335	2·770	0·000
4.	39·7150	1·7730	0 6980	2·770	0·000
5.	39·7150	1·7730	1·1840	2·810	0·040

The weight of sulphonchloride equivalent to 1·7730 grms. aluminium bromide is 1·1749 grms.; the amount added is 1·1840 grms.; the elevation of the boiling-point calculated for the difference, assuming—what is only approximately true—that the constant for the solution is the same as that for the pure solvent, is 0·045; the elevation found is 0·040.

Effect of Adding Aluminium Bromide to a Solution of Benzene Sulphonchloride.

	Solvent. Grms.	Sulphonchloride. Grms.	Bromide. Grms.	Boiling-point.	Change in boiling-point
1.	41·8860	—	—	2·590	—
2.	41·8860	2·5150	—	3·394	+0·804
3.	41·8860	2·5150	0·5050	3·342	−0·052
4.	41·8860	2·5150	1·3800	3·247	−0·142
5.	41·8860	2·5150	2·5950	3·118	−0·275

The molecular weight of aluminium bromide calculated from these lowerings, assuming K=2370, is as follows:—

	Solvent. Grms.	Bromide. Grms.	Lowering of boiling-point.	Molecular weight.
1.	41·8860	0·5050	0·052	560
2.	41·8860	1·3800	0·142	548
3.	41·8860	2·5950	0·275	536
	Calculated for Al_2Br_6			534

No better proof of the formula Al_2Br_6 seems possible. No other assumption would explain these results. It will be observed that the error introduced by the presence of the sulphonchloride is small in comparison with the normal error of these determinations, which is unavoidably large, partly owing to the sensitiveness of the substances and partly to their great molecular weight. Knowing that aluminium chloride combines with nitrobenzene to form a compound $(AlCl_3.C_6H_5NO_2)_x$, it is possible to determine whether the formula of the chloride is analogous to that of the bromide or not.

Aluminium Chloride and Nitrobenzene.

Solvent: Carbon disulphide. K = 2370.

3.	40·2250	2·1310	2·0310	0·444	270
	Mean				276·33
	Calculated for Al_2Cl_6				266·9

The facts established up to this point supply an elegant method for determining what happens when an aluminium halide is brought in contact with a given substance in an indifferent medium. It is sufficient for this purpose to prepare a solution of aluminium bromide, of known concentration and boiling-point, to add to this successive portions of the substance under investigation until it is present in excess, and then add a fresh portion of aluminium bromide. The thermometer readings after each addition of material, give an accurate account of what goes on in the solution. The following results were obtained in this way:—

Aluminium Bromide and Benzoyl Chloride.

The calculations are based on the equation—

$$Al_2Br_6+2C_6H_5COCl=Al_2Br_6.2C_6H_5COCl.$$

Calculated for Al_2Br_6	534
Calculated for $C_6H_4Br_2$	236

Of other substances examined, acetophenone benzene sulphonacetone, and ethyl benzoate form addition-products with aluminium halides, and behave like benzophenone. Benzene and naphthalene give results like those of dibrombenzene, but they slowly react to form insoluble compounds. Pyridine and quinoline form crystalline addition-products insoluble in carbon disulphide.

The results thus far given show conclusively that in an indifferent medium the aluminium halides form addition-products that are not measurably dissociated. The results are quite different when a large excess of one of the components is present. It was shown above that, in carbon disulphide, aluminium bromide combines with nitrobenzene to form a compound of the formula $Al_2Br_6.2C_6H_5NO_2$. If this compound, or aluminium bromide itself, is dissolved in nitrobenzene and the lowering of the freezing-point of the latter measured, the results lead to a much simpler formula.

Aluminium Bromide in Nitrobenzene.

K = 7070.

	Nitrobenzene. Grms.	Bromide. Grms.	Lowering of freezing-point.	Molecular weight.
1.	15·2470	1·2530	2·11	275·5
2.	15·2470	1·9040	3·20	276·0
3.	15·2470	2·4250	4·08	277·0
	Mean			276·17
	Calculated for $AlBr_3$			267

Aluminium Chloride in Nitrobenzene.

K = 7070.

	Nitrobenzene. Grms.	Chloride. Grm.	Lowering of freezing-point.	Molecular weight.
1.	19·7640	0·1893	0·520	130·4
2.	19·7640	0·5953	1·675	127·5
3.	19·7640	0·8923	2·500	131·0
	Mean			129·63
	Calculated for $AlCl_3$			133·4

The results are exactly like those obtained in pyridine solution. As a mean of six determinations of the molecular weight of aluminium chloride in pyridine, Werner and Schmujlow obtained the value 129 6, and Werner concludes that $AlCl_3$ is the only formula permissible. The conclusion is not justified. Pyridine combines with aluminium chloride to form a well-crystallised compound, and there is no experimental evidence that molecular weight determinations, made in solvents that combine with the substance under investigation, are trustworthy. In aqueous solutions they are not, and my results show that they are equally unreliable in this case. Between the results in carbon disulphide and those in nitrobenzene or pyridine, it is easy to decide by the aid of the following considerations:—In the absence of any solvent, benzoyl chloride combines with aluminium bromide to form a well-crystallised compound which, as shown by analysis, has the composition $(AlBr_3.C_6H_5COCl)_x$. The molecular weight must, therefore, correspond to some multiple of this formula. The determination in carbon disulphide gave a value corresponding to the double formula—

$$(AlBr_3.C_6H_5COCl)_2$$

—a possible value. The determination in nitrobenzene gives an impossible value—

$$(AlBr_3.C_6H_5COCl)_x.$$

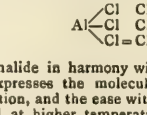
Solvent: Nitrobenzene. K = 7070.

	Solvent. Grms.	Substance. Grms.	Lowering of freezing-point.	Molecular weight.
1.	20·2500	0·5820	0·424	371
2.	20·2500	1·0105	0·952	370
3.	20·2500	1·8200	1·710	371

Calculated for $(AlBr_3.C_6H_5COCl)_x$, $(407·5)_x$.

It is evident from these results that nearly all the values for inorganic salts obtained by Werner and his pupils will need re-determination, since they purposely selected solvents that combine with salts and in many cases proved combination by isolating the products. The same is true of the determinations made by Lespeau (*Bull. Soc. Chim.*, [3], xvii., 934) in ether, and those by Rosenheim and Woge (*Zeit. Anorg. Chem.*, xv., 283) in pyridine.

The principal objections to the double formulæ for the aluminium halides have been based on the assumption that these formulæ imply quadrivalent aluminium (Erdman, "Lehrbuch d. Anorg. Chem.," 587). To avoid this, Traube (*Ber. d. Deut. Chem. Ges.*, xxv., 1716) assumed that these salts are derived from an hexavalent complex of two aluminium atoms, $[Al{\equiv}Al]^{VI}$. Neither of these assumptions is necessary. The aluminium halides behave like typical double halides with the formula $^{III}\ \ ^{III}\ \ \ ^{III}\ \ ^{III}$ $AlCl_3.Cl_3Al$ or the formula $(AlX_6)Al$. Their behaviour in nitrobenzene and pyridine, moreover, makes it fairly certain that no double molecules are present in aqueous solution. The hydrous salt that crystallises out of aqueous solutions is probably $AlCl_3.6H_2O$. The anhydrous salt is probably—



a double halide in harmony with Remsen's law.* The formula expresses the molecular weight, the power of direct addition, and the ease with which the substance is dissociated at higher temperatures and in solution. In any case, I believe that the matter can be reached by experiment, and the work will be continued in this direction and extended to include the compounds of iron.

* This formula is essentially the same as that used by Remsen (*Am. Chem. Journ.*, xi., 316) to account for the peculiar results obtained in the determination of the vapour-density of aluminium chloride.

SOME PRINCIPLES AND METHODS OF ROCK ANALYSIS.*

By W. F. HILLEBRAND.

(Continued from p. 196).

XVIII. *Vanadium (Chromium) and Molybdenum. Distribution of Vanadium and Molybdenum.*

THE wide distribution of vanadium throughout the earth's crust has in recent years been clearly established (see *ante*, p. 67), not only in ores and in coals, but in clays, limestones, sandstones, and igneous rocks.† The writer has shown (*loc. cit.*) that vanadium occurs in quite appreciable amounts in the more basic igneous and metamorphic rocks up to 0·08 per cent or more of V_2O_3, but that it seems to be absent or nearly so, from the highly siliceous ones. Some of their ferric aluminous silicate constituents carry still higher percentages—up to 0·13 per cent V_2O_3 in a biotite separated from a pyroxenic gneiss. Molybdenum, on the other hand, appears to be confined in quantities susceptible of detection to the more siliceous rocks, and, except perhaps in rare instances, is not present in them in quantitatively determinable amount when operating on 5 grms. of material. Hence the quantitative search for vanadium will usually be limited to rocks with less than 60 per cent of silica. The search for it even then will perhaps not often warrant the necessary expenditure of time, but in this connection it is to be remembered that neglect to estimate it introduces an error in the figures for both ferrous and ferric oxides, which in extreme cases met with may be of considerable moment. (See p. 151, and also *prox*).

Description of Method.

In the following method there is nothing absolutely novel except that chromium and vanadium, when together, need not be separated, but are determined, the former colorimetrically, as already described (p. 195), the latter volumetrically, in the same solution. (W. F. Hillebrand, *Journ. Am. Chem. Soc.*, 1898, vol. xx., p. 461; CHEMICAL NEWS, 1898, vol. lxxviii., p. 295; *Bull. U.S. Geol. Survey*, No. 167, p. 44).

Five grms. of the rock are thoroughly fused over the blast with 20 of sodium carbonate and 3 of sodium nitrate. After extracting with water and reducing manganese with alcohol, it is probably quite unnecessary, if the fusion has been thorough, to re-melt the residue as above, though for some magnetites and other ores containing larger amounts of vanadium than the generality of rocks, this may be necessary, as Edo Claassen has shown (*Am. Chem. Journ.*, 1886, vol. viii., p. 437). The aqueous extract is next nearly neutralised by nitric acid, the amount to be used having been conveniently ascertained by a blank test with exactly 20 grms. of sodium carbonate, &c., and the solution is evaporated to approximate dryness. Care should be taken to avoid overrunning neutrality, because of the reducing action of the nitrous acid set free from the nitrite produced during fusion, but when chromium is present it has been my experience that some of this will invariably be retained by the precipitated silica and alumina, though only in one case have I observed a retention of vanadium, it being then large. The use of ammonium nitrate instead of nitric acid for converting the sodium carbonate into nitrate does not seem to lessen the amount of chromium retained by the silica and alumina.

As a precautionary measure, therefore, and always when chromium is to be estimated also, the silica and alumina precipitate should be evaporated with hydrofluoric and sulphuric acids, the residue fused with a little sodium carbonate, and the aqueous extract again nearly neutralised with nitric acid and boiled for a few moments, the filtrate being added to the main one.

Mercurous nitrate is now added to the cold alkaline solution in some quantity, so as to obtain a precipitate of considerable bulk, containing, besides mercurous carbonate, chromium, vanadium, molybdenum, tungsten, phosphorus, and arsenic, should all happen to be in the rock. The mercurous carbonate serves to counteract any acidity resulting from the decomposition of the mercurous nitrate. Precipitating in a slightly alkaline instead of a neutral solution renders the addition of precipitated mercuric oxide unnecessary for correcting this acidity. If the alkalinity, as shown by the formation of an unduly large precipitate, should have been too great, it may be reduced by careful addition of nitric acid until an added drop of mercurous nitrate no longer produces a cloud.

After heating and filtering, the precipitate is ignited in a platinum crucible, after drying and removing from the paper to obviate any chance of loss of molybdenum and of injury to the crucible by reduction of arsenic. The residue is fused with a very little sodium carbonate, leached with water, and the solution, if coloured yellow, filtered into a graduated flask of 25 or more c.c. capacity. The chromium is then estimated accurately in a few minutes by comparing with a standard alkaline solution of potassium monochromate (p. 196). Then, or earlier in absence of chromium, sulphuric acid is added in slight excess, and molybdenum and arsenic, together with occasional traces of platinum, are precipitated by hydrogen sulphide, preferably in a small pressure bottle.* If the colour of the precipitate indicates absence of arsenic the filter with its contents is carefully ignited in porcelain, and the delicate sulphuric-acid test for molybdenum is applied as follows:—The molybdenum compound is heated in porcelain with a single drop of strong sulphuric acid till the acid is nearly volatilised. On cooling a beautiful blue colour is proof of the presence of molybdenum.

The filtrate, in bulk from 25 c.m.³ to 100 c.m.³ is boiled to expel hydrogen sulphide, and titrated at a temperature of 70° to 80° C. with a very dilute solution of permanganate representing about 1 m.grm. of V_2O_5 per c.c. as calculated from the iron strength of the permanganate, one molecule of V_2O_5 being indicated for each one of Fe_2O_3. One or two checks are always to be made by reducing again by means of a current of sulphur dioxide gas, boiling this out again,† and repeating the titration. The latter results are apt to be a very little lower than the first, and are to be taken as the correct ones.

In case the volume of permanganate used is so small as to make doubtful the presence of vanadium, it is necessary to apply a qualitative test, which is best made as follows:—The solution is evaporated and heated to expel excess of sulphuric acid, the residue is taken up with 2 or 3 c.c. of water, and a few drops of dilute nitric acid, and a couple of drops of hydrogen peroxide are added. A characteristic brownish tint indicates vanadium. Unless the greater part of the free sulphuric acid has been removed the appearance of this colour is sometimes not immediate and pronounced, hence the above precaution. It is also necessary that the nitric acid shall be in considerable excess, since in a neutral or only faintly acid solution the colour does not appear strongly.

The above is a surer test to apply than the following:—Reduce the bulk to about 10 c.c., add ammonia in excess,

* *Bulletin of the United States Geological Survey*, No. 176.

† W. F. Hillebrand, "Distribution and Quantitative Occurrence of Vanadium and Molybdenum in Rocks of the United States." *Amer. Journ. Sci.*, 1898, 4th Ser., vol. vi., p. 209; CHEM. NEWS, 1898, vol. lxxviii., p. 216; *Bull. U.S. Geol. Survey*, No. 167, p. 49.

* From a sulphuric solution the separation of platinum and molybdenum by hydrogen sulphide is much more rapid and satisfactory than from a hydrochloric solution.

† The direct use of a solution of sulphur dioxide or of an alkali sulphite is inadmissible unless these have been freshly prepared, since after a lapse of time they contain other oxidisable bodies than sulphurous acid or a sulphite. The sulphur dioxide is best obtained as wanted by heating a flask containing a solution of sulphur dioxide, or of a sulphite to which sulphuric acid has been added. The expulsion of the last traces of sulphur dioxide is said to be more effectively accomplished by boiling with simultaneous passage of a rapid current of carbon dioxide for a few minutes at the last than by boiling alone. Because of the small amount of air carried with it, long passage of the gas is said to result in slight oxidation of the vanadium (Manasse, *Ann. Chem. u. Pharm.*, 1887, vol. ccxl., p. 23; *Zeit. fur Anal. Chemie*, 1893, vol. xxxii., p. 225).

and introduce hydrogen sulphide to saturation. The beautiful cherry-red colour of vanadium in ammonium-sulphide solution is much more intense than that caused by hydrogen peroxide in acid solution, but the action of ammonia is to precipitate part or all of the vanadium with the chromium or aluminum that may be present or with the manganese used in titrating, and ammonium sulphide is unable to extract the vanadium wholly from these combinations. Usually, however, the solution will show some colouration, and addition of an acid precipitates brown vanadium sulphide, which can be collected, ignited, and further tested if desired.

Application of the Method in presence of Relatively much Chromium.

The application of the method in its foregoing simplest form is subject to one limitation—the chromium must not be present above a certain moderate amount. This limitation is due to the considerable amount of permanganate then required to produce a clear transition tint when titrating in a hot solution, as is advisable with vanadium. In a cold solution of chromic sulphate much less permanganate is needed to produce the peculiar blackish tint without a shade of green, which affords a sure indication of excess of permanganate, but in a hot and especially a boiling solution the oxidation of the chromium itself takes place so rapidly that a very large excess of the reagent may be added before a pronounced end reaction is obtained. Nevertheless, quite satisfactory determinations of as little as 1 or 2 m.grms. of vanadium pentoxide can be made in presence of as much as 30 m.grms. of chromic oxide. To accomplish this it is only necessary to apply a simple correction obtained by adding permanganate to a like bulk of equally hot chromic sulphate solution containing approximately the same amount of chromium.

Ridsdale (*Journ. Chem. Soc.*, 1888, vol. vii., p. 73), titrated the cold solution to avoid oxidation of chromium, and obtained accurate results, but in the writer's experience the end reaction is then uncertain.

Tables V. and VI. contain the results of a considerable number of tests, those in Table VI. being tabulated separately in order to show the degree of accuracy attainable with a large excess of chromium by applying the correction above mentioned and also the amount of this correction.

In spite of the fact that the correction in most of the trials of Table VI. represents a large proportion of the permanganate used, the results must be considered satisfactory in view of the small amount of vanadium present, and they show that the method in competent hands after a little experience affords trustworthy figures.

The method of T. Fischer ("Inaugural Dissertation," Rostock, 1894)—digestion of the precipitated lead salts with a strong solution of potassium carbonate—appears to offer the long-needed satisfactory quantitative separation of arsenic, phosphorus, chromium, tungsten, and molybdenum from vanadium, the normal lead meta-vanadate remaining quite unattacked, according to the author, while the other lead salts are wholly decomposed, but the applicability of this method to the separation of the minute amounts often found in rocks and ores has not been tested. The object has been in the present case to reach satisfactory results with the greatest expedition, and when chromium is not present in considerable amount this is accomplished.

Fortunately, chromium is almost never a prominent constituent of clays, coals, iron ores, and those rocks in which vanadium has thus far been reported, for although it is usually certain of the most basic of the silicate rocks that are highest in chromium—as the peridotites—yet in these, so far as present experience teaches, vanadium is lacking, a fact doubtless connected with the simultaneous absence from them of ferric-aluminous silicates.

Condition of Vanadium in Rocks.

The above and elsewhere mentioned connection of vanadium with the ferric-aluminous silicates of rocks,

taken in connection with the existence of the mineral roscoelite, classed as a vanadium mica, indicates a condition of the vanadium corresponding to aluminum and ferric iron, and that it is to be regarded as replacing one or both of these elements. Hence it should be reported as V_2O_3 and not as V_2O_5.

What its condition may be in matter of secondary origin, like clays, limestones, sandstones, coals, and ores of iron, is yet open to discussion. It was the writer's opinion until recently that it should then be regarded as in the pentavalent state (V_2O_5), but his work upon certain remarkable vanadiferous sandstones (Hillebrand and Ransome, *Amer. Journ. Sci.*, 1900, Fourth Series, vol. x., p. 120), of Western Colorado, in which it unquestionably occurs as trivalent vanadium (V_2O_3), has led to a decided unsettling of this view. It is but proper to recall that Czudnowicz (*Pogg. Ann.*, 1863, vol. cxx., p. 20), because of the extreme

difficulty in completely extracting it from iron ores by an alkali-carbonate fusion, and because of the easy reducibility of vanadic acid by ferrous salts, under the conditions in which brown iron ores are supposed to form, considered the vanadium in such ores to be in a lower condition of oxidation (V_2O_3). Lindemann's ("Dissertation," Jena., 1878, through *Zeit. fur Anal. Chemie*, 1879, vol xviii., p. 99), contrary conclusion with regard to certain iron ores, because the vanadium was extracted as V_2O_5 by sodium-carbon fusion without nitre, is not valid, since this would probably be the case even if it existed in the ore as V_2O_3.

(To be continued).

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Ordinary Meeting, April 18th, 1901.

Prof. Emerson Reynolds, F.R.S., President, in the Chair.

Messrs. B. F. Howard, L. Dobbin, W. H. Oates, and Maj.-Gen. Waterhouse were formally admitted Fellows of the Society.

The following certificates were read for the first time:—Guy Ashwell, Standard Bank, Bulawayo; Thomas Aspinall, 42, Gilnow Road, Bolton; William George Aston, 4, Dalkeith Road, Ilford; Edwin Sloper Beaver, 5, Bonham Terrace, Warminster; Fred Bedford, 9, Market Place, Sleaford, Lincs.; Arthur Crabtree, 9, Bigg Market, Newcastle-on-Tyne; Daniel McLaren, Brookdale, Gray Street, Stalybridge; John Powell, Bailiol House, Wentworth Street, E; John Davidson Spence, 2, Hawkhill Place, Perth Road, Dundee; William Arthur Whitton, Bristol Brewery, Brighton.

The following certificate was authorised by the Council under By-law I. (3):—

Joseph de Verteuil, Clarence Street, Port of Spain, Trinidad, B.W.I.

The following letter has been received from Professor Markownikoff in reply to the letter of congratulation addressed to him by the Council:—

Moscow, 22nd March/4th April.

Dear Sir,—Some years ago I was highly honoured to be received into the list of Foreign Members of the most appreciated Chemical Society of London, and am now deeply moved by the new sign of attention and the hearty congratulations of my dear colleagues.

I beg you to convey to them that devotion to our science will not leave me until the very last.—Your respectful obedient servant,

W. Markownikoff.

Prof. Meldola, Foreign Secretary.

Extraordinary General Meeting.

The President stated that, having received a requisition signed by a sufficient number of Fellows asking that an Extraordinary General Meeting of the Society be called to consider the change of the day and hour of meeting which the Council had decided upon for the ordinary meetings during the ensuing session, he had fixed Wednesday, May 15th, at 8 p.m. for this meeting.

Of the following papers, those marked * were read:—

*55. "*Action of Alkyl Haloids on Aldoximes and Ketoximes.* Part II. *Alkylated Oximes and Isoximes and the Constitution of Aliphates Oximes.*" By W. R. Dunstan and E. Goulding.

In a previous paper (*Trans.*, 1897, lxxi., 573), the authors showed that the direct action of alkyl haloids on aldoximes and ketoximes results in the formation of alkyl nitrogen derivatives only, these being derivatives of the isoximes—

$$RHC{=}NH \quad \text{and} \quad R_2C{=}NH$$
$$\diagdown\!\diagup \qquad\qquad \diagdown\!\diagup$$
$$O \qquad\qquad O$$

When the alkyl haloid acts on the sodium derivatives of the oximes, that is, on the oximes in presence of sodium methoxide, these derivatives of the isoximes are formed, but together with the true ethers of the oximes, RHC:NOH and R_2C:NOH.

The alkyl isoximes are highly unstable, and have been studied chiefly as the compounds they form with sodium iodide. On hydrolysis they furnish the corresponding aldehyde or ketone, together with a β-substituted hydroxylamine. On reduction in the ordinary manner they are converted into the primary amine of the substituted alkyl and the corresponding aldehyde or ketone. By careful reduction with sodium amalgam and acetic acid in alcoholic solution they are changed, by substitution of hydrogen for oxygen, into the corresponding secondary amines. This is a satisfactory method of preparing pure secondary amines.

The alkyl ethers of the oximes are stable liquids. On hydrolysis they furnish the aldehyde or ketone, and an α-substituted hydroxylamine.

Isomeric alkyl derivatives of acetaldoxime, acetoxime, and acetophenoxime were described, and also their hydrolytic and reduction products.

The authors consider that their results support the view that the isoximido-form represents the ordinary structure of the aliphatic oximes, only alkyl nitrogen derivatives being obtained from them by the direct action of alkyl haloids, the hydroxylic structure in the formation of ethers being determined by the formation of the so-called "salts" with highly electro-positive metals. These salts are, however, readily dissociated, so that by acting on them, in alcoholic solution, with the alkyl haloid, some alkyl isoxime is always formed from the free oxime present.

*56. "*The Supposed Existence of Two Isomeric Triethyloxamines.*" By W. R. Dunstan and E. Goulding.

The triethyloxamine, $(C_2H_5)_3NO$, obtained by the authors (*Trans.*, 1899, lxxv., 792, and *Trans.*, 1900, lxxvii., 1006), was shown to possess properties which differ from those of the compound described by Bewad, to which he assigned the same constitution. This difference has been since investigated and confirmed by Lachman (*Ber.*, 1900, xxxiii., 1022), who, however, was unable to offer any explanation of it. The question is now settled by the observation that the compound described by Bewad is in reality β ethyl-*sec*-butylhydroxylamine, as Bewad himself has shown (*Journ. Russ. Phys. Chem.*, 1900, xxxii., 455). The triethyloxamine obtained by the authors is at present therefore the only known compound having this constitution.

*57. "*Nitrocamphene, Aminocamphene, and Hydroxycamphene.*" By M. O. Forster.

1-*Nitrocamphene*,—

$$C_8H_{14}\begin{cases}\text{CH}\\ \|\\ \text{C·NO}_2\end{cases},$$

prepared by heating an alcoholic solution of 1 : 1-bromonitrocamphane with silver nitrate, crystallises from alcohol in long, hard, striated prisms, and melts at 56°; it has $[\alpha]_D = +112{\cdot}0°$ in alcohol, and $+137{\cdot}5°$ in benzene. 2 : 1-*Bromonitrocamphane*,—

$$C_8H_{14}\begin{cases}\text{CHBr}\\ |\\ \text{CH·NO}_2\end{cases},$$

obtained when nitrocamphene is treated with hydrobromic acid, crystallises from alcohol, and melts at 178°. 1 : 2-*Dibromo*-1-*nitrocamphane*,—

$$C_8H_{14}\begin{cases}\text{CHBr}\\ |\\ \text{CBr·NO}_2\end{cases},$$

produced by the action of bromine on nitrocamphene,

crystallises in long, flat, transparent needles, and melts at 195°. 2 : 1-*Iodonitrocamphane*,—

prepared from nitrocamphene and hydriodic acid, crystallises in thin, lustrous plates, and melts at 118°.

1-*Aminocamphene*,—

formed on reducing nitrocamphene with zinc dust and glacial acetic acid, melts at 46°, and boils at 191—192° under 758 m.m. pressure; it has $[\alpha]_D = +59{\cdot}7°$ in alcohol. The *sulphate*, *picrate*, *platinichloride*, and the *benzoyl*, *benzylidene*, and *phenylcarbamide* derivatives are well-defined.

1-*Hydroxycamphene*,—

obtained on heating aminocamphene sulphate with potassium nitrite, crystallises in long needles, melts at 74°, and boils at 212° under 750 m.m. pressure; it has $[\alpha]_D = +34{\cdot}1°$ in absolute alcohol. Hydroxycamphene is indifferent towards alkalis, but warm dilute mineral acids transform it immediately into ordinary camphor.

58. "*A Contribution to the Chemistry of the Triazoles.*" By G. Young and W. H. Oates.

The authors discuss the possibility of isomerism in the triazole series as compared with the pyrazoles.

The following compounds have been obtained :—

Benzal-2-methylsemicarbazone,—

$$C_6H_5{\cdot}CH{:}N{\cdot}N(CH_3){\cdot}CO{\cdot}NH_2,$$

m. p. 159—160°; 3-*phenyl*-1-*methylhydroxytriazole*,—

m. p. 218—219°; *acetyl* derivative, m. p. 72·5—73°; *silver* derivative, $C_9H_8ON_3Ag$; 3 *phenyltriazole*, m. p. 118·5—119°; *cinnamal-2-methylsemicarbazone*, m. p. 155°; *strenylmethylhydroxytriazole*, m. p. 204—205°; *silver* derivative, $C_{11}H_{10}ON_3Ag$; *acetyl* derivative, m. p. 88—89°; *m-nitrobenzalmethylsemicarbazone*, m. p. 207—208°; *m-nitrophenylmethylhydroxytriazole*, m. p. 285—285·5°; *silver* derivative, $C_9H_7O_3N_4Ag$; *benzoyl-4-methylthiosemicarbazide*, $C_6H_5{\cdot}CO{\cdot}NH{\cdot}N{:}C(SH){\cdot}NHCH_3$, m. p. 198°; 2-*phenyl*-1-*methyltriazole*,—

m. p. 112—113°; 2-*phenyl*-1-*methylmercaptotriazole*, m. p. 163—164°. Methylsemicarbazide, formed by the action of potassium cyanate on methylhydrazine sulphate, has the methyl group in position (2), $NH_2{\cdot}N(CH_3){\cdot}CO{\cdot}NH_2$, and not in position (1), $CH_3NH{\cdot}NH{\cdot}CO{\cdot}NH_2$ (compare Brüning, *Ann.*, 1889, cclxiii., 11).

Discussion.

Dr. Silberrad pointed out that Knorr's theory affords a better explanation than that given by the author of facts such as that illustrated by the identity of the triazoles represented by the formulæ—

a phenomenon to which attention was drawn on the conversion of dihydrotetrazine into the triazole represented above (Hantsch and Silberrad, *Ber.*, 1900, xxxiii., 89).

In reply, Dr. Young said that the identity of Freund's triazole with that prepared from tetrazine was in agreement with the view put forward in the paper as to the "amidine" nature of the triazole ring.

59. "*Researches on Moorland Waters.* Part II. *On the Origin of the Combined Chlorine.*" By W. Ackroyd.

The object of the investigation has been to discover the origin of the common salt in the water of the Widdop reservoir in Yorkshire, about midway between the two seas, this water being continually removed, and as continually replenished from the saltless area of Millstone Grit and Yoredale rocks. The chlorine in the winter rainfall more than accounts for it, and the conclusions arrived at are (1) that the combined chlorine in the reservoir water is wholly derived from rain water; (2) that the quantity of chlorine in the reservoir, whose capacity is 640½ million gallons, closely approximates to a yearly average of 1·188 parts per 100,000, and (3) that in winter the chlorine in the rainfall is in excess of the average for other seasons of the year.

60. "*Robinin, Violaquercitrin, and Osyritrin.*" By A. G. Perkin.

Robinin, isolated from the flowers of *Robinia pseudacacia* by Zwenger and Dronke (*Ann. Sup. I.*, 1861, 257), was considered by them as a glucoside of quercetin. The formula $C_{33}H_{38}O_{20},8H_2O$ is now assigned to the air-dried substance, and its decomposition with dilute mineral acids may be thus represented,—

$$C_{33}H_{38}O_{20}+4H_2O=C_{15}H_{10}O_6+3C_6H_{12}O_6.$$

The *colouring matter*, $C_{15}H_{10}O_6$, melts at 271—272°, yields a *sulphate*, $C_{15}H_{10}O_6,H_2SO_4$, and a *tetracetyl* derivative, $C_{15}H_6O_6(C_2H_3O)_4$. On decomposition with alkali, phloroglucinol and *p*-hydroxybenzoic acid are formed. It is identical with *kampherol*, which is present as its monomethyl ether, kampheride, in galanga root (*Alpinia officinarum*) (Gordin, *Dissert.*, Berne), and as glucoside in *Delphinium consolida* (*Proc.*, 1900, xvi., 182). The sugar gave a mixed osazone, from which dextrosazone (m. p. 204—205°), and a more soluble compound, m. p. 190—196° (possibly the galactose derivative), were isolated.

Osyritrin, the quercetin glucoside of *Osyris compressa* (*Trans.*, 1897, lxxi., 1131), has at 130° the formula $2C_{27}H_{28}O_{16},H_2O$, and not $C_{27}H_{30}O_{17}$, as previously stated. Air dried, it contains $3H_2O$, and is anhydrous at 160°. Violaquercitrin (Mandelin, *Jahres.*, 1883, 1369), present in the *Viola tricolor*, has at 160° the formula $C_{27}H_{28}O_{16}$, and not $C_{42}H_{42}O_{24}(=C_{27}H_{26}O_{15})$ there given. Air dried, it contains $3H_2O$, and is identical with osyritrin.

(To be continued).

PHYSICAL SOCIETY.

Ordinary Meeting, April 26th, 1901.

Dr. R. T. Glazebrook, Foreign Secretary, in the Chair.

A paper on "*The Thermodynamical Correction of the Gas Thermometer*" was read by Prof. H. L. Callendar.

This paper commences by giving a short historical sketch of the thermodynamic correction of the gas thermometer, describing some of the solutions to Thomson's fundamental equation for the Joule-Thomson plug experiment. The assumptions made in the solutions have sometimes been erroneous, and wrong corrections have been obtained. From 1885 to 1888 Chappuis made a series of careful comparisons between various gas thermometers and a very delicate mercury thermometer, and drew up a table of differences between the hydrogen and the nitrogen thermometer. The author has taken the observations of Chappuis, and calculated a new table of differences. The index "n" in the modified Joule-Thomson equation is not constant. For steam it is about 3·5, and for carbonic acid about 2. The thermodynamic correction is very small, especially in the case of hydrogen and helium, and is very much less than the correction for the expansion of the thermometer bulb.

Prof. Herschell asked whether the co-volume came into the correction.

Dr. Harker looked forward to the experiments which Prof. Callendar proposes to make with a constant pressure thermometer.

The Chairman expressed his interest in the extreme delicacy of the observations of Chappuis.

A paper on "*The Production of a Bright Line Spectrum by Anomalous Dispersion and its Application, the 'Flash Spectrum,*'" by R. W. Wood, was read and experimentally illustrated by Mr. Watson.

It has been suggested by W. H. Julius that the "flash spectrum" seen immediately at totality may be due to photosphere light abnormally refracted in the atmosphere of metallic vapours surrounding the sun. The light which will be thus abnormally refracted will be of wave-lengths almost identical with the wave-lengths which the metallic vapours are themselves capable of radiating. The sun is supposed to be surrounded by an atmosphere of metallic vapours, the refractive index of which decreases with increasing distance from the surface. In this atmosphere the rays of light coming from the photosphere move in curved paths. The refractive index is, however, very small except for wave-lengths very near those absorbed by the vapour. Consequently, the light which resembles that emitted by the vapours is most strongly refracted, and therefore curves sufficiently to reach us after the photosphere has been hidden by the moon. The flash spectrum of sodium was shown by focussing the light of an arc lamp on a horozontal slit in front of a flat metal plate supported so that the plane in which its under surface lay coincided with the plane of the slit. At a distance of about two metres a direct vision spectroscope was arranged to give a vertical spectrum, and placed at such a height that the prism barely caught the rays coming from the slit and grazing the plate. On looking into the spectrosocope a bright continuous spectrum is seen. A Bunsen burner was then placed underneath the metal plate, and fed with sodium. This produced a layer of sodium vapour of varying refractive index. On raising or lowering the spectroscope sodium lines are seen due to anomalous dispersion. By arranging screens these lines can be obtained so that on cutting out the arc lamp the flash spectrum vanishes.

Prof. Herschell expressed his interest in the experiments, and their application to the case of the flash spectrum seen at totality.

The Society then adjourned until May 10th, 1901.

NOTICES OF BOOKS.

Researches on Leadless Glazes. By William J. Furnival. Stone, Staffordshire: W. J. Furnival. Pp. 135.

The value and importance of a satisfactory leadless glaze for pottery can hardly be over-estimated, not so much from the point of view of durability, though this must not be forgotten, but from the fact that there is a very large amount of unnecessary suffering and injury to health, often followed by early death, caused by the use of carbonates and oxides of lead as ingredients of the fluxes from which the glazes are formed.

It has been claimed that the fritting of the lead compounds with siliceous materials renders lead glazes less injurious, but even in this state danger still exists. If, it is asked, fritted lead compounds are to be used for glazes, how are they to be obtained? Who is to frit them, and how are they, who do the fritting, to be protected? These questions can be best disposed of by doing away with lead glazes altogether.

The problem is no doubt a difficult one, but, as the author says, "to fold our hands and say it cannot be solved, finality has been reached, discoveries are at an end; or to be content simply to prepare a defence for the continued use of lead in glazes, is both impolitic and unprogressive."

It is a fact that durable glazes free from lead have been and are now being used for hard porcelain, and to some extent for stoneware and bricks, and the recipes for a number of such glazes will be found in these pages.

The *durability* of leadless glazes has been greatly contested, but the author brings forward a number of historical examples which prove beyond question the exact opposite; he is, however, content to abide by the statement that the durability of a leadless glaze is not necessarily less than that of a lead glaze.

The chapter on "Special Research Experiments" is both of importance and interest, and though many of the experiments were associated with failure they all have their value; it is not unfrequent that more is learnt from a so-called unsuccessful experiment than from a successful one. This chapter is followed by one on "Practical Recipes," of which a considerable number are given.

Opalinity and opaline tendencies have probably been the most troublesome defects experts have had to overcome in the preparation of satisfactory leadless glazes; experience seems to point to lime, potash, zinc, and silica as the chief offenders, though some experiments show that calcium compounds are not always in fault. Blistering has been another cause of trouble, though it may be remarked that this will also occur with some lead glazes. A very important matter is regularity in mixing, and probably few things are more essential than good firing.

The book is well printed, serviceably bound, and furnished with a good index. The author has written as a practical man, and his knowledge and experience of the subject should be of great assistance to all those, and they must be many, who are interested in leadless glazes.

CORRESPONDENCE.

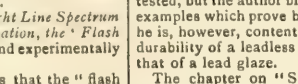
TAUTOMERISM.

To the Editor of the Chemical News.

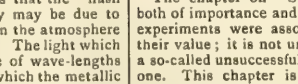
Sir,—There is a remarkable point about tautomerism that I have not seen mentioned before, and which is certainly worth recording, viz., that the mobile hydrogen atom always travels from a position which we may call (1) into the position (3).

Examples.

Cyanic acid.



Guanin.



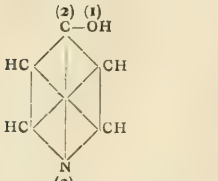
Isatin.

Diazobenzene.

Ethylaceto-acetate.

The following two examples require the adoption of particular formulæ which have been put forward.

Azobenzene phenol.



γ-Pyridone.

If this rule be correct it will favour the peroxide formulation for quinones, &c., and the γ bond in the pyridine series (when γ substituents).—I am, &c.,

A. Lionel Landau.

20, Highbury New Park,
April 22, 1901.

RAPID ESTIMATION OF PHOSPHORUS IN STEEL.

To the Editor of the Chemical News.

Sir,—In reply to a correspondent, referring to my communication on the "Rapid Estimation of Phosphorus in Steel" (Chem. News, vol. lxxxiii., p. 154), the letter "E" stands for "Equivalent," and an E solution is one containing a gramme equivalent of reacting substance per litre, or a milligramme equivalent in 1 c.c. For example—

16 E HNO_3 contains 16 grms. equivalents HNO_3 per litre.
10 E HCl „ 10 „ „ HCl „

Your correspondent will find a description of the "Equivalent System" in an article by J. Reddrop, F.I.C., which appeared in the Chemical News, May 23, 1890 (vol. lxi., p. 245), also in Morgan's "Tables for Quantitative Metallurgical Analysis."—I am, &c.,

J. Jas. Morgan.

Wednesbury, April 25, 1901.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Note.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. cxxxii., No. 14, April 9, 1901.

Generalisation of Trouton's Law.—M. de Forcrand.—In 1844 Trouton enunciated the law bearing his name. This law establishes an empirical relation between latent heats of vaporisation, measured at the normal temperature of ebullition, and this temperature reckoned from absolute zero, $\frac{L}{T} = K$; K varying from 20 to 26. The author investigates this law, and finds that it can be stated more generally as follows:—In all chemical or physical phenomena, the heat of solidification of any gas whatsoever is proportional to its temperature of vaporisation under atmospheric pressure, $\frac{L+S}{T} = 32{\cdot}1$. The constant varies very slightly for the substances on which the experiments were made, viz., ammonia, water, glycol, chlorine, bromine, iodine, phenol, benzene, naphthalene, ethylene bibromide, methyloxalate, butyric, formic, and acetic acids. The mean value of the constant from all the experiments being 30.

New Method of Distinguishing Colouring-matters. Application to Indophenols.—C. Camichel and P. Bayrac.—The authors' experiments prove—(1) That when a tertiary nitrogen is replaced by a primary nitrogen, the minimum of transparence is displaced towards the most refrangible end of the spectrum, whatever be the solvent (alcohol, ether, carbon disulphide, or chloroform); (2) an ortho-substitution in the phenol from which indophenol is derived produces a considerable displacement of the minimum of transparence, whatever be the solvent; (3) a meta-substitution in the same phenol produces a very slight displacement of the transparence minimum towards the red or towards the blue. This displacement is often zero, and it differs little from experimental errors.

Reaction of Amido-substituted Benzophenones and the Aromatic Amines in Sulphuric Medium.—Paul Lemoult.—In a sulphuric medium, the para-amido-substituted benzophenones give, with certain aromatic amines, but not with others, reaction products which are colouring-matters. The only amines which are capable of this reaction are those which have at least two aromatic radicles joined directly to the nitrogen. It is also necessary that one of these radicles be a phenyl, and that it have the free para-position (nitrogen being in 1); in this case the splitting of the two molecules takes place at that point.

MEETINGS FOR THE WEEK.

Monday, 6th.—Society of Arts, 8. (Cantor Lectures). "Alloys," by Sir William Chandler Roberts-Austen, K.C.B., F.R.S.

—— Society of Chemical Industry, 8. "Action of Caustic Potash and Soda on Stannous Sulphide," by Dr. F. Mollwo Perkin. "The Relative Leather-forming Value of the Different Tanning Materials—their Speed of Tanning, with Notes on the Quality," by John Youl and R. W. Griffith. "The Need of Greater Care in introducing Gas-Firing into Small Gas-works," by W. Cecil Jones. "Arsenic in Coal and Coke," by R. F. Wood Smith and R. L. Jenks.

Tuesday, 7th.—Royal Institution, 3. "On Cellular Physiology, with special reference to Enzymes and Ferments," by Allan Macfadyen, M.D., B.Sc.

—— Society of Arts, 4.30. "The Coal Problem—its Relations to the Empire," by Lieut. Carlyon W. Bellairs, R.N.

Wednesday, 8th.—Society of Arts, 8. "School Work in relation to Business," by Sir Joshua Fitch, LL.D.

Thursday, 9th.—Royal Institution, 3. "Arthur Sullivan" (with Vocal and Instrumental Illustrations), by Sir Alex. Campbell Mackenzie, Mus.Doc.

Friday, 10th.—Royal Institution, 9. "The Response of Inorganic Matter to Mechanical and Electrical Stimulus," by Professor Jagadis Chunder Bose, M.A., D.Sc.

—— Society of Arts, 8. (Howard Lectures). "Polyphase Electric Working," by Alfred C. Eborall, M.I.E.E.

—— Physical, 5. "Applications of Elastic Solids to Metrology," by Dr. C. Chree, F.R.S. "The Thermal Properties of Isopentane compared with those of Normal Pentane," by Prof. S. Young, F.R.S., and J. Rose-Innes.

Saturday, 11th.—Royal Institution, 3. "The Rise of Civilisation in Egypt," by Prof. W. M. Flinders Petrie, D.C.L.

THE USE OF METALLIC SODIUM IN BLOWPIPE ANALYSIS.

By CHARLES LATHROP PARSONS.

The use of sodium carbonate to assist the action of the reducing flame has long been customary in blowpipe analysis, and is adopted by all text-books on the subject. The reducing action is partly due to the formation of sodium cyanide, but more largely to the formation of gaseous sodium and carbon monoxide. At best its action is slow, and nothing more severely tests the skill of the beginner than the attempt to obtain a button of metallic tin from cassiterite, or the sulphur reaction from gypsum. In general it is much more difficult to reduce an oxide or sulphide before the blowpipe, than it is to cause the opposite reaction to take place by means of the oxidising flame. Therefore, if the assay is not kept in the reducing zone of the flame, a re-oxidation will almost certainly take place.

The great reducing power of powdered aluminum has been well illustrated by Goldschmidt and Vautin (*Journ. Soc. Chem. Ind.*, xvii., 545), and, although the fact that this property is possessed also by magnesium and sodium has long been known, W. Hempel (*Zeit. Anorg. Chem.*, xvi., 22), seems to have been the first to propose the use of the latter as a reagent in qualitative analysis. Hempel calls attention to the ease with which reduction may be brought about by sodium, but states that it does not give satisfactory results on charcoal. He recommends that the sodium be flattened out upon an ordinary filter-paper, and after being mixed with the powdered substance, folded once and then rolled so that a double layer of paper is between each layer of sodium. This roll is next enclosed in a spiral of iron wire, set on fire in a Bunsen flame, and cooled in the unburned gas below. It is next triturated with water in an agate mortar, and the residue carefully examined.

I have found these details to be quite unnecessary, and that the reaction takes place with the greatest ease upon charcoal. To the operator who has been used to the much more tedious reduction with sodium carbonate the quickness and certainty of the results are almost startling, and the reduction takes place with silicates, chlorides, carbonates, borates, sulphates, sulphides, &c., with as much ease and accuracy as with the oxides themselves. The method is extremely simple.

A small piece of metallic sodium, not more than 3 or 4 m.m. in diameter, is hammered out flat on some smooth surface. The substance to be reduced is powdered and spread upon it, pressed into the metal with the hammer, and the whole turned and kneaded into a little ball with a knife-blade. It is then placed upon a slight depression in a piece of charcoal, and ignited with a match or the Bunsen flame. A momentary flash ensues, and the reduction is accomplished. The residue is now heated before the blowpipe, and as the sodium oxide and hydroxide immediately sink into the charcoal, any fusible metallic particles collect easily into a button, and may be recognised in the usual manner. Volatile metals, like zinc, oxidise and yield with surprising readiness their characteristic coatings, and on digging up a little of the charcoal, moistening with water, and placing upon a silver coin, the "Hepar" reaction is obtained if sulphur was present in any form. It is perhaps superfluous to add that this last reaction is certain in its conclusions only when carried out upon a piece of charcoal uncontaminated by previous tests.

Applied to minerals the method yields results but little less certain than when pure salts or oxides are reduced. Galenite yields at once a button of lead which in the oxidising flame gives the lead coating without a trace of the white coating of sulphate which ordinarily results. Garnierite gives a residue of silicon and magnetic nickel to which the bead test can be immediately applied. Chrysocolla and cassiterite yield buttons of copper and tin respectively as readily as a button of lead is obtained from cerusite. Even chromite is immediately reduced, and if the residue is powdered the iron may be quite largely separated from the chromium by means of the magnet. Barite, celestite, and gypsum show with ease the sulphur reaction, and the residue if moistened with hydrochloric acid gives the flame tests far more rapidly than if applied to the powdered minerals. In general the method is applicable whenever reduction can take place, and whenever the reduced material yields characteristic reactions more readily than the mineral itself.

The metallic sodium does not need to be kept under naphtha, but may be supplied to a class in small rubber-stoppered wide-mouthed bottles. A lump of sodium two or three centimetres in diameter will keep for months in this manner with only superficial oxidation. It must, of course, be carefully kept away from water or moisture. In rolling up the sodium and substance to be reduced into a ball, the metal should not be touched with the fingers, for with one or two of the more easily reduced oxides or sulphides, the reaction sometimes begins spontaneously. This takes place quite readily with the peroxide of lead. Large quantities of sodium should be avoided or the reaction may become dangerously violent.

From my experience in its use with classes during the last two years, I feel sure that sodium will soon be universally employed as a reagent in blowpipe laboratories. —*Journal of the American Chemical Society*, vol. xxiii., No. 3.

THE ESTIMATION OF SULPHYDRIC ACID IN COAL-GAS.

By A. MULLER.

I have had occasion to use the following method for the estimation of sulphuretted hydrogen in coal-gas (*Stahl und Eisen*, 1896, p. 865). This process being simple, exact, and rapid, I thought it would be of interest to describe it, as it can be employed with great advantage in the laboratories of large gas-works.

Two solutions are required:—

1. *Solution of Acetate of Cadmium.*—Twenty-five grms. of acetate of cadmium and 200 c.c. of acetic acid are made up to 1 litre with distilled water.
2. *Solution of Sulphate of Copper.*—Eighty grms. of powdered crystals of sulphate of copper in 750 c.c. of distilled water. After cooling, 175 c.c. of concentrated sulphuric acid are added, and the whole made up to a litre; if necessary, the solution is filtered.

Twenty-five c.c. of No. 1 solution are placed in an Erlenmeyer flask fitted with a cork pierced with two holes. Two glass tubes pass through these holes: one, for the entry of the gas, reaches to the bottom of the flask; the other opens directly to the air.

The volume of gas which passes through the solution is measured accurately. A carboy of about 15 litres capacity could be used, and the gas driven from it by means of a known volume of water; the whole must be arranged so that the current of gas is not too rapid. There need be no fear that the whole of the sulphuretted hydrogen will not be absorbed; this can easily be guarded against, however, by having two absorption flasks in series, instead of one only.

The operation terminated, the cork with the glass tubes

is removed, and the contents of the flask are heated to 50—60°, and 10 c.c. of the solution of sulphate of copper are added. The sulphide of cadmium and the sulphate of copper immediately react, and the precipitate, which is first yellow becomes black. It is then filtered, washed with warm water, dried, calcined, and weighed. The reactions which take place are the following:—

$$H_2S+Cd(C_2H_3O_2)_2=CdS+2C_2H_4O_2,$$
$$CdS+CuSO_4=CdSO_4+CuS,$$
$$CuS+3O=CuO+SO_2,$$

One molecule of sulphydric acid thus corresponds to one molecule of oxide of copper, and we get the proportion—

$$CuO : H_2S :: 79 : 34.$$

Under normal conditions, the weight of 1 litre of sulphuretted hydrogen is 1·5232 grms.

We may take it, as a rule, that the temperature at which the analyses are made is 18°. At this temperature 1 litre of gas weighs 1·43 grms. We arrive at the number of litres of sulphuretted hydrogen contained in the quantity of coal-gas analysed, by multiplying the weight in grms. of the oxide of copper found by $\frac{34}{79 \times 1{\cdot}43} = 0{\cdot}301$.—

Journ. für Gasbeluchtung und Wasserversorgung, xliii.

SOME PRINCIPLES AND METHODS OF ROCK ANALYSIS.*

By W. F. HILLEBRAND.

(Continued from p. 213).

XIX. *Ferrous Iron.*

Comparison of Sealed-tube and Hydrofluoric Acid Methods —Comparative Worthlessness of the Former in Rock Analysis.

No point in rock analysis has been the cause of greater solicitude to the chemist, and especially to the mineralogist and petrographer, than the determination of iron in ferrous condition. The sealed-tube or Mitscherlich method with sulphuric acid, for a long time the only available one, is in theory perfect, since complete exclusion of oxygen is easily attainable. Its chief hitherto recognised defect lies in the inability to always secure complete decomposition of the iron-bearing minerals, and even to ascertain, oftentimes, whether or not the decomposition has been complete. The addition of hydrofluoric acid to the sulphuric in the tube, in order to insure this breaking up, is to be regarded as of very doubtful utility in most cases, since the glass may be so strongly attacked as to add an appreciable amount of iron to the solution, and the hydrofluoric acid may have exhausted itself in attacking the glass before the more refractory minerals succumb. Nevertheless, if decomposition can be effected by sulphuric acid alone the results obtained are sharp and concordant, and what has seemed especially remarkable, and up to almost the present moment without a satisfactory explanation, they are in rock analysis usually higher than when made by any of the modifications of the hydrofluoric acid method now so extensively practised. This difference is not very marked with rocks containing but 1 or 2 per cent of ferrous iron, but it increases with rising percentages to such an extent that where the sealed-tube method will show 12 per cent FeO the other may indicate no more than 10 per cent. This is a fact of which the writer has long been cognisant, but it does not seem to be known to chemists or petrographers at large, though Wülfing (*Ber. Deutsch. Chem. Gesell*, 1899, vol. xxxii., p. 2217, footnote), has noticed this difference in certain analyses without appreciating its significance. Experiments with soluble iron salts of known composition, like ferrous sulphate and ferrous-ammonium sulphate, throw no light on the subject, for both methods give with them the same sharp and accurate results.

In spite of several attempts to find a solution to the problem, none presented itself until very recently, when, as a result of observations made in this laboratory by Dr. H. N. Stokes in a pending investigation on the action of ferric salts on pyrite and other sulphides, the clue was given. Dr. Stokes found that ferric salts exercise a most marked oxidising effect on pyrite and probably other sulphides. The reaction is not new (see J. H. L. Vogt in *Zeit. fur Prakt. Geol.*, 1899, pp. 250—251), but the ease with which the change takes place, and the completeness of the oxidation of the pyrite, not only of its iron but of the greater part of the sulphur as well, were entirely unexpected. Pure pyrite itself is attacked with extreme slowness by boiling dilute sulphuric and hydrofluoric acids, either alone or mixed, but the moment a ferric salt is introduced the case is altogether different.

However, experiment has shown (see *prox.*), that with the amounts of sulphides usually found in igneous rocks their effect upon the estimation of ferrous iron by the hydrofluoric acid method at atmospheric pressure and boiling heat is negligible, though by increasing the amount of sulphide the effect becomes more and more apparent, because of the greater surface of pyrite exposed to the action of the ferric iron of the rock.

Under the conditions of the Mitscherlich method, on the other hand—a temperature of 150 to 200° C., and even higher, high pressure, much longer time of action, and im possibility of escape of any hydrogen sulphide that may be formed—the sulphur of the sulphides becomes nearly, if not fully oxidised to sulphur acid at the expense of the ferric iron in the rock, with the production of an equivalent amount of ferrous iron in addition to that resulting from the sulphide itself. Now, rocks with hardly an exception, and many minerals, carry pyrite or pyrrhotite, or both, often in considerable amount, often in traces only. My own experience has been that sulphur can almost always be detected in 2 grms. of rock powder.

Let us now see what the effect of these traces when fully oxidised amounts to. One atom of sulphur (32) requires for its complete conversion to trioxide the oxygen of three molecules of ferric oxide (480), which then becomes six molecules of ferrous oxide (432). In other words, 0·01 per cent of sulphur may cause the ferrous oxide to appear too high by 0·135 per cent, and 0·10 per cent of sulphur may bring about an error of 1·35 per cent in ferrous oxide. The case is still worse if the sulphur is set free as hydrogen sulphide from a soluble sulphide, for then the above percentages of sulphur produce errors of 0·18 and 1·8 per cent respectively, in the ferrous oxide determination.

The error caused by sulphides tends to become greater the more there is present of either or both sulphide and ferric salt. Now, the highly ferruginous rocks usually carry more ferric iron than the less ferruginous ones, and they are often relatively high in pyrite and pyrrhotite; hence the increasing discrepancy between the results by the two methods as the iron contents of the rocks rise is fully in accord with the above explanation.*

Notwithstanding that the Mitscherlich method has thus been discredited in its general applicability to rocks and minerals, it is still capable of affording valuable assistance with those which are totally free from sulphides. Hence the conditions under which success can best be achieved by it are set forth in the following paragraphs.

The Modified Mitscherlich Method.

Strength of Acid.—The method in its original and usual application calls for a mixture of three parts of sulphuric

* *Bulletin of the United States Geological Survey*, No. 176.

* For details of experiments showing the worthlessness of the Mitscherlich method for rocks and minerals which contain even a trace of free sulphur or sulphides see Hillebrand and Stokes, in an as yet unpublished paper in *Journ. Am. Chem. Journ.*, vol. xxii., and *Zeit. fur Anorg. Chem.*, 1900, vol. xxv., entitled "Relative Value of the Mitscherlich and Hydrofluoric Acid Methods for Ferrous Iron Determinations."

acid and one of water by weight, or about three to two by volume, though a still stronger acid is sometimes used. In some cases, however, perhaps in most, much better decomposition of the silicates is effected by reversing the proportions of water and acid, or at any rate by diluting considerably beyond the above proportion. Hereby the separation of salts difficultly soluble in the stronger acid is avoided, and the actual solvent effect on the minerals seems to be in no wise diminished.

Filling, Sealing, and Heating of the Tube.—The very finely powdered mineral having been introduced into a tube of resistant glass free from ferrous iron, the open end is drawn out, so as to leave a funnel for the introduction of the acid. A very little water is then introduced, and carefully heated to boiling for a moment to expel all air from the powder. The diluted acid—which has just been boiled down from a state of greater dilution in order to have it free from air—is then poured in until the tube is about three-fourths filled. Carbon dioxide is then introduced from a generator which has been in active operation for some time, through a narrow glass tube drawn out of the same kind of glass as that of which the decomposing tube consists. In a few moments the air is expelled, and the small tube is then sealed into the large one over the blast-lamp without interrupting the gas current until the very last instant, when to prolong it would perhaps cause a blowing out of the softened glass. The interruption of the current at the proper moment is easily effected by the pressure of the thumb and finger holding the small tube at the point where it enters the rubber tube leading from the gas generator. No breakage in the oven ever occurs as a consequence of thus fusing one tube into the other.

The heating is done in a bomb oven at any desired temperature up to, say, 200° C., and continued at intervals until examination by aid of a low-power lens shows that decomposition is complete or has progressed as far as can be hoped for. By enclosing the glass in an outer tube of strong steel, properly capped (Ullmann, *Zeit. fur Angew. Chemie*, 1893, p. 274; *Zeit. fur Anal. Chemie*, 1894, vol., xxxiii., p. 582), and containing a little ether or benzene to equalise the pressure on both sides of the glass, the temperature can be elevated far beyond what is otherwise permissible, and the decomposition will then doubtless be more complete with refractory silicates.

Reason for Introducing Gas and Sealing as above Directed.—The usual practice in employing the above method has been to expel air before sealing by introducing a few crystals or lumps of an alkali carbonate or bicarbonate, the gas set free on their contact with the acid being supposed to effectively expel all air. That this is not accomplished the following series of comparative results long since published elsewhere (*Bull. U.S. Geol. Survey*, No. 78, p. 50; CHEMICAL NEWS, 1891, vol. lxiv., p. 232) fully show. The material used was the oxide of uranium, U_3O_8, requiring by theory 32·07 per cent of UO_2. Operating as just above described on from 0·3 to 0·5 grm., the results were—

31·06, 31·07, 29·72, 29·33, 29·89, 30·69,

whereas after filling the tube with gas from a generator there was found—

32·11, 31·90, 32·15, 32·12, 32·06, 32·17, 32·28.

the average error of the former series being 1·78 per cent. The percentage error would, of course, be reduced by increasing the weight of mineral operated on. An average error equal to the above when employing 1 grm. of ferrous minerals would make the percentage for FeO about 0·3 per cent too low. While the absolute error might be the same in all cases, the relative error would increase with minerals low in ferrous iron.

The Hydrofluoric Acid Method.

This method is the one which has been almost exclusively used since the earliest years of the Survey's existence.

This specially ground powder, in a capacious crucible, is placed, after stirring up with dilute sulphuric acid, on a small water-bath of a single opening (Fig. 13), and covered with a glass funnel, the stem of which has been cut off near the flare, resting in a depression of the specially made cover, into which water constantly drops from a tubulated bottle, thus securing a perfect water joint, and serving to keep the bath full. Through a small metal pipe carbonic-acid gas flows into the bath above the surface of the water, and rising through orifices in the cover fills the funnel and crucible (J. P. Cooke, *Amer. Journ Sci.*, 1867, Second Series, vol. xliv., p. 347). The lamp under the bath is lighted, and hydrofluoric acid is poured into the crucible through a platinum funnel, which is left in place to serve as an occasional stirrer, for which a rod or wire may be substituted. After boiling commences the rapid gas current can be safely interrupted, to be restored when the lamp is extinguished after one-half to one or more hours. A full stream of cold water is then caused to flow from the tubulated bottle into the bath, the overflow from the outlet tube being caught in a receiver. As soon as cool the contents of the crucible are emptied into a platinum

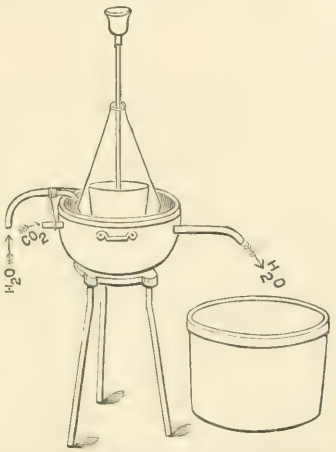

FIG. 13.—COOKE'S APPARATUS FOR THE DETERMINATION OF FERROUS IRON.

dish containing cold water, and titrated till the first permanent colour appears, which usually will last for only a few seconds. Duplicate determinations are to be advised whenever possible, since even with the utmost care the results will occasionally differ more than is allowable.

In absence of a suitable water-bath an ordinary one can be used covered with a beaker, through a hole in the bottom of which a strong current of carbon dioxide is introduced, or the crucible may be set in a sand-bath, and covered in the same way with a broken beaker (Doelter).

The cause of the rapid disappearance of the first pink blush when titrating in hydrofluoric-sulphuric solution appears to be the ready oxidisability of manganous fluoride by permanganate. The latter can be added by the cubic centimetre to solutions already containing manganous sulphate in presence of hydrofluoric acid without producing a more than passing pink blush. The solution, however, takes on in ever-increasing intensity the red-brown colour characteristic of manganic salts. The decolorisation due to this cause is hence much more pronounced in the case of rocks high in ferrous iron than of those low in this

constituent, because of the greater amount of manganous salt resulting from reduction of a correspondingly larger amount of permanganate.

When pyrite is present the bleaching is in part due to its action on any permanganate added in excess of the requirements of the ferrous oxide. But this action is not so immediate as to affect the ferrous oxide determination if the end point in the latter has been properly observed.

Pratt's Modification of the Hydrofluoric Acid Method.

J. H. Pratt (*Amer. Journ. Sci.*, 1894, Third Series, vol. xlviii., p. 149), has shown that very satisfactory ferrous iron determinations can be secured by simple boiling of the rock powder with hydrofluoric and sulphuric acids in a large crucible fitted with a cover and platinum tube for introduction of carbon dioxide. His test experiments on ferrous sulphate show that there need be practically no oxidation, even if the heating lasts several hours. The directions given on page 150 of his paper, with reference to the treatment of very refractory minerals which are not fully decomposed by this treatment, must be understood as referring only to homogeneous minerals, and not to rocks, where the relations of ferrous and ferric iron in the undecomposed portion are certainly different from those in the part dissolved.

Influence of Sulphides, Vanadium, and Carbonaceous Matter on the Determination of Ferrous Iron by the Hydrofluoric Acid Method.

A dark colour of the undissolved residue may be due to pyrite, graphite, or carbonaceous matter. The first of these affects the result but little, the second probably not at all, and they can be distinguished by their behaviour toward nitric acid. Organic matter of course renders impossible the estimation of ferrous iron.

Sulphides.—Pyrite in the quantities usually met with in igneous rocks, is probably without serious effect on the ferrous-iron determination by any of the hydrofluoric acid methods. This sulphide is very resistant toward attack in the absence of oxygen, as is shown by the fact that if present in any quantity it can be readily recognised in the residue after titration. In any case it is impossible to allow for an error introduced by its possible decomposition, and the result of titration must count as ferrous iron. In the case of soluble sulphides two sources of error are introduced—that of reduction of ferric iron by hydrogen sulphide evolved, and that due to the ferrous iron which the sulphides themselves may contain, especially if pyrrhotite is present. The first of these is perhaps negligible, since most of the hydrogen sulphide would probably be expelled without reducing iron. The second is approximately measurable if it is known that pyrrhotite is the only soluble sulphide present, and its amount has been ascertained by determining the hydrogen sulphide set free on boiling with hydrochloric acid in a current of carbon dioxide. In this case a correction is to be applied to the result of titration for total ferrous iron. See also *prox.*, under "Sulphur."

In order to obtain quantitative data regarding the effect of pyrite on the ferrous-iron estimation by the hydrofluoric acid method the following tests were recently made:—Part of a fine crystal of pyrite was rather finely powdered and boiled with dilute sulphuric acid, which extracted considerable ferrous iron, derived presumably from admixed or intergrown pyrrhotite, since a second boiling with fresh acid gave a negative test for ferrous iron. After washing by decantation with water, followed by alcohol and ether, the powder was dried and further pulverised. A quarter of a grm. of it when treated with hydrofluoric and sulphuric acids in a large crucible by the Cooke method for ferrous iron, then rapidly filtered through a very large perforated platinum cone fitted with filter-paper, required but 2 drops of a permanganate solution representing only 0·0032 grm. FeO to the c.c.

Since, however, Dr. H. N. Stokes has found in a pending investigation that the oxidising effect of ferric salts on pyrite and other sulphides is vastly greater than seems to have been suspected (see p. 218), the following tests were made in order to ascertain the probable error due to this action under the conditions prevailing in rock analysis:—Successive portions of 1 grm. each of a hornblende-schist, free from sulphur, and carrying 10·09 per cent FeO as the mean of several determinations, and 4·00 per cent Fe_2O_3, were mixed in a large (50 c.m.³) platinum crucible with 0·02, 0·025, and 0·10 grm., respectively, of the above purified pyrite powder, and treated with hydrofluoric and sulphuric acids by the Cooke method, the water-bath being at boiling heat for one hour. The cooled contents of the crucible were poured into a platinum dish containing water, and titrated rapidly nearly to an end. Then, in order to get rid of the pyrite, which would obscure the end reaction by its reducing effect on the permanganate, the solution was filtered as above, and in the clear filtrate the titration was carried to completion. The results were 10·02, 10·16, and 10·70. Inasmuch as the smallest of these three charges of pyrite was several times greater than what may be considered an unusually high amount for an igneous rock, it is very evident that for all practical purposes the influence of pyrite on the ferrous estimation by the Cooke method is negligible. At the same time it is to be borne in mind that with increased content in ferric iron an increased amount of pyrite will be attacked, and that the extent of this attack is undoubtedly influenced by the degree of fineness of the pyrite powder.

Vanadium.—If vanadium, when present, exists in the trivalent condition, it necessarily affects with an error varying with its amount the result of titration for ferrous iron. Knowing the amount of vanadium a correction can be applied as follows:—One molecule of V_2O_3 (150·8) in oxidising to V_2O_5 requires as much oxygen as four molecules of FeO (288) when oxidised to Fe_2O_3. The proportion, 150·8 : 288 :: V_2O_3 present : x, therefore gives the figure to be deducted from the uncorrected value for FeO. That this correction is very needful with many of the basic rocks becomes at once evident from the following perhaps extreme example.—

Found 2·50 per cent apparent FeO in a rock containing 0·13 per cent V_2O_3.
Deduct 0·25 per cent FeO equivalent in its action on $KMnO_4$ to 0·13 V_2O_3.
Leaving 2·25 per cent FeO corrected.
Found 5·00 per cent apparent total iron as Fe_2O_3 in the same rock.
Deduct 0·14 per cent Fe_2O_3 corresponding to 0·13 per cent V_2O_3.
Leaving 4·86 per cent corrected total iron as Fe_2O_3.
Deduct 2·50 per cent Fe_2O_3 equivalent to 2·25 per cent FeO.
Leaving 2·36 per cent Fe_2O_3 in the rock.

Failure to correct for the vanadium in both cases would have made the figures for FeO and Fe_2O_3, respectively, 2·50 and 2·22 instead of 2·25 and 2·36 as shown above.

Carbonaceous Matter. — As said before, matter of organic origin other than graphitic carbon renders the results of the ferrous iron determination altogether unreliable.

Uncertainties of the Ferrous Iron Determination.

From the foregoing it is apparent that, despite the utmost care in practical manipulation, the exact estimation of ferrous iron in rocks is one fraught with extraordinary difficulties and uncertainties. Only in absence of decomposable sulphides, and when the amount and condition of vanadium are known, can the result be regarded as above suspicion.

(To be continued).

THE VOLUMETRIC ESTIMATION OF COPPER AS THE OXALATE, WITH SEPARATION FROM CADMIUM, ARSENIC, TIN, AND ZINC.*

By CHARLES A. PETERS.

It is a well-known fact that copper oxalate is insoluble in water and scarcely attacked by moderate amounts of dilute nitric acid (Storer, "Dictionary of Chemical Solubilities," p. 463). Upon this fact Bournemann (*Chem. Zeit.*, xxiii., 565) has recently based a method for the separation of copper from cadmium by precipitating copper as the oxalate in the presence of nitric acid, filtering hot, and estimating the copper, after ignition, by any of the well-known gravimetric methods. Six to 10 grms. of copper, as the oxide, were used for a single determination, and the errors were large. Bournemann does not recommend this process as an accurate analytical method. Classen (*Ber.*, x., *b*, 1316) describes a method for the separation of metals as oxalates by adding to the solution of the salt of the metals a dilute solution of the potassium oxalate (1:6) and concentrated acetic acid to 80 per cent of the total volume. Regarding copper salts in particular, Classen states that precipitation takes place only in dilute solution and then not completely.

It has been the experience of the writer, that the precipitation of copper oxalate from solutions containing at least 0·0128 grm. of the oxide and saturated with the oxalic acid is practically complete. The filtrate in such cases gives no blue colour with ammonia, looking down on a column of liquid in a test-tube, and only a faint brown colour is developed when the filtrate is neutralised, made acid with acetic acid, and tested with potassium ferrocyanide. It is the object of this paper to show that moderate amounts of copper may be determined quantitatively as the oxalate by precipitation with oxalic acid and titration of the precipitate by potassium permanganate, and also to show that moderate amounts of copper may be separated from other metals in the presence of nitric acid by the addition of considerable amounts of oxalic acid.

Before attempting the quantitative separation of copper from solution by the addition of oxalic acid, a few qualitative experiments upon the precipitation of varying amounts of copper sulphate by varying amounts of oxalic acid were tried at different dilutions. In all the experiments the mixtures stood sixteen to twenty hours, and were filtered from two to four times through four filters folded together, and the filtrates were tested both with ammonia and with potassium ferrocyanide. In cases where the filtrate gave no blue colour with ammonia and only a slight precipitate with ferrocyanide, the precipitation was considered practically complete, and the conditions were regarded suitable for the trial of the method quantitatively. In Table I. is recorded the work upon the precipitation of copper sulphate by 0·5 grm., 1·0 grm., and 2·0 grms. of oxalic acid in 50 c.m.³ of solution.

It will be seen readily by comparison of the right

* Precipitate re-dissolved.

† Precipitate remained.

and left hand sides of Table I. that somewhat smaller amounts of copper may be precipitated completely by the addition of crystallised oxalic acid than by the same amount of oxalic acid already in solution. Thus, when dissolved oxalic acid is added to the solution of 50 c.m.³ amounts of copper sulphate less than 0·040—0·050 grm. are not precipitated completely, while under conditions otherwise the same excepting that the oxalic acid is added in crystalline form, the precipitation of amounts as small as 0·030 grm. is practically complete. The amount of oxalic acid in solution necessary for the complete precipitation (after sixteen to twenty hours) of this minimum amount of copper, 0·031 grm. of copper oxide taken as the sulphate, appears, as shown in Table II., A, which follows, to be about 3·5 grms. in 50·0 c.m.³. If the amount of oxalic acid is increased to 5 grms., making the solution saturated for that substance, using the same volume of liquid, the minimum amount completely precipitable is reduced to 0·0128 grm., but not to one-half that amount.

It appears from the experiments of Table II., B, that the volume of liquid in which precipitation takes place influences the complete precipitation of the copper oxalate. Thus the precipitation of 0·0064 grm. of copper oxide taken as the sulphate by 0·5 grm. of oxalic acid is complete in 5 c.m.³ of liquid. The precipitate which falls from 0·0003 grm. of the oxide taken as the sulphate dissolves in 5 c.m.³ of liquid, but remains visible in 1 c.m.³.

As a result of the preliminary experiments, it may be said that the presence of a certain minimum amount of copper, varying with the conditions, is essential to complete precipitation. Thus, at a dilution of 50 c.m.³ a saturated solution of oxalic acid will precipitate with practical completeness copper taken as the sulphate in amounts exceeding the equivalent of 0·0128 grm. of copper oxide; that 2·0 grms. of oxalic acid will precipitate almost completely for the same volume of solution the equivalent of 0·03 grm. of copper oxide; and that 1·0 grm or 0·5 grm. of oxalic acid will precipitate the equivalent of 0·064 grm. of the oxide.

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Ordinary Meeting, April 18th, 1901.

Prof. EMERSON REYNOLDS, F.R.S., President, in the Chair.

(Concluded from p. 214).

61. "*Preparation of Orthodimethoxybenzoin, and a New Method of Preparing Salicylaldehyde Methyl Ether.*" By J. C. IRVINE, B.Sc.

The author described a new and rapid method of obtaining salicylaldehyde methyl ether. A mixture of salicylaldehyde and methyl iodide reacts energetically with dry silver oxide, giving a brown oil, from which a 90 per cent yield of the pure product is obtained on distillation. The product (b. p. 236—238°) readily solidifies to a crystalline mass melting at 39—40°. On boiling with potassium cyanide in alcoholic solution, this substance may be condensed to *o*-dimethoxybenzoin, a yellow, crystalline solid melting at 101·5°. A notable reaction of this benzoin is its quantitative conversion into the corresponding methyl ether by the action of silver oxide and methyl iodide. This substance crystallises from ether in prisms melting at 59—60°.

62. "*Action of Hydroxylamine on the Anhydrides of Bromonitrocamphane.*" By M. O. FORSTER.

The compound $C_{10}H_{17}O_2N_2Br$, obtained by the action of hydroxylamine on the anhydrides of 1 : 1-bromonitrocamphane, crystalliises from alcohol in rectangular plates, and melts at 197°; it reduces ferric chloride and ammoniacal silver nitrate. The *hydrochloride, sulphate, picrate, platinichloride,* and the *carbamide* and *benzoyl* derivatives are well-defined. When nitrous acid acts on the substance, the anhydride melting at 240° is regenerated, and potassium permanganate oxidises it to the compound $C_{10}H_{14}O_2NBr$.

The compound $C_{10}H_{16}O_2N_2$, produced by the action of aqueous sodium hydroxide on the foregoing hydroxylamino-derivative, crystallises in rhomboidal plates, and melts at 208°; the *picrate* and *platinichloride* are well-defined.

63. "*On the Estimation of Cocaine and on Di-iodococaine Hydriodide.*" By W. GARSED and J. N. COLLIE, F.R.S.

The object of this research was to find a method for the fairly accurate estimation of cocaine in small quantity.

The estimation of cocaine in presence of cinnamyl cocaine and isatroypl cocaine, and other substances, with which it is associated in coca leaves, has not been attemped, the method only dealing with the estimation of cocaine when free or mixed with benzoyl ecgonine and ecgonine, the products of hydrolysis of pure cocaine. When a solution of cocaine in the form of a salt containing about 1 per cent of cocaine base is titrated by adding excess of decinormal iodine solution till the supernatant liquid contains excess of iodine, a precipitate of di-iodo-cocaine hydriodide, $C_{17}H_{21}NO_4HII_2$, is formed. The excess of iodine in solution can then be estimated by a decinormal sodium thiosulphate solution. The precipitated di-iodo-compound can be collected and weighed, or the cocaine estimated by the amount of iodine used. Any cocaine salt can be used, since the potassium iodide in the solution reacts with the salt, producing the iodide. Di-iodo-cocaine hydriodide is a remarkably stable and crystalline compound, crystallising in large, glistening crystals of constant composition.

Cocaine can be estimated in presence of ecgonine, as ecgonine forms a soluble iodo-compound.

Benzoyl ecgonine, however, interferes to a considerable extent with the estimation of cocaine. Making use of the fact that both benzoyl ecgonine and ecgonine are insoluble in ether or light petroleum, a separation can be effected, as cocaine is soluble in both these solvents. The extracted cocaine can then be weighed directly or titrated with iodine.

64. "*Note on Acetonylacetone.*" By T. GRAY.

The density (0·973) and refractive index (1·4232) of acetonylacetone purified by conversion into the bisulphite compound, $C_6H_{10}O_2,2NaHSO_3+H_2O$, and regeneration therefrom, were determined, and the molecular refraction $\mathfrak{M}_D = 29·85$ found to agree with the value required by the "keto"-formula. Attention was directed to the readiness with which acetonylacetone is resinified by alkalis, by concentrated sulphuric acid, and by gaseous hydrochloric acid.

65. "*Condensation of Acetonylacetone with Hydrazine Hydrate.*" By T. GRAY.

The products of the interaction of acetonylacetone and hydrazine hydrate were described. Condensation in molecular proportions results in the formation of a base, $C_{12}H_{20}N_4$, b. p. 157—158° at 13 m.m., which readily oxidises in air; it forms a hydrochloride, $C_{12}H_{20}N_4,2HCl$, and a chloroplatinate, $C_{12}H_{20}N_4H_2PtCl_6$. The product of the reaction of the ketone with excess of hydrazine hydrate is a white, crystalline substance having the formula $C_{12}H_{24}N_6$, m. p. 130—132°. The substance gradually undergoes decomposition at the ordinary temperature, is a powerful reducing agent, and is readily decomposed by dilute acids with formation of hydrazine salts.

66. "*Preparation of Synthetical Glucosides.*" By H. RYAN, M.A., D.Sc., and W. S. MILLS, M.A.

Acetochlorogalactose was obtained as a faint yellow, semi-solid syrup slowly soluble in cold alcohol, hot

ligroin, ether, and chloroform, scarcely soluble in cold ligroin, by the action of acetyl chloride on well-dried galactose in a dry, cooled, sealed tube. It was extracted with chloroform, washed with iced water and cold sodium carbonate solution; the chloroform solution, dried with calcium chloride and evaporated in a vacuum, left acetochlorogalactose.

By the action of α-naphthol and potassium hydroxide on acetochlorogalactose in alcoholic solution *α-naphthylgalactoside* ($C_6H_{11}O_5{\cdot}O{\cdot}C_{10}H_7$) was obtained as rectangular plates soluble in hot alcohol and hot water, slightly soluble in cold water, insoluble in ether, chloroform, benzene, and ethyl acetate. It reduces Fehling's solution after inversion by hot dilute sulphuric acid. The galactoside does not dissolve in dilute potash, and melts at 202—203°.

m-*Cresylglucoside* was obtained from acetochloroglucose and *m*-cresol in alkaline solution as long, silky, branching needles, scarcely soluble in benzene, chloroform, ethyl acetate, and carbon bisulphide, soluble in cold water and alcohol, readily soluble in hot water and alcohol. It reduces Fehling's solution only after hydrolysis by dilute sulphuric acid, m. p. 167·5—168·5°.

The carvacryl glucoside already prepared from acetochloroglucose was obtained from carvacrol potash and acetobromoglucose prepared by the method of Königs.

67. "*The Influence of Cane Sugar on the Conductivities of Solutions of Potassium Chloride, Hydrogen Chloride, and Potassium Hydroxide; with Evidence of Salt Formation in the last Case.*" By C. J. MARTIN and O. MASSON.

Sugar-solution is generally considered to be a non-electrolyte, but in view of the fact that saccharates exist, it may more probably be viewed as a very slightly ionised acid. To test this point, the conductivities of solutions of hydrogen chloride and of potassium chloride containing varying amounts of sugar were determined, and it was found that the conductivity did not appreciably differ from that of aqueous solutions of these compounds, except in so far as the viscosity of the sugar solution had to be allowed for. On the other hand, when sodium hydroxide was added to sugar solutions of different strengths, it was obvious that the sugar took part in the conduction, and this is attributable to the formation of sodium saccharate, which, like other salts, is largely ionised in dilute solution. The conductivity, even in this last case, was of course influenced by the viscosity of the sugar solution, but even after allowing for this, the proof of ionisation was unmistakable.

68. "*The Aluminium-mercury Couple.* Part III. *Chlorination of Aromatic Hydrocarbons in presence of the Couple. The Constitution of the Dichlorotoluenes.*" By J. B. COHEN and H. D. DAKIN.

The authors have continued their investigation on the action of the aluminium-mercury couple as a halogen carrier in the preparation of the chlorine derivatives of the aromatic hydrocarbons. They have obtained in this way a series of chlorobenzenes from mono- to hexa-chlorobenzene as well as mono-, di-, and tri-chlorotoluenes. Their work, was, however, chiefly devoted to the identification of the dichlorotoluenes formed by this process, a subject which has been under investigation since 1866, with very conflicting results. By careful fractional crystallisation of the following solid derivatives of the mixed dichlorotoluenes, nitro-, dinitro-, sulphonic acids and salts, sulphonic chlorides and amides, and the dichlorobenzoic acids obtained by oxidation, and by a comparison of these with the same derivatives of the six isomeric dichlorotoluenes which they have prepared in a pure state, the authors have now proved that four, namely, (CH_3=1), 1:2:3, 1:2:4, 1:2:6, and 1:3:4, and very probably 1:2:5 dichlorotoluenes are formed in this reaction. The authors propose to investigate the dibromotoluenes in the same manner, as no very satisfactory evidence has been given of the nature of the mixture formed by brominating toluene.

69. "*A Modification of Gutzeit's Test for Arsenic.*" By E. DOWZARD.

An apparatus to free the gas from hydrogen sulphide, &c., by washing was described along with a series of experiments, which show that lead acetate solution only absorbs hydrogen sulphide, whilst a 15 per cent solution of cuprous chloride in hydrochloric acid absorbs hydrogen sulphide, stibine, and phosphine, but has no effect on arsine.

70. "*On the Chemistry of 'Nerium Odorum.'*" By R. C. L. BOSE, M.B.

In his investigations on the poisonous constituents of *Nerium odorum*, the sweet-scented oleander, two methods of analysis of the roots were employed by the author, namely, that adopted by Greenish (*Pharm. Journ.*, 1881, [iii.], xi., 873), with certain modifications, and the method of plant analysis of Dragendorff. A third active constituent, besides the two already discovered in the root by Greenish, neriodorein and neriodorin, has thus been discovered, and named *karabin*, from *karabi*, the Bengali name of the plant.

The root gave the following percentages of the different extracts by Dragendorff's method:—Light petroleum extract, 2·88; ether extract, 1·38; absolute alcoholic extract, 3·40; aqueous extract, 5·81 per cent.

The ether extract was found to contain the *karabin*. This extract was partly soluble in absolute alcohol, giving a clear yellow solution, and on being evaporated to dryness left a brownish-yellow, sticky residue, *karabin*, which, on analysis, gave numbers corresponding to the formula $C_{21}H_{40}O_6$.

The alcoholic extract contained a substance identified as the neriodorin, and the aqueous extract contained the neriodorein. Neriodorein is readily soluble in water, neriodorein in boiling water only, while *karabin* is insoluble both in cold and boiling water. Neriodorein and neriordorin are insoluble in ether and benzene, but *karabin* dissolves readily in both. The colour reactions with concentrated sulphuric acid are also distinctive.

The author was also able to separate *karabin* by employing the following modification of Greenish's plan of analysis. The acidified aqueous solution of the alcoholic extract of the root was first shaken up with light petroleum, which removed a quantity of a viscid yellowish, oily substance. After the separation from the light petroleum, the solution was next agitated with ether *instead of chloroform*. The ethereal solution on evaporation left a brownish-yellow residue which gave all the reactions of *karabin*. The acidified fluid was next agitated with chloroform, which caused the separation of some oily looking globules which floated between the two layers of fluids; these were separated, washed, and evaporated to dryness; the residue gave all the reactions of neriodorein. The chloroform solution was then separated, and on evaporation left a golden-yellow brittle residue which satisfied all the tests for neriodorin.

The author considers that neriodorin is a variety of saponin. Neriodorein is very readily soluble in water, forming a pale yellow solution of neutral reaction which froths considerably on agitation. It has the acrid taste of saponin, and satisfied most of the tests for this widely distributed substance. It also closely resembles, in its behaviour with certain reagents, the variety of saponin described by the author and Warden (*Pharm. Journ.*, 1882, [iii.], xii., 302).

The author believes that both neriodorin and karabin are not glucosides, but possess the characters of a resin; neither contains nitrogen.

71. "*Change and Interaction in Organic Compounds.*" By A. LAPWORTH.

The apparently very general law to which the author has recently endeavoured to draw attention (*Proc.*, xvii., 2), receives a very simple explanation if it be supposed that isomeric change is due to dissociation and that *the dissociation between two atoms which leads to change in organic compounds exists, in general, only once in the*

molecule at any instant. Such a view leads to the $\alpha\gamma$- and $\alpha\beta$-rules, whether the labile group in an isomeric change never leaves the molecule as previously suggested (*Trans.*, 1898, lxxiii., 448), or whether ionisation occurs, for the above law holds true for weak electrolytes. In the author's opinion, therefore, the cause of change in general in organic compounds is probably to be sought for in a dissociation resembling ionisation, doubtless often in very small amount, a view arrived at independently of Euler (*Ber.*, 1900, xxxiii., 3202), and Zengelis (*Ber.*, 1901, xxxiv., 198), who used a similar assumption in order to explain the phenomena of hydrolysis and etherification.

The influence of a catalytic agent might be of very varying character, and can only be properly discussed in reference to particular cases. It may not only increase the velocity of change by raising the concentration of ions representing a labile group in isomeric change, or remove certain ions from the sphere of action by converting them into undissociated compounds, a suggestion which has been made by Euler and Zengelis, but, what is of equal importance, it may convert a molecule into an individual possessing the properties of a dissociated group or ion by supplying simpler groups with which it may unite, a process analogous to the formation of a complex ion by union of a simple ion with a neutral component (compare Abegg and Bödlander, *Zeit. Anorg. Chem.*, 1899, xx., 453).

It is to be observed that a molecule may also become a dissociated group by union with a dissociated part of a substance directly concerned in an interaction.

The atom from which a group has been removed will, of course, have an apparent valency of one unit less than that which it has in an undissociated compound; such an atom may be said to be "*subvalent*," or to represent a position of "*subvalency*." Whilst the atoms within a dissociated group will not change their relative positions in any way, the position of "subvalency" may conceivably be altered by a slight re-adjustment of the mutually attractive forces between the atoms; the removal of a group from one already dissociated does not mean a double dissociation, but the transference of the subvalency (and charge) to that group, and is analogous to the conversion of a complex ion into a simple ion and a neutral component. Perhaps, therefore, the above law should be stated—*No alteration of the relative positions of the atoms in a dissociated group can take place, and as a rule only one position of subvalency exists in such a group at any instant; in other words, it is usually subvalent.*

By means of the conception, the following rule may be deduced for some cases of interaction. If, during a reaction, a group M might be expected to become associated, even momentarily, with an atom R_α in the complex, $\cdot R_\alpha \cdot R_\beta : R_\gamma$, then the product may contain, not only substances with the grouping $R_\alpha M.R_\beta : R_\gamma$, but also, and sometimes exclusively, those with the grouping, $R_\alpha : R_\beta \cdot R_\gamma M$, or their tautomeric forms.

This rule at once gives some reason for the simultaneous formation of *ortho-* and *para*-derivatives when substitution occurs in a benzene mono-derivative, and for the similar but more complicated phenomena in the naphthalene series. Certain equations of considerable interest and importance may also be deduced. For example, if $X \cdot Y + A:B = AX \cdot BY$ is a possible reaction, then, expanding in terms of the rule, we obtain the following possibilities:—

$$X \cdot Y + A:B_\alpha \cdot B_\beta : B_\gamma = AX \cdot B_\alpha : B_\beta \cdot B_\gamma \quad .. \quad .. \quad .. \quad .. \quad (R)$$

at once recognisable as the form to which so much importance has been attached by Thiele.

$$X \cdot Y_\alpha \cdot Y_\beta : Y_\gamma + A:B = AX \cdot BY_\gamma \cdot Y_\beta : Y_\alpha \quad .. \quad .. \quad .. \quad .. \quad (S)$$

a form which is not translatable in terms of Thiele's rule. It is probably the basis of the Claisen reaction, the reactions between aldehydes and phenols, or the alkali salts of isonitro-compounds, and the change which occurs when *o*-acetylacetoacetic ester is converted into diacetylacetic ester by a trace of alkali. Expanding both B and Y, we obtain the form—

$$X \cdot Y_\alpha \cdot Y_\beta : Y_\gamma + A:B_\alpha \cdot B_\beta : B_\gamma = AX \cdot B_\alpha : B_\beta \cdot B_\gamma \cdot Y_\gamma \cdot Y_\beta : Y_\alpha \quad (T)$$

which finds examples in the interactions of ethyl sodio acetoacetate, malonate, cyanacetate, &c. (*iso*-forms), or $\alpha\beta$-unsaturated esters and ketones. In the above examples, X = K or Na, and $Y_\alpha = O$.

72. "*The Mechanism of the Claisen Reaction.*" By A. Lapworth.

The author takes the following view of this reaction in its simplest form:—

(1). A sodium ion unites with the carbonyl group of the ketone or ester to form a subvalent group which then loses a hydrogen ion,—

$$\dot{N}a + O:CR^1 \cdot CH_2R^2 \rightarrow Na \cdot O \cdot \dot{C}R^1 \cdot CH_2R^2 \rightarrow$$
$$\rightarrow Na \cdot O \cdot CR^1 : CHR^2 + \dot{H}.$$

The apparently direct replacement of a hydrogen atom in many esters, ketones, or even hydrocarbons (Thiele, *Ber.*, 1901, xxxiv., 68) is probably to be ascribed to the same cause; the reaction with hydrocarbons may be represented,—

$$\dot{K} + CR_2 : CR \cdot CHR_2 \rightarrow CR_2K \cdot \dot{C}R \cdot CHR_2 \rightarrow$$
$$\rightarrow CR_2K \cdot CR : CR_2 + \dot{H},$$

or, another possible type,—

$$CHR : CR_2 + \dot{K} \rightarrow CHRK \cdot \dot{C}R_2 \rightarrow CRK : CR_2 + \dot{H}.$$

(2). The metallic derivative then dissociates, part reacting with a subvalent group—produced by union of a sodium ion with ethyl oxalate, formate, &c.—as roughly represented by equation S (see preceding abstract).

$$Na \cdot O \cdot CR^1 : CHR^2 + CR^3(OEt) : O \rightarrow$$
$$\rightarrow [\dot{O} \cdot CR^1 : CHR^2 + \dot{C}R^3(OEt) \cdot ONa] \rightarrow$$
$$\rightarrow O:CR^1 \cdot CHR^2 \cdot CR^3(OEt) \cdot NaO \rightarrow$$
$$\rightarrow O:CR^1 \cdot CR_2 : CR^3 \cdot ONa + HOEt.$$

In the case of ethyl crotonate (*Proc.*, 1900, xvi., 132), the $\alpha\gamma$-rule must be applied a stage farther,—

$$Na \cdot O \cdot \overset{1}{C}(OEt) : CH \cdot CH : CH_2 + O : \overset{2}{C}(OEt) \cdot CO_2Et =$$
$$= Na \cdot O \cdot \overset{2}{C}(OEt)(CO_2Et) \cdot CH_2 \cdot CH : CH \cdot \overset{1}{C}(OEt) : O =$$
$$= Na \cdot O \cdot C(CO_2Et) : CH \cdot CH : CH \cdot CO_2Et + HOEt.$$

Exactly similar changes may be supposed to go on in the case of *o*-nitrotoluene, but here the nitro-group takes the place of the carbonyl group in the above cases. In *p*-nitrotoluene a further extension of the $\alpha\gamma$-rule is involved.

The action of hydrogen chloride in promoting the condensation of aldehydes with ketones, phenols, &c., may be ascribed to a similar series of changes, the hydrogen ions acting perhaps in this way:—

(1). $\dot{H} + O:C(CH_3) \cdot CH_3 \rightarrow H \cdot O \cdot \dot{C}(CH_3) \cdot CH_3 \rightarrow$
$\rightarrow H \cdot O \cdot C(CH_3) : CH_2 + \dot{H}.$

(2). $\dot{H} + O:CHPh \rightarrow H \cdot O \cdot \dot{C}HPh.$

(3). $\dot{O} \cdot C(CH_3) : CH_2 + \dot{C}H(OH)Ph \rightarrow$
$\rightarrow O:CMe \cdot CH_2 \cdot CH(OH)Ph \rightarrow$
$\rightarrow O:CMe \cdot CH : CHPh + HOH.$

Further experiments on diethyl oxalocrotonate (*Proc.*, 1900, xvi., 132), have strengthened the belief that it is the γ-oxalo-derivative; it has the normal molecular weight in acetic acid.

γ-Oxalocrotonic acid, $CO_2H \cdot C(OH) : CH \cdot CH \cdot CH \cdot CO_2H$, is a strong acid which is sparingly soluble in the ordinary organic media. It melts and decomposes at about 190°, being converted into α pyrone-α'-carboxylic acid. Its aqueous solution gives an intense black colour with ferric chloride which is not discharged by a large excess of hydrochloric acid.

Preliminary experiments on other $\alpha\beta$-unsaturated esters and ketones indicate that the following substances yield acidic compounds resembling ethyl oxalocrotonate: ethyl di-methylacrylate, ethyl β-chlorocrotonate, phorone, camphorone, and benzylidenemesityl oxide. The products, which have as yet been obtained only as oils, give intense

black colourations with ferric chloride; they are still under examination.

Ethyl α-methylacrylate, which does not contain the requisite grouping, gives no product of a similar kind, indicating that it is not the mere presence of the group $\cdot CH_2 \cdot C{:}C$ which is necessary.

73. "*A New Series of Di-mercuri-ammonium Salts.*" Part I. By P. C. Ray, D.Sc.

When a solution of mercuric nitrite is treated with ammonia in slight excess, a di-mercuri-ammonium nitrite of the formula $2NHg_2NO_2,H_2O$ is formed; if this compound be dissolved in hydrochloric acid, and the solution evaporated nearly to dryness, a white crystalline salt of the formula $NHg_2Cl,4HCl$ is obtained. Hydrobromic acid also yields the corresponding double bromide $NHg_2Br,4HBr$. Both haloid salts dissolve in water, and if the solutions be cautiously treated in the cold with dilute potassium hydroxide, the chloride and bromide, $2NHg_2Cl,H_2O$ and $2NHg_2Br,H_2O$, are formed respectively.

ROYAL SOCIETY CONVERSAZIONE.

On Wednesday evening last, the 8th May, a most successful Conversazione was held at the Society's Rooms at Burlington House, Piccadilly. The Fellows and Guests were received by the President, Sir William Huggins, K.C.B.

There was a large number of interesting and curious exhibits.

Mr. J. Mackenzie Davidson, M.B., showed some Stereoscopic Transparencies of Electrical Discharges. These photographs are taken by means of a small stereoscopic camera, and allow of the exact path of the discharge to be seen. In *single* photographs small bright dots are often seen, giving a "beaded" appearance. The stereoscopic views show that these "beads" are zig-zag discharges seen end-on.

A collection of Cloud Photographs by Commander D. Wilson-Barker, R.N.R., attracted some attention.

In the Council Room Mr. J. E. Barnard and Dr. Allan Macfadyen, B.Sc., &c., exhibited a number of Luminous Bacteria. These bacteria are a group of organisms, whose natural habitat is sea-water. They are the cause of the so-called phosphorescence to be seen at times on such objects as dead fish, meat, or other substances which are suitable soils for their growth and development. Their luminous properties are dependent on a supply of free oxygen, and a suitable percentage of a soluble chloride in the nutritive medium. The exhibit consists of artifical cultivations of these organisms on suitable nutrient soils, and shows their luminous properties, and the variations that occur under different physical conditions.

(1). Tube cultivations.
(2). Plate cultivations.
(3). Specimens showing illuminating power, *e.g.*, on printed matter.
(4). Influence of stream of oxygen on light production.
(5). Effect of agitation.
(6). Effect of electrolysis.

The Carl Zeiss Optical Works had several of their Stereoscopic Binocular Range-finders. This range-finder is founded on the same principle as their stereo-telescope, and is quite portable. The reading is taken direct from a scale within the instrument without calculations, giving the distances in metres. The range is from 75 to 3000 metres. The instrument can also be used for ascertaining the distance of a single light appearing only for a short time. A second scale is given by which the breadth and height of objects can be measured.

Prof. J. C. Bose's experiments on Binocular Alternation of Vision were very curious; by means of a specially made stereoscope each eye is impressed with the vision of a slanting bar of light; on closing the eyes these bars appear dark alternately—as one fades the other becomes apparent, and vice versa; this continues for some time.

A very serviceable Mechanical Interrupter for Induction Coils was shown by Dr. Dawson Turner. The contact is made and broken between two rollers immersed in paraffin; the rollers are mechanically rotated so that the burning at the break is distributed uniformly round the surfaces of contact which maintain their original form. It is adapted for working directly from the main.

Sir J. Norman Lockyer, K.C.B., exhibited some Photographs of the Spectra of *Nova Persei*. The photographs show that the spectra in the earlier stages consists of both bright and dark lines, the dark lines being displaced towards the more refrangible side of their normal positions, and indicating a great velocity of about 700 miles per second towards the earth. The bright line spectrum indicates a small movement away from the earth. The two superposed spectra indicate that *two* bodies are in question. The spectra show that as the star diminished in magnitude the continuous spectrum gradually became less intense, the bright metallic lines became fainter until the spectrum showed little more than the bright hydrogen and a few other chief lines. Details in the hydrogen lines themselves, indicating probable internal movements of the particles composing the Nova, are shown in the light curves of the hydrogen lines.

The Musical Arc exhibited by Mr. W. Duddell, and the Telegraphone, shown by the Syndicate bearing its name, both attracted a good deal of attention. The latter instrument, the invention of Mr. Poulsen, of Copenhagen, depends for its action upon the fact that the variations of the magnetic field of an electro-magnet are so accurately represented by the magnetisation of a steel-wire which is drawn through it, that if the wire be again passed through the field, currents exactly similar to those which produced the magnetisation of the wire are reproduced in the coils of the magnet. This principle has been applied to the reproduction of speech transmitted through an ordinary microphone transmitter.

During the evening three demonstrations took place in the Meeting Room. At 9.45, "Life-zones in the White Chalk," by Dr. Arthur Rowe; at 10.15, "Some Engineering Problems and their Solutions," by Mr. Francis Fox, C.E.; and at 11.0, "Kinematograph Diagrams, Illustrating Magnetic Fields," by Professor Silvanus P. Thompson.

NOTICES OF BOOKS.

Elements of Agriculture, for use in Schools. By James Bolton McBryde. Richmond, Va.: B. F. Johnson Publishing Co. 1901. Pp. 270, 12 mo.

American schoolbooks are not often reviewed in the columns of the Chemical News, but there is special propriety in naming this work, since it deals with agriculture from a scientific standpoint and its author is a chemist, having been for several years Chief Chemist of the Experiment Station at Knoxville, Tennessee, and at present connected with the Virginia Polytechnic Institute.

In the preface Mr. McBryde refers to the pressing need of agricultural instruction in the schools of the Southern States, and shows that seventy-five per cent of the seventeen million inhabitants cultivate the soil, whereas only one person in ten thousand is receiving any instruction in agriculture.

The book contains forty-six short chapters in seven parts, and gives in simple language the more important principles of scientific agriculture. Beginning with rudimentary studies of climate, plants (their composition and

manner of growth), soils (their classification and cultivation), manure and fertilisers, farm crops, animal production (stock foods, &c.), he writes in final chapters of the useful parts played by birds and by insects, of the care of forest trees, and the making of good roads, the importance of which he demonstrates. A pleasant feature of the book is the excellent manner in which abstract science is gradually introduced in the simplest language; the fundamental facts of chemistry and of botany are given, but these words themselves do not appear, so that the pupil is scarcely aware that he is studying these sciences.

In adapting chemical language to the comprehension of beginners the author rarely errs, but the reviewer does object to the use of the word "part" where atom is meant; on page 64 "CO_2" is said to signify "one part of carbon and two parts of oxygen." We imagine the author felt the difficulty himself, for in the very next sentence he accidentally gives the formula for water as "HO_2," and says this indicates "two parts of hydrogen and one part of oxygen." This small blemish can be corrected in a second edition.

The book contains a great many important truths, and corrects a number of prejudices and errors; it is intensely practical, constantly placing before the student the all-important "dollar and cent" question. Many of the statements are illustrated by facts drawn from personal experience, as well as from reports of high authorities.

As an introduction of the study of agriculture the work possesses great merit, and though primarily written for the southern portion of the United States it could be advantageously used in the Colonies of Great Britain and Ireland for the instruction of young classes, the members of which would find around them opportunities for supplementing the text by their own observations, as recommended by the author.

The book is well printed and illustrated with neat engravings; the proof-reading is generally clean, but on page 234 an amusing blunder occurs—for "Biographical Survey of the Department of Agriculture" read "Biological Survey." There is an index. H.C.B.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Note.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. cxxxii., No. 15, April 15, 1901.

New Researches on the Action of Hydrogen Peroxide on Silver Oxide.—M. Berthelot.—Hydrogen peroxide, when acting on silver oxide under certain conditions, forms first a dioxide, Ag_2O_2, which is extremely unstable, $Ag_2O+H_2O_2=Ag_2O_2+H_2O$. This equation represents the first phase of the phenomenon. This dioxide decomposes almost immediately, giving rise to two simultaneous reactions. A portion is resolved directly into silver and oxygen, $Ag_2O_2=Ag_2+O_2$, whilst another portion of the dioxide is decomposed in a less complete manner, being resolved into oxygen and silver protoxide; the latter combining with a further portion of the dioxide, $\left\{\begin{array}{l} Ag_2O_2 = Ag_2O + O \\ Ag_2O_2 + Ag_2O = Ag_4O_3 \end{array}\right.$. The following equation represents the second phase of the reaction:—$3Ag_2O+3H_2O_2=Ag_4O_3+Ag_2+O_2$. Unless great precautions are taken, the Ag_4O_3 decomposes spontaneously into Ag_2O and oxygen. The author examines all these reactions thermochemically.

Action of Radium Rays on Selenium.—Eugène Bloch.—In 1873, W. Smith discovered that the electric resistance of selenium diminished under the action of light. M. Perreau has generalised this property by showing that the Röntgen rays produce on selenium an action similar to that of light. The author examines the action of the rays from the new radio-active substances on selenium, and finds that the action of the rays of radium on selenium is of the same order of magnitude as the two preceding actions, though it is somewhat more slow. A selenium wire possessing at first a normal resistance of about 654,000 ω, fell in ten minutes to 640,000 ω under the action of the rays from radium; this being scarcely less than the effect of very feeble diffused light.

Examination of the Alkaloids by Micro-chemical Methods.—E. Pozzi-Escot.—The author's experiments were carried out on sulphate of strychnine, chlorohydrate of cocaine, brucine, sulphate of atropine, chlorohydrate of morphine, codeine, and sulphate of quinine. One per cent solutions, or saturated solutions in the case of slightly soluble alkaloids, were treated with picric acid on a glass slip and then examined with the microscope. The only picrate which was particularly characteristic was that of strychnine. As for the others, contrary to the statements of M. Popoff, the crystallisation took place with difficulty, and the crystals were ill-defined and not characteristic. The author therefore concludes that picric acid, the general reagent for alkaloids, has not the value as a micro-chemical reagent which M. Popoff has attributed to it.

Bulletin de la Société Chimique de Paris.
Series 3, Vol. xxv., No. 1.

Measurement of the Speed of the Evolution of Gases. Application to the Voltameter.—André Job.—A test-glass with a foot is closed by means of a cork pierced with three holes, two of these holes are for the passage of the wires holding cylindrical electrodes of iron or nickel. The electrolyte is a 15 per cent solution of soda. The gas which is given off when the current passes goes through a tube with two arms; at one end a water manometer is adjusted, and at the end of the other arm there is fixed a piece of capillary thermometer tubing. When the current is made to pass, gas is given off, and we know from Graham's work on the transpiration of gases that, if the capillary tube is sufficiently long, the excess of pressure shown by the manometer will be proportional to the quantity of gas coming off; it will, therefore, at the same time, be proportional to the intensity (quantity) of the current. Thus we have a true ampèremeter.

New Method for the Separation of the Rare Metals which accompany Platinum.—E. Leidié.—Already inserted in full.

Action of Formate of Amyl on Cyanacetic Soda Ether.—E. Grégoire de Bollemont.—A mixture of 20 grms. of dry cyanacetic soda ether and 34 or 35 grms. of formate of amyl is heated for three hours on the water-bath in a flask fitted with a vertical condenser. The mass, which is colourless at first, becomes orange and then red, and changes into a thick liquid. The secondary products and the unacted on formate are eliminated by distillation *in vacuo*. The residue consists of a crystalline powder impregnated and coloured by certain very abundant oils, which are easily separated after adding boiling water. The aqueous solution, supposed to contain the sodium salt of formylcyanacetic ether, was decomposed by dilute sulphuric acid with the object of isolating the free ether. In this way a yellow oil was separated, which, when taken up with ether, dried over anhydrous sulphate of soda, and rectified *in vacuo*, gave hardly anything else than products of decomposition with abundant carbonaceous residues. There was, however, a trace of a well-crystallised body which distilled over at about 160° under 22 m.m., but it could not be obtained in a pure state.

Ethoxy- and Methoxymethene-cyanacetic Ethers.—E. Grégoire de Bollemont.

Oxymethene-cyanacetic Ethers.—E. Grégoire de Bollemont.

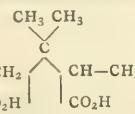
Action of Ammonia and Aniline on the Oxymethenecyanacetic Ethers and their Alcoylised Derivatives.—E. Grégoire de Bollemont.—Three very long papers, not suitable for abstraction.

On the Acid Suphuric Ethers of the Phenols.—Albert Verley.—The author has examined a general method for preparing these derivatives, especially those of eugenol, iso-eugenol, and vanilline. As a typical example, he describes the preparation of these latter derivatives and their application to the manufacture of vanilline.

Researches on the Tautomery of *o*-Benzoyl-benzoic Acid.—A. Haller and A. Guyot.—A consideration as to the correct formula for *o*-benzoyl-benzoic acid, in which the views of many other authors are discussed.

Separation of some Amidised Acids and their Active Components.—E. Fischer and A. Mouneyrat.—Not suitable for abstraction.

Experiments on the Synthesis of $\alpha\beta\beta$-Trimethylglutaric Acid.—G. Blanc.—The object of this research was to prepare synthetically $\alpha\beta\beta$-trimethylglutaric acid—



by a different method to that employed by W. H. Perkin and J. F. Thorpe (*Proc. Chem. Soc.*, 1899, p. 61). This result, however, was not achieved, but the synthesis was effected of a lactonic acid, $C_8H_{12}O_4$, which is of some interest from the point of view of the constitution of camphoric acid.

The Constitution of Camphoric Acid, and on one of the Migrations effected in its Molecule.—G. Blanc.—Already noticed.

Action of Bromine on Cinchonidine, and on two Bibromocinchonidine Isomers, α and β.—J. Galimard.—Using a method devised by M. Causse, the authors have attempted to bromise cinchonidine by the action of bromine in solution in hydrobromic acid. This process has given them two isomeric bromised derivatives, bibromocinchonidine α and bibromocinchonidine β, whose properties are here described.

Method of Analysis for the Estimation of Dextrose and Dextrin in Commercial Glucoses.—L. Lindet.—To estimate dextrose in the presence of dextrin, we can take the rotation of the mixture of the dissolved bodies, subtract from this the rotation given by dextrose to Fehling's solution, and calculate the weight of dextrin from the remaining rotation, always admitting that dextrin has a definite rotatory power. The author has, however, devised an improved method, which is based on an elementary analysis of the product; that is to say, on an estimation of the carbon, and on the rotation given by the dissolved product to polarised light. The correctness of the estimation of the carbon is beyond question; the only uncertainty rests on the exact rotatory power of dextrin adopted, that of dextrose (52·5°) being incontestable. 0·4 grm. of the material is burnt in the presence of oxide of copper, and from the weight of the carbon found the quantity of carbohydrates present is deduced, using the formula $C_6H_{12}O_6$. We then take about 5 grms., and, as above, calculate the contents of hydrates of carbon; let this weight be called S. We then obtain an equation, $S = D + d$; where D is the weight of dextrose, and d the weight of dextrin. This done, the material is dissolved in 100 c.c. of water, and the rotation taken with a ray of yellow light. The rotation observed, R, is equal to the sum of the rotations of dextrose and dextrin. Now each of these rotations can be determined by the formula $\rho = \frac{p\,a\,l}{v}$. We then use the following equation:—

$$\frac{D \times \alpha \times 2}{100} + \frac{d \times \alpha' \times 2}{100} = R,$$

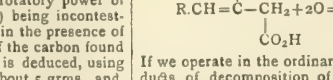
$$\frac{D \times 52{\cdot}5 \times 2}{100} + \frac{d \times 195 \times 2}{100} = R.$$

We then successively replace D and d by their value in functions of S, and obtain the weight of dextrose, and of dextrin reckoned as dextrose. This latter is reduced to its true weight by multiplying by 0·9.

MISCELLANEOUS.

Royal Institution.—The Annual Meeting of the Members of the Royal Institution was held on May 1st, Sir James Crichton-Browne in the Chair. The Annual Report of the Committee of Visitors for the year 1900, testifying to the continued prosperity and efficient management of the Institution, was read and adopted, and the Report on the Davy-Faraday Research Laboratory of the Royal Institution, which accompanied it, was also read. Forty-seven new Members were elected in 1900. Sixty-three Lectures and nineteen Evening Discourses were delivered in 1900. The Books and Pamphlets presented in 1900 amounted to about 262 volumes, making, with 653 volumes (including Periodicals bound) purchased by the Managers, a total of 915 volumes added to the Library in the year. Thanks were voted to the President, Treasurer, and the Honorary Secretary, to the Committees of Managers and Visitors, and to the Professors, for their valuable services to the Institution during the past year. The following gentlemen were unanimously elected as Officers for the ensuing year:—President—The Duke of Northumberland; Treasurer—Sir James Crichton-Browne; Secretary — Sir William Crookes; Managers — Sir Frederick Abel, Bart., Sir William de W. Abney, Sir James Blyth, Bart., Sir Frederick Bramwell, Bart., Dr. Thomas Buzzard, Viscount Gort, Dr. Donald William Charles Hood, the Right Hon. Lord Kelvin, Sir Francis Henry Laking, Mr. Hugh Leonard, Dr. Frank McClean, Mr. James Mansergh, Mr. George Matthey, Mr. William Hugh Spottiswoode, and the Right Hon. Sir James Stirling; Visitors—Sir Andrew Noel Agnew, Bart., Dr. Charles Edward Beevor, Mr. William Henry Bennett, Dr. Francis Elgar, Mr. Joseph G. Gordon, Dr. James Dundas Grant, Lord Greenock, Mr. Maures Horner, Mr. Henry Francis Makins, Sir Thomas Henry Sanderson, Mr. William Stevens Squire, Mr. Harold Swithinbank, Mr. John Jewell Vezey, Mr. Roger William Wallace, and Mr. James Wimshurst.

Formation of Oxalacetic Acid by Oxidation by means of Permanganate in Alkaline Solution.—R. Fittig.—The oxidation of the itaconic acids partially transforms them into bibasic oxylactonic acids, while the remainder obeys the general equation, and gives oxalacetic acid,—



If we operate in the ordinary manner, we only obtain products of decomposition of oxalacetic acid. Thus, dimethylitaconic acid gives acetone and oxalic and acetic acids. But if we repeat this oxidation by permanganate of potash in slightly alkaline solution at 0°, and then, after filtering off the MnO_2 and acidulating with H_2SO_4, we exhaust with ether to remove the unoxidised original acid, we obtain oxalacetic acid in the aqueous solution. By

the careful addition of concentrated sulphuric acid, the acid passes over in a form soluble in ether, from which it is afterwards extracted by evaporation. No other product is formed besides acetone and oxalacetic acid. The reaction may be therefore briefly formulated thus:—

$$CH_3>C=C<\begin{matrix}CO_2H\\CH_2.CO_2H\end{matrix}+2O=$$
$$=\begin{matrix}CH_3\\CH_3\end{matrix}>CO+OC<\begin{matrix}CO_2H\\CH_2.CO_2H\end{matrix}.$$

The determinations made on this body exactly confirm those given by Fenton and Jones.—*Berichte*, vol. xxxiii., p. 1295.

The Acetylation of Acetylacetic Ether.—L. Claisen and E. Haase.—The chlorides of the acids react on the soda derivatives of the β-ketonic ethers, giving principally acidylised derivatives of the type $CO—CH(COR)—CO_2C_2H_5$; their isomers, $C(O.COR)=CH—CO_2C_2H_5$, are obtained, on the contrary, by acting with the chloride of the acid on δ-ketonic ether in the presence of pyridine or an analogous base. The authors have applied this last method to the case of acetylacetic ether. They obtained the ether, $CH_3.C(OCOCH_3)=CH.CO_2C_2H_5$, by dropping chloride of acetyl (1·5 mols.) into a well-cooled mixture of acetylacetic ether (1 mol.) and anhydrous pyridine (2 mols.). After standing for two days, the acetyl-derivative is isolated by means of ether, the ethereal solution is washed with dilute soda to eliminate the excess of acetylacetic ether, then with dilute sulphuric acid and with water; it is then dried and distilled. The pure product distils at 104—105° at 10 m.m., at 112—113° at 17 m.m., and at 214—216° at the normal pressure, with partial decomposition; the return is 104 per cent of the weight of the acetylacetic ether. It is insoluble in the alkalis, which only attack it slowly. The same treatment has been applied to diacetylacetic ether, $(CH_3.CO)_2.CH.CO_2C_2H_5$; it gave the derivative $CH_3—C(OCOH_3)=C(COCH_3)—CO_2C_2H_5$. The product is fractionated at 15 m.m. without washing; the return is 70—80 per cent. It boils at 142—144° at 10 m.m., at 145—147° at 13 m.m., and at 148—150° at 15 m.m. It is a yellowish liquid decomposed instantly by water and by alkalis. It is obtained in very small quantities by the action of chloride of acetyl on diacetylacetic ether.—*Berichte*, vol. xxxiii., p. 1242.

The Compounds of Carbonic Oxide with Iron, and their Importance with regard to Water-gas.—M. van Breukeleveen and A. Ter Horst.—Roscoe and Sendder have already observed that water-gas kept for some time in an iron cylinder at a pressure of eight atmospheres contains a volatile ferric compound. Strache and Dicke, on the other hand, have shown that, under certain circumstances, the use of water-gas, even when not under pressure, leaves a brown powder on the Auer mantles which quickly renders them unserviceable. But these two authorities did not agree as to the cause of the phenomenon. According to Strache, iron carbonyl is formed near the generator, at the point where the gas comes in contact with the red-hot iron. Dicke, on the other hand, asserts that this product is formed in the iron pipes by the action of the gas on the iron in the cold. The authors have taken up the examination of this subject, and they confirm Dicke's opinion and have proved it to be correct by means of a series of experiments. The gas taken at the factory, or gas which has passed through lead pipes only, does not contain any iron carbonyl; but gas which has passed through iron pipes, or has even simply been in contact with polished iron for a week, contains this body. This action is in strict relation to the proportion of CO present; a synthetic mixture of CO_2, O, CO, H, and N gave the same results. To do away with this inconvenience, it is proposed to coat the interior of the pipes with tar, or to pass the gas through H_2SO_4, or to decompose the $Fe(CO)_5$ by means of heat; the authors have used $KMnO_4$ with success on the small scale.—*Revue Tr. Ch.*: *P.-B.*, [vol. xix., p. 27.

MEETINGS FOR THE WEEK.

Monday, 13th.—Society of Arts, 8. (Cantor Lectures). "Alloys," by Sir William Chandler Roberts-Austen, K.C.B., F.R.S., and T. Kirke Rose, D.Sc.

Tuesday, 14th.—Royal Institution, 3. "On Cellular Physiology, with special reference to Enzymes and Ferments," by Allan Macfadyen, M.D., B.Sc.

Wednesday, 15th.—Society of Arts, 8. "Syntonic Wireless Telegraphy," by Guglielmo Marconi.

—— Microscopical, 7.30. An Exhibition of Aquatic Life.

—— Institution of Mining and Metallurgy 8. "The Assaying of Complex Gold Ores," by Ernest A. Smith, Assoc.R.S.M. "Notes on Brine and Oil Wells in Western China," by J. V. Burne Murdoch. "Vein Structure at the Reynolds Mine, Georgia," by G. E. Collins. "Cherroloque Tin Mines and Alluvial Deposits, Bolivia," by Malcolm Roberts.

Thursday, 16th.—Royal Institution, 3. "Arthur Sullivan" (with Vocal and Instrumental Illustrations), by Sir Alex. Campbell Mackenzie, Mus.Doc.

—— Chemical, 8. "The Nutrition of Yeast" (Part III.), by A. L. Stern, D.Sc. "Derivatives of Methylorcinol," by H. J. H. Fenton and Miss Mildred Gostling. "The Preparation and Optical Inversion of Optically Active Nitrogen Compounds, Dextro- and Lævo-α-benzylphenylallylmethylammonium Salts," by W. J. Pope and A. W. Harvey.

—— Society of Arts, 5 (at the Imperial Institute, South Kensington). "The Town and Island of Bombay—Past and Present," by L. R. Windham Forrest.

Friday, 17th.—Royal Institution, 9. "Turkish Kurdistan," by Earl Percy, M.P.

—— Society of Arts, 8. (Howard Lectures). "Polyphase Electric Working," by Alfred C. Eborall, M.I.E.E.

Saturday, 18th.—Royal Institution, 3. "The Rise of Civilisation in Egypt," by Prof. W. M. Flinders Petrie, D.C.L.

NOTES AND QUERIES.

**** Our Notes and Queries column was opened for the purpose of giving and obtaining information likely to be of use to our readers generally. We cannot undertake to let this column be the means of transmitting merely private information, or such trade notices as should legitimately come in the advertisement columns.

Determining Naphthaline.—I would be pleased if some one of your readers would give a method of determining naphthaline in dead oil distilled from coal-tar.—Donald Davidson, Detroit, Mich.

TO MANUFACTURERS OF CHEMICAL, &c., APPARATUS.

The BECKENHAM URBAN DISTRICT COUNCIL invite Tenders for the Supply of the necessary APPARATUS for teaching Chemistry and Physics.

Tenders (by Discount from published Price List) to reach the undersigned not later than 4 p.m. on Monday, the 20th inst.

(By Order) F. STEVENS,
May 9th, 1901. Clerk of the Council.

INSTITUTE OF CHEMISTRY
OF GREAT BRITAIN AND IRELAND.
Incorporated by Royal Charter.

NOTICE IS HEREBY GIVEN that the INTERMEDIATE EXAMINATION and the FINAL EXAMINATION for the ASSOCIATESHIP of the Institute of Chemistry (A.I.C.) for persons desirous of qualifying themselves to be Public and Technical Analysts, will commence at the Laboratories of the Institute, 30, Bloomsbury Square, London, W.C., on Tuesday, July 2, 1901.

The Arrangements for the Examinations depend upon the number of Candidates; therefore, Candidates for the Final Examination may be required to present themselves from Tuesday, 9th, to Friday, July 12, 1901.

The Final Examination in Branch F (Biological Chemistry) will be held in October.

Notice will be given to all Candidates whose applications for examination are received and accepted by the Council not later than Wednesday, June 5, on which day the examination lists will be closed.

Forms of application and further particulars can be obtained from the Registrar.

(By Order of the Council)
30, Bloomsbury Square, London, W.C. RICHARD B. PILCHER, Registrar and Secretary.

"The Regulations for Admission to Membership" may be obtained from Messrs. Blundell, Taylor, and Co., 173, Upper Thames Street, London, E.C., price One Shilling.

THE CHEMICAL NEWS.

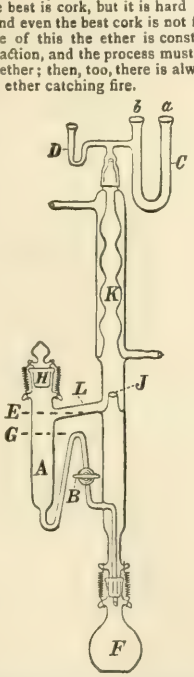
NEW FAT-EXTRACTION APPARATUS.

By Dr. W. JERWITZ.

Everyone who has worked with the Soxhlet fat-extraction apparatus is aware of the difficulty of obtaining a tight joint between the condenser and the extractor, on account of the great volatility of the ether. India-rubber stoppers cannot be used, because they become partially dissolved in ether, and besides spongy substances swell up in strong ether vapour. The material that has been found to be the best is cork, but it is hard to obtain it of good quality, and even the best cork is not free from pores. In consequence of this the ether is constantly escaping during the extraction, and the process must be interrupted to put in fresh ether; then, too, there is always the danger of the escaping ether catching fire.



Another objection to the use of cork is that it soon wears out, becomes loose, and must often be renewed.

The apparatus has none of these disadvantages, for by means of having the extractor joined to the side of the condenser, it becomes possible to make the extractor and condenser in one piece, thus dispensing with all connections of cork, &c. As the stability of the apparatus much depends on the way of fixing it, the apparatus has been supplied with two clamps especially constructed for it, which give a solid, safe, but not absolutely rigid grip, so that the apparatus is not likely to be crushed in handling.

The clamps allow the apparatus to be turned round its own length axially, and the necessity of taking it from its stand after once being fixed never arises; this will certainly in a great degree minimise the danger of breakages.

The tube of calcium chloride which is attached prevents the entrance of moisture. To do away with any danger of an explosion, which might take place if the calcium chloride tube should chance to get choked, the steam in that case can get out through the second little U-tube which is merely filled with mercury.

So that the condenser and the fat flask need not be connected by cork or rubber, the flask is slid into the other and held there by two spiral springs. Thus no support need be placed under the flask, and there is no danger of the neck being broken by striking it against it.

The two accompanying clamps are to be fastened to a wooden partition or a board fixed to the wall. Place the open clamp vertically above the other and a suitable distance from it, say 35 to 40 c.m. = about 15 inches. Slide the top end of the condenser through the top clamp, and let the bottom end rest on the lower one. Connect the condenser to the water pipe in the usual way. Then connect with the condenser the two U-tubes—a larger one, C, and a smaller one, D—after having greased the edge of the glass, which may be done without any danger to the analysis. C is filled with calcium chloride and closed at *a* by a stopper of wadding or a perforated cork; it is made air-tight at *b*. D contains a mercury trap and is likewise closed by a piece of wadding.

To start the apparatus attach the flask, F, to the bottom end of the apparatus with an ungreased joint by means of the enclosed spiral springs. Place the fat-cartridge which contains the material to be extracted in A, and fill the extractor, A, to a height of about E with anhydrous ether, having the stopcock, B, closed. Then put in the glass stopper, H, which for safety is also held on by two spiral springs. Open the cock at B, which sets the syphon working, and the fat-saturated ether will flow from A into F.

The condenser is now completely arranged. Heat F by a water-bath; do not support F, but allow it to hang free in the water. It is advisable to govern the temperature of the water-bath by a thermo-regulator. This, if once introduced, never allows the temperature to rise above the desired point, and thus makes other precautions unnecessary. Without this it is difficult, even with the greatest attention, to keep the temperature uniform, especially when the pressure of the gas varies, as is frequently the case.

The fat remains behind in F, whilst the ether distils off through J into the condenser, K, and is condensed. The ether flowing down the windings of the condenser is prevented from flowing back through J into F, but gets back through L into A, and acts over again on the fat-cartridge. As soon as A is filled up to G the ether again flows off and the process is repeated.

When the extraction is complete close the stopcock B again, and the ether will collect in A. When all the ether has been distilled over, take away the flame, disconnect F, and let the ether flow off through the stopcock B into another vessel; then take A away and remove the cartridge by means of a long tongs or a wire hook.

If the calcium chloride tube, *b*, should become choked the steam can get out through D, which acts as a safety valve.

Laboratory,
74, Rogerson's Quay, Dublin.

Royal Institution.—A General Monthly Meeting of the Members of the Royal Institution was held on the 6th inst., Sir James Crichton-Browne, Treasurer and Vice-President, in the Chair. Dr. D. W. Buxton, Mr. W. I. Last, Mr. J. Stirling, Mr. H. P. Whiting, were elected Members. It was announced that His Grace the President had nominated the following Vice-Presidents for the ensuing year:—Sir Frederick Bramwell, Bart., The Right Hon. Sir James Stirling, Sir William Abney, K.C.B., The Right Hon. Lord Kelvin, G.C.V.O., Mr. George Matthey, Mr. Frank McClean, Sir James Crichton-Browne, Treasurer, and Sir William Crookes, Hon. Sec.

THE PREPARATION OF URANIUM.

By J. ALOY.

The most convenient methods for the preparation of uranium are the reduction of the anhydrous oxides, either by carbon or by other metals.

Electric Furnace Method.

In a series of papers presented to the Academy of Sciences, M. Moissan describes the conditions under which uranium and its carbide are formed in the electric furnace (*Comptes Rendus*, vol. cxv., p. 1031; vol. cxvi., p. 347; vol. cxxii., p. 274). He used an arc of 500—800 ampères, and 45—55 volts. The densities of such currents being much greater than those generally in use, it seemed to me to be of interest to try if uranium could be prepared by means of currents of much less strength. With this object I undertook two series of experiments, the first with 15—25 ampères, and the second with 100—200 ampères. In the furnace I placed a mixture of U_3O_8 in slight excess, and sugar charcoal. The temperature of the mass being a function of the dimensions of the apparatus, I constructed a series of small furnaces with bricks of dressed lime.

The first experiments gave me very mediocre results; with the maximum current of 25 ampères, and by reducing the cavity of the furnace to 4 or 5 c.c., I obtained in the immediate neighbourhood of the electrodes fragments of carbide, the weight of which did not exceed 4 or 5 decigrammes.

The results in the second case were, on the other hand, fairly satisfactory; even with 100 ampères the arc, which was very small at the commencement of the experiment, could soon be considerably lengthened, and after about ten minutes the experiment was finished; in the cavity of the furnace I found, after cooling, several grains of carburised uranium.

I found, however, on varying the conditions that not more than 30 or 40 grms. of material should be operated upon; a current of 150 ampères gave 20 to 25 grms. of uranium in a few minutes, and may be considered as sufficient for the preparation of small quantities of the metal.

The conditions for getting the best returns were obtained with 50 to 60 volts.

Reduction of the Oxides by Metals.

Peligot has already pointed out the possibility of reducing the oxides of uranium by means of potassium, but the difficulty of obtaining a homogeneous mixture renders this method impracticable. I tried to effect the same reduction with the help of metals which, besides having a great affinity for oxygen, also have the advantage of being easily worked; I succeeded with magnesium and aluminium.

A mixture of the green oxide U_3O_8 with one of these metals reacts under the influence of heat alone. The reduction takes place at a dull red heat with magnesium, and is very violent; a bright red heat is required in the case of aluminium, but the reaction is much more regular. If we prevent the subsequent oxidation of the metal by operating in an inert atmosphere we can prove the presence of uranium by the action of dilute hydrochloric or sulphuric acids which give green solutions, and which do not attack the oxides U_3O_8 and UO_2.

But these methods, like that of Peligot, must be looked upon simply as methods of production, as the metal cannot be afterwards separated from the gangue.

Uranium can be separated by fusion by using a modification of Goldschmidt's method. It suffices to substitute the oxide UO_2, which is much more easy to reduce, and to combine the action of internal heat with that which is produced by the reaction itself. In a fire-clay crucible an intimate mixture of sugar-charcoal and the oxide UO_2, prepared at as low a temperature as possible by the reduction of the oxide $UO_3.H_2O$, is placed; after heating the mass to dull redness the reaction is started as in the case of the aluminothermy of metals, by means of a small cartridge formed of magnesium and binoxide of barium. The reaction starts immediately throughout the mass, and the melted metal collects at the bottom of the crucible in the form of an ingot.

Uranium thus prepared is not absolutely pure, it contains a small quantity of aluminium; nevertheless, I have obtained samples containing as much as 96 to 97 per cent of uranium.

M. Moissan has already shown (*Comptes Rendus*, vol. cxiii., p. 2), the possibility of obtaining alloys of uranium and aluminium by introducing the oxide U_3O_8 into a bath of melted aluminium.—*Bull. Soc. Chim.*, Series 3, vol. xxv., No. 7.

THE VOLUMETRIC ESTIMATION OF COPPER AS THE OXALATE, WITH SEPARATION FROM CADMIUM, ARSENIC, TIN, AND ZINC.*

By CHARLES A. PETERS.

(Continued from p. 222).

In the quantitative separation of copper as the oxalate the method of treatment was in general as follows:—Copper sulphate in 50 c.m.³ of water was thrown down by the addition of dry oxalic acid to the hot solution, and, after standing over night, the precipitate was filtered on asbestos, washed two or three times with small amounts of cold water. The precipitate, still in the crucible, was returned to the beaker in which precipitation took place, 5 or 10 c.m.³ of dilute sulphuric acid (1 : 1) were then added together with a convenient amount of water, and, after heating the liquid to boiling, the oxalic acid was titrated with permanganate, the oxalate of copper dissolving readily as fast as the excess of oxalic acid is removed by the permanganate. The precipitate may also be dissolved in 10 c.m.³ of strong hydrochloric acid (Gooch and Peters, *Am. Journ. Sci.*, 1899, vii., 461; Chemical News, vol. lxxx., p. 78), 0·5 grm. manganous chloride added, and titrated at 30—50°. Experiments 4 and 5 were conducted after this manner. In Table III., A, are recorded results of the quantitative tests of the method.

In Experiments 1 to 4, deficiencies are found in the amounts of oxalate precipitated at different degrees of dilution and by different amounts of the precipitant which are in agreement with the results obtained in the preliminary work; the results of Experiments 5 to 9, in which 0·5 grm. and 1·0 grm. of oxalic acid act in a total volume of 50 c.m.³, show the precipitation to be essentially complete under these conditions.

To study the insolubility of the copper oxalate in nitric acid, the experiments in Section B (Table III.) were made.

In Experiments 10 to 13 amounts of oxalic acid varying from 0·5 grm. to 3·0 grms. appear to precipitate the copper completely in the presence of 5 c.m.³ of strong nitric acid. In Experiment 14 the amount of oxalic acid used was not sufficient to throw down all the copper in the presence of 10 c.m.³ of nitric acid, but the copper does come down completely in the presence of the large amount of the nitric acid upon the addition of more oxalic acid, as seen in Experiments 15 and 16. In Experiments 17 and 18, with a larger volume of water and a larger absolute amount—though approximately the same percentage—of nitric acid present as in Experiments 10 to 13, there is a slight loss of copper; but in Experiments 21 and 22, when the amount of nitric acid is reduced to 5 c.m.³ in the

* About 9 grms. of ammonium nitrate present in addition to the 5 c.m.³ of nitric acid.

larger total volume, the results are normal. Experiments 19 and 20 show the increased loss when still larger amounts of nitric are present. These facts would make it seem best to limit the absolute amount of nitric in solution to about 5 c.m.³.

One observation may well be noted here; namely, that while ½ grm. oxalic acid is all that is needed for the complete precipitation of the copper in the presence of 5 c.m.³ strong nitric acid, still the oxalic acid may be added up to the point of saturation of the solution. More than this causes difficulty, owing to the fact that a large amount of water is necessary to wash the precipitated oxalate. About 2·0 grms. of oxalic acid to 50 c.m.³ of water is a convenient proportion.

In Experiments 23 and 24, 5 c.m.³ of nitric acid were neutralised with ammonium hydroxide before adding the 5 c.m.³ strong nitric acid in excess. The results show the solubility of copper oxalate in ammonium nitrate and exclude the possibility of such a procedure in this work.

Some experiments were made to show the time necessary for the complete precipitation, both in the presence and absence of nitric acid. The record of such work is given in Sections D and E (Table III.).

The results in Section D would seem to show that a solution containing copper may be precipitated hot as the oxalate and filtered either hot or after cooling with a very slight loss. Tests of the filtrates made with potassium ferrocyanide confirmed these results. When nitric acid is present, however, the mixture must stand after the addition of the precipitant. In Section E the gradual decrease of the minus error is noticed as the time of standing is extended, the precipitation being practically complete upon standing over night.

(To be continued).

SOME PRINCIPLES AND METHODS OF ROCK ANALYSIS.*

By W. F. HILLEBRAND.

(Continued from p. 220).

XX. *Alkalis.*

The Lawrence Smith Method.

The various methods for getting at the alkalis in insoluble silicates differ more in the mode of attack of the mineral powder, and in the immediately subsequent treatment, than in the final stages. With very few exceptions, since the early days of the Survey's existence, all alkali determinations have been made by the method of J. Lawrence Smith (*Amer. Journ. Sci.*, 1871, Second Series, vol. l., p. 269: *Amer. Chemist*, 1871, vol. i.; *Anal. Chem. und Pharm.*, 1871, vol. clix., p. 82), which is far more convenient than and fully as accurate as those in which decomposition is affected by hydrofluoric and sulphuric acids, or by bismuth, lead, or boric oxides. One of its chief advantages is the entire elimination of magnesia at the start.

* *Bulletin of the United States Geological Survey*, No. 176.

Decomposition of the powder is effected by heating it with its own weight of ammonium chloride, and eight times as much precipitated calcium carbonate.

The ammonium chloride used must be purified, preferably by sublimation, or made by neutralising pure ammonia by pure hydrochloric acid, and the calcium carbonate is best obtained from pure calcite by solution and re-precipitation. However obtained, this last is rarely free from alkalis, which must be estimated once for all in a blank test in order to apply a correction. Eight grms. of the carbonate will contain usually from 0·0012 to 0·0016 grm. of alkali chlorides, almost entirely the sodium salt, but the amount has been brought down to half the above by very long washing. This correction may be admitted at once to be a defect of the method, but it is one easily applied with safety.

The ignition may be made in a covered crucible of ordinary shape, and of about 20 to 30 c.m.^{3} capacity, heated to dull redness for not more than two-fifths of its height, but the heat has to be kept so low in this case to avoid loss by volatilisation that perfect decomposition is not always assured. Hence, to avoid waste of time in very fine grinding, the form of crucible with cap originally advocated by Smith is very much to be preferred, since it permits, when set at an angle through an opening in the side of a fire-clay cylinder, of the application of the full heat of two burners, and perfect decomposition invariably results without the need of extraordinary care in grinding. The crucible used in this laboratory (Fig. 14)

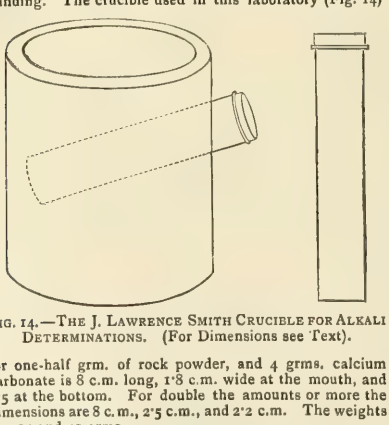

Fig. 14.—The J. Lawrence Smith Crucible for Alkali Determinations. (For Dimensions see Text).

for one-half grm. of rock powder, and 4 grms. calcium carbonate is 8 c.m. long, 1·8 c.m. wide at the mouth, and 1·5 at the bottom. For double the amounts or more the dimensions are 8 c.m., 2·5 c.m., and 2·2 c.m. The weights are 25 and 40 grms.

Treatment of the Mineral Powder.—Perfectly satisfactory results are to be obtained with but half a grm. of rock powder. This is weighed out, ground down somewhat finer in a large agate mortar, mixed with its own weight of sublimed ammonium chloride, and the two thoroughly ground together. Then nearly all of 4 grms. of calcium carbonate is added, and the grinding continued till a thorough mixing has resulted. The contents of the mortar are transferred to the long crucible, the rest of the carbonate being used for rinsing off mortar and pestle. The crucible is then capped and placed in a clay cylinder (Fig. 14), or through a hole in a piece of stout asbestos board clamped in a vertical position, and heated for about ten minutes by a low, flat flame placed at considerable distance beneath. As soon as the odour of ammonia is no longer perceptible the nearly full flame of two Bunsen burners is applied, and continued for forty to fifty minutes.

* To avoid the formation of a melted cake with silicates very high in iron it is advisable to increase the proportion of calcium carbonate.

The sintered cake* detaches readily from the crucible as a rule; if not, it is softened up in a few minutes by hot water, and digested in a dish until thoroughly disintegrated. It is first washed by decantation, and any lumps are broken up by a pestle, then thrown on the filter, and well washed with hot water. The residue should dissolve completely in hydrochloric acid without showing the least trace of unattacked mineral, not even of quartz.

Separation of Calcium and Sulphuric Acid.—All but a trifling amount of the calcium is separated at boiling heat in a large platinum dish by double precipitation by ammonia and ammonium carbonate. The combined filtrates are evaporated to dryness, and the ammonium salts are carefully driven off. From the aqueous solution of the residue—but a few cubic centimetres in bulk—the rest of the calcium is thrown out by ammonia and ammonium oxalate, this last being more effective than the carbonate. The filtrate, caught in an untared platinum crucible or small dish, is evaporated to dryness, and gently ignited; the residue is moistened with hydrochloric acid to decompose any alkali carbonate that may have been formed, again evaporated, ignited, and weighed. On solution in water a few tenths of a milligrm. of fixed residue is invariably left, which should be collected, ignited, and weighed in the same crucible or dish in order to arrive at the weight of the chlorides.

If the rock contains sulphur this will be in part found with the chlorides as sulphate. Therefore, if the sulphur is at all considerable in amount it must be removed by a drop of barium chloride before the final precipitation of the calcium. The excess of barium is removed by ammonium carbonate, and the last of the calcium by ammonium oxalate, as above. If the sulphur is not thus removed there is danger, if not certainty, of the potassium-platinic chloride carrying sodium sulphate. A faint reaction for sulphate can usually be obtained, anyway, if the evaporations have been made on a water-bath heated by gas.

Precipitation of Potassium.—To the solution of the chlorides in a small porcelain* dish an excess of platinic chloride solution is added. The dilution should be such that when heated on the water-bath any precipitate that may form wholly re-dissolves. Evaporation is then carried on till the residue solidifies on cooling. It is then drenched with absolute alcohol,† or with that of 80 per cent strength, filtered by decantation through a very small filter, and washed by decantation with alcohol of the same strength. The precipitate is not brought on to the filter more than can be avoided. Dish and filter are then dried for a few minutes to remove adhering alcohol, the contents of the former are transferred to a weighed platinum crucible or very small dish, and what still adheres to the porcelain is washed through the filter with hot water into the weighed receptacle. This is now placed on the water-bath, and afterwards heated to 135° C. in an air-bath. The factor used for reduction of K_2PtCl_6 to 2KCl is 0·307, and of 2KCl to K_2O, 0·632.

Lithium.

After separation of the potassium platinic chloride, the alcoholic filtrate is evaporated and tested spectroscopically for lithium. This element is almost invariably present, but almost never in amount to warrant quantitative estimation. Should it be so, however, the very excellent Gooch method (summarised below), of separation by amyl alcohol, is to be followed, after removal of the

* Preferred to platinum because of the possibility, under certain rare and ill-understood conditions, of the formation of an insoluble sub-chloride of platinum, probably by reaction between the platinum of the dish and that of the salt. (See also Bohn, *Zeit. fur Anal. Chemie*, 1899, vol. xxxviii., p. 349).

† Precht (*Zeit fur Anal. Chemie*, 1879, vol xviii., p. 513), claims that this is to be preferred to 80 per cent alcohol, especially if evaporation has been carried to dehydration of the sodium salt. Atterberg disputes this final statement, and says that 80 per cent alcohol gives better results.

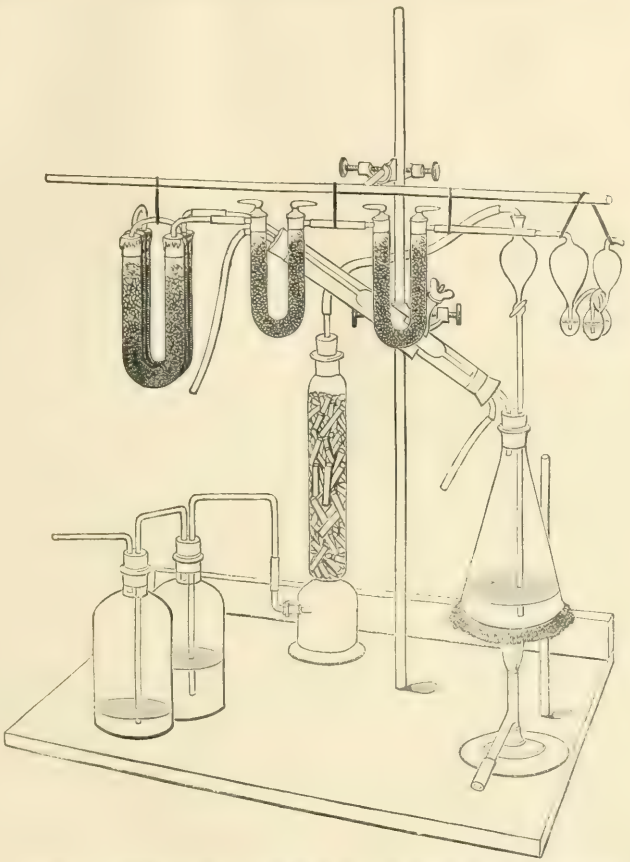

Fig. 15.—Compact Form of Apparatus for Estimation of Carbon Dioxide.

platinum by hydrogen gas.* In rock analysis there need be no fear of enough lithium falling with the potassium to cause any concern.

If ammonium carbonate alone has been relied on to separate all calcium (see above), the few tenths of a milligrm. of calcium chloride that escaped precipitation can now be found with the sodium.

* When haste is not an object, this way of Bunsen's for removing platinum from the chlorides of the alkalis is by far the neatest and most satisfactory. The small flask containing the solution is placed in a water-bath and attached to a hydrogen generator. After expelling all air the flask is closed, without breaking connection with the generator, and left to itself, except for occasional light shaking up, till reduction is accomplished. A more expeditious and very satisfactory reduction is effected by evaporating the solution to dryness with metallic mercury, then heating to expulsion of the excess of mercury and of its chloride (Sonstadt, *Journ. Chem. Soc.*, 1895, vol. lxvii., p. 984), who thus reduce potassium-platinic chloride in order to weigh its platinum.

Gooch's Method for Separating Lithium.*

To the concentrated solution of the chlorides amyl alcohol is added, and heat is applied, gently at first, to avoid danger of bumping, until, the water disappearing from solution, and the point of ebullition rising and becoming constant for some minutes at a temperature which is approximately that at which the alcohol boils by itself, the chlorides of sodium and potassium are deposited and lithium chloride is dehydrated and taken into solution. At this stage in the operation the liquid is cooled, and a drop or two of strong hydrochloric acid added to reconvert traces of lithium hydrate in the deposit, and the boiling continued until the alcohol is again free from water. If the amount of lithium chloride present is

* *Proc. Amer. Acad. Arts Sci.*, 1886, p. 177; *Bull. U.S Geol. Survey*, 18-7, No 42, p. 73; Chemical News, 1887, vol. lv., pp. 18, 29, 40, 56, 78; *Amer. Chem. Journ.*, 1887, vol. ix., p. 33.

small, it will now be found in solution, and the chlorides of sodium and potassium will be in the residue, excepting the traces for which correction will be made subsequently. If, however, the weight of lithium chloride present exceeds 10 or 20 milligrms., it is advisable at this point, though not absolutely essential to the attainment of fairly correct results, to decant the liquid from the residue, wash the latter a little with anhydrous amyl alcohol, dissolve in a few drops of water, and repeat the separation by boiling again in amyl alcohol. For washing, amyl alcohol, previously dehydrated by boiling, is to be used, and the filtrates are to be measured apart from the washings. In filtering it is best to make use of the perforated crucible and asbestos felt, and apply gentle pressure. The crucible and residue are ready for the balance after drying for a few minutes directly over a flame turned low. The weight of insoluble chlorides actually obtained in this manner is to be corrected by the addition of 0·00041 grm. for every 10 c.m.³ of amyl alcohol in the filtrate, exclusive of washings, if the insoluble salt is entirely sodium chloride, 0·00051 grm. for every 10 c.m.³ if potassium chloride constitutes the residue, and if both sodium and potassium chlorides are present, 0·00092 grm.; but . . . the entire correction may in any case be kept within very narrow limits if due care be given to the reduction of the volume of residual alcohol before filtration. The filtrate and washings are evaporated to dryness, treated with sulphuric acid, the excess of the latter driven off, and the residue ignited to fusion, and weighed. From the weight thus found the subtraction of 0·00050 grm. is to be made if sodium chloride constitutes the precipitate, 0·00059 grm. if potassium chloride alone is present in the residue, and 0·00109 grm. if both these chlorides are present, for every 10 c.m.³ of filtrate, exclusive of washings.

Amyl alcohol is not costly, the manipulations of the process are easy, and the only objectionable feature—the development of the fumes of amyl alcohol—is one which is insignificant when good ventilation is available.

The process has been used for some months frequently and successfully, by others as well as by myself, for the estimation of lithium in waters and minerals.

Separation of Alkalis by other Methods.

When, as may happen in rare instances, it is necessary to estimate alkalis in the main portion after the elimination of silica, alumina, lime, &c., in one of the usual ways, the question of a suitable method for separating magnesium becomes important.

The Mercuric Oxide Method.—The old barium-hydroxide method is not to be recommended. The mercuric oxide method of Zimmermann, whereby the magnesia is precipitated, from solution of the chlorides by moist, freshly precipitated, and alkali-free mercuric oxide, can give satisfactory results. The oxide is added in excess to the solution in a platinum crucible, and evaporated to dryness. Then the mercuric chloride and most or all of the excess of oxide are expelled by cautious heating. On leaching with water the magnesia remains on the filter. With more than 1 per cent of magnesia the operation must be repeated (Dittrich).

The Ammonium Carbonate Method.—Lately the once favoured method of precipitating the magnesium by neutral ammonium carbonate in concentrated solution has been again recommended.* The magnesium solution must be as strongly concentrated as possible, and a great excess of ammonium carbonate solution must be used. A voluminous precipitate forms, which dissolves on vigorous stirring if enough of the precipitant was used. After a time a crystalline precipitate falls—a double carbonate of magnesium and ammonium—which is insoluble in a concentrated solution of ammonium carbonate. Allow to stand for six to twenty-four hours. Wash with the concentrated ammonium carbonate solution. It is probably no exercise of undue caution to re-dissolve and re-precipitate, to make sure of getting all alkali in the filtrate.

The Amyl Alcohol Method.—Under certain circumstances, notably absence of lithium, the method of Gooch developed by Riggs (*Am. Journ. Sci.*, 1892, Third Series, vol. xliv., p. 103), may be satisfactory. It is similar to that of Gooch for separating lithium from sodium and potassium chlorides by amyl alcohol, and involves the same solubility corrections for the alkali chlorides above noted in the description of Gooch's method. Riggs's summary is as follows:—

Evaporate the solution nearly or quite to dryness. Dissolve the residue in as little water as possible, and add a few drops of hydrochloric acid. Then add 30—40 c.c. of amyl alcohol, and expel the water by bringing the alcohol to boiling. Continue the boiling until the volume of the solution is reduced to 10 c.c., or even considerably less. In filtering, it is of great advantage to use a perforated crucible and an asbestos felt, and to filter under pressure. In case the total chlorides exceed 0·2 grm. it may be advisable to decant the liquid, wash the residue, re-dissolve, and repeat the precipitation. If this be not done, the precipitate should be re-dissolved with the least quantity of water, a few drops of hydrochloric acid added, and the precipitation repeated in the original solution. The filtrate is transferred to a weighed platinum dish and evaporated. Water is added before the alcohol has been expelled, and the evaporation continued. The residue is dissolved in water. Sulphuric acid is added in slight excess. This solution is evaporated to dryness, the residue ignited and weighed, and the treatment with sulphuric acid is repeated. The residue of insoluble chlorides may be transferred to the weighed perforated crucible, and dried at a temperature below their melting points, or it may be dissolved and the solution transferred to a weighed platinum dish, evaporated, and the residue dried as above and weighed.

As with the Gooch method for lithium, the numerous tests results are good.

XXI. *Carbon Dioxide, Carbon.*

For this estimation an apparatus (Fig. 15) permanently set up is used, of which several forms have been described by different writers. The rock powder is boiled with dilute hydrochloric acid in a small Erlenmeyer flask, attached to an upward-inclined condenser, whence, after passing through a compact arrangement of drying tubes—first, one of calcium chloride, then one of anhydrous copper sulphate to retain hydrogen sulphide from decomposable sulphides, and any hydrochloric acid that may pass over, and, finally, a second calcium chloride tube—the carbon dioxide is retained by absorption tubes filled with soda-lime followed by calcium chloride. Of course arrangement is made for a current of CO_2 free air with which to sweep out the apparatus before and after the experiment, and for a slow current during its continuance. The results are very accurate, and the determination can be quickly carried out.

In the preliminary qualitative test for carbon dioxide, it must be remembered that while calcite gives off its carbon dioxide on treatment with cold acid, dolomite and siderite do not, and hence warming should not be omitted; otherwise, a few tenths per cent of carbon dioxide can very well be overlooked. Moreover, the powder should first be stirred up with a little hot water, to remove all entangled air which might otherwise be mistaken for carbon dioxide.

It has been already shown under "Water" (p. 112) how, in case of need, the determination of carbon dioxide can be combined with that of water by fusion with lead chromate or potassium chromate. This latter method must always be resorted to when the carbon of graphite or carbonaceous matter has to be estimated. If carbonates are present at the same time the result of the test includes

* Wülfing, *Ber. Deutsch. Chem. Gesell.*, 1899, vol. xxxii., p. 2214. The neutral carbonate is prepared by dissolving 230 grms. of ammonium carbonate in 180 c.c. of ammonia of 0·92 specific gravity and enough water to make 1 litre.

the carbon from both sources, and a separate determination by the wet way of that of the carbonates is necessary.

XXII. *Chlorine.*

To make sure of getting all the chlorine, it is best to fuse with chlorine-free sodium-potassium carbonate, or even sodium carbonate alone, first over the full burner, then for a moment or two over the blast, leach with water, acidify with nitric acid, and precipitate by silver nitrate without preliminary separation of silica. If 1 grm. of material has been used no precipitation of silica need be feared on acidifying or on standing.

In many cases it is quite sufficient to attack the powder by chlorine-free hydrofluoric acid and a little nitric acid, with occasional stirring, and after filtering through paper fitted into a large platinum cone or rubber funnel, to throw down the chlorine by silver nitrate. The presence of nitric acid is necessary, since otherwise ferrous fluoride reduces silver nitrate with deposition of crystallised silver. When coagulated by heating and stirring, the precipitate is collected on the filter, washed, dissolved by a little ammonia, and re-precipitated by nitric acid, when it can be collected in a Gooch crucible and weighed, or, if very small in quantity, on a small paper filter, which is then dried, wound up in a tared platinum wire, and carefully ignited. The increased weight of the wire is due to the metallic silver of the chloride which has alloyed with it.

(To be continued).

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Ordinary Meeting, May 2nd, 1901.

Prof. EMERSON REYNOLDS, F.R.S., President, in the Chair.

MESSRS. Storr and Talbot were formally admitted Fellows of the Society.

The following certificates were read for the first time:—Ormsby Gore Adams, Stawell, Victoria; Joseph Samuel Bridges, 45, Thistlewaite Road, Clapton, N.E.; Adolf Ludwig Ferdinand Lehmann, Bangalore, Mysore, India; William Lowson, 83, Kyrle Road, Clapham Common, S.W.; James Bertram Russell, 356, Padiham Road, Burnley; Thomas Sandford, 2, Market Place, Ulverston; Samuel Edward Sheppard, Ravensmere, Bromley Road, Catford, S.E.; Andrew Biggam Smith, Queenstown, Cape Colony; George William Gerald Tatam, Mercers' Hall, Cheapside, E.C.; James Whittle, 30, Bridge Street, Morpeth.

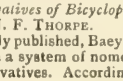
A ballot for the election of Fellows was held, and the following were subsequently declared duly elected:—Messrs. William C. Anderson, M.A., D.Sc.; George Stanfield Blake; Edward Richards Bolton; Edward G. P. Bousfield; Percival J. Burgess, M.A.; William Carter; Ernest Clark, B.Sc.; Thomas Kennedy Cockburn; Eustace Coddington, B.A.; Walter Stevens Crocker; Henry Drysdale Dakin; Raymond Dubois, B.Sc.; William Henry Duckworth; Albert Ernest Dunstan, B.Sc.; Samuel Philip Eastick; Hugh Edward Ellis; John Vargas Eyre; John Hanley; John A. Harrison, B.Sc.; Francis R. Henley, B.A.; Henry Herbert Higgs, B.Sc.; Alfred James Hyder; William Henry C. Jemmett, B.A.; Ernest Alfred Lewis; Oscar Loewenthal; Alex. McKenzie, M.A., Ph.D., D.Sc.; Charles Edward Kenneth Mees; Albert John Murphy; Arthur Theodore Neil, B.A.; Edgar Neumann, B.A., Ph.D.; William Oldershaw; Arthur Peacock, B.Sc.; William Robertson; William Hammond Robinson, M.A.; William Shepperson; C. Edmund Shaw Sherratt; Samuel Slefrig, B.Sc.; Henry Ewing Smith; James Smith; Samuel Fenton Stell; William Henry Taylor; Herbert Ackerman Tozer, B.A.; Joseph De Verteuil; George Edward Welch, B.Sc.; Adam Storer Wylie.

Professor ARMSTRONG requested that the abstract of Professor Perkin's paper might be read, and suggested that it might be desirable to arrange for accounts to be given by persons specially selected of the work of authors who were unable to be present in person.

Of the following papers, those marked * were read:—

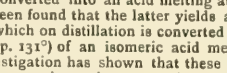
*74. "*The Synthetical Formation of Bridged Rings.* Part I. *Some Derivatives of Bicyclopentane.*" By W. H. PERKIN, jun., and J. F. THORPE.

In a paper recently published, Baeyer (*Ber.*, 1901, xxxiii., 3771) has developed a system of nomenclature for bridged-rings and their derivatives. According to this system, the hydrocarbon—

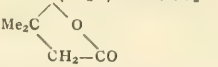


is named *bicyclopentane*, and the acid—

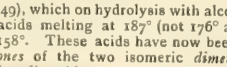
previously described (*Proc.*, 1900, xvi., 151)) is therefore *trimethylketobicyclopentanedicarboxylic acid.* It has already been stated that this acid, when digested with potash, is converted into an acid melting at 237°, and it has since been found that the latter yields an anhydride (m. p. 96°) which on distillation is converted into the anhydride (m. p. 131°) of an isomeric acid melting at 181°. Careful investigation has shown that these acids, which are evidently stereoisomeric, are not furfuran derivatives, as was at first supposed, but are *lactones* of *trimethylhydroxybutanetricarboxylic acid*—



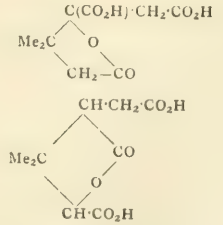
disruption of the whole bicyclopentane ring having taken place during their formation. A somewhat similar decomposition is shown by *ethyl dimethyldicarboxytrimethylenemalonate*—



(*loc. cit.*, p. 149), which on hydrolysis with alcoholic potash yields two acids melting at 187° (not 176° as previously stated) and 158°. These acids have now been shown to be the *lactones* of the two isomeric *dimethylhydroxybutanetricarboxylic acids*—

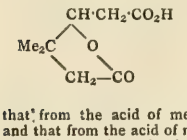


and—



the trimethylene ring having been broken during hydrolysis; but unfortunately so far it has not been possible to decide which formula belongs to the former and which to the latter of the two acids.

Both acids on heating lose carbon dioxide, and are converted into the *lactones* of two isomeric *dimethylhydroxybutanedicarboxylic acids*, probably—



that from the acid of melting-point 187° melts at 108°, and that from the acid of melting-point 158° at 154°.

During the investigation of the bicyclopentane derivatives, it became necessary to prove conclusively that ethyl dimethyldicarboxytrimethylenemalonate really had the constitution assigned to it above, and that it was not a tetramethylene derivative of the formula—

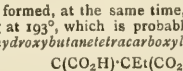
which was the only other possibility.

This was done by treating the ester with sodium ethylate and ethyl iodide, when it yielded *ethyl dimethylethyldicarboxytrimethylenemalonate*—

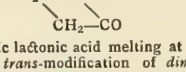
a colourless oil boiling at 230—232° (30 m.m.). The formation of this ethyl derivative shows that the original ester must have contained a hydrogen atom replaceable by sodium, and the tetramethylene formula given above is therefore excluded.

When this ethyl substitution product is digested with alcoholic potash, it yields a dibasic acid (m. p. 175°) which is probably *dimethylethylethoxyketopentamethylenedicarboxylic acid*—

and there is formed, at the same time, a tribasic lactonic acid melting at 193°, which is probably the *lactone* of *dimethylethylhydroxybutanetetracarboxylic acid*—



and a dibasic lactonic acid melting at 213°, which is probably the *trans*-modification of *dimethylethylhydroxybutanetricarboxylic acid*—



The corresponding *cis*-modification, which is obtained by the action of hydrochloric acid on the dimethylethyloxyketopentamethylenedicarboxylic acid mentioned above, melts at 144°, and gives an anhydride melting at 168°.

The ease with which disruption of the trimethylene ring takes place in the formation of these lactones is very remarkable; the only other similar case which is known is that described by Buchner and Witter (*Ber.*, 1894, xxvii., 871).

During the course of the investigation of the bicyclopentane derivatives, some interesting derivatives of *ββ-dimethyl glutaric acid*, $CO_2H{\cdot}CH_2{\cdot}CMe_2{\cdot}CH_2{\cdot}CO_2H$, have been prepared and examined, and the results may be briefly summarised as follows:—

$\alpha\alpha_1$-Dibromodimethylglutaric acid—

$$CO_2H{\cdot}CHBr{\cdot}CMe_2{\cdot}CHBr{\cdot}CO_2H,$$

is obtained on treating dimethylglutaric anhydride with phosphorus pentachloride and bromine and digesting the product with anhydrous formic acid; it melts at 187—189°, and when treated with pyridine or boiled with water it yields the lactone of *α-bromo-α_1-hydroxydimethylglutaric acid*—

This melts at 169—170°, gives an ethyl ester boiling at 201° (45 m.m.), and is characterised by the great stability of its bromine atom, which is not removed even by boiling with silver nitrate and nitric acid. Strong potash, however, converts it into the *lactone* of *$\alpha\alpha_1$-dihydroxydimethyl glutaric acid*—

which melts at 142°.

During the bromination of dimethylglutaric acid, a small quantity of *αα-dibromodimethylglutaric acid*—

$$CO_2H{\cdot}CBr_2{\cdot}CMe_2{\cdot}CH_2{\cdot}CO_2H,$$

is formed, and this, on boiling with sodium carbonate, yields *αα-dihydroxydimethylglutaric acid*—

$$CO_2H{\cdot}C(OH)_2{\cdot}CMe_2{\cdot}CH_2{\cdot}CO_2H,$$

which melts at 84° and behaves in many of its reactions as the keto-acid, $CO_2H{\cdot}CO{\cdot}CMe_2{\cdot}CH_2{\cdot}CO_2H$, containing 1 molecule of water less. Thus it combines with *o*-toluylene diamine, and on reduction with sodium amalgam is converted into the lactone of *a-hydroxydimethylglutaric acid*—

which melts at 112°, and has already been described (*Trans.*, 1899, lxxv., 56).

*75. "*Lead Silicates in Relation to Pottery Manufacture.*" By T. E. Thorpe, C.B., F.R.S., and C. Simmonds, B.Sc.

As is well known, the use of oxides and basic carbonates of lead in glazes employed by potters is attended with danger to the health of the workpeople on account of the ready solubility of these compounds in the acids of the animal organism. Attention was drawn to the fact that lead silicates or boro-silicates, or complex silicates of lead and other metals, can be used instead of the oxides or carbonates as a means of introducing lead into the glaze. On the Continent this use of lead silicates is far more common than in England, and it is generally recognised that their employment has greatly tended to minimise the risk of lead-poisoning. This is due to the fact that the lead silicates used in the continental factories are of a high degree of insolubility so far as the lead is concerned.

On examining a number of lead silicates used or proposed for use in England, it was found that many were attacked by dilute acids practically to the same extent as the oxides or carbonates. That is, they yielded the whole, or nearly the whole, of their lead to the action of acids comparable with the acids found in the human system—such as, for example, the hydrochloric acid of the gastric juice. Other specimens were more resistant, but still yielded a large proportion of their lead. On the other hand, the specimens obtained from the Continent, as well as many which have recently been produced by English manufacturers, gave up only small quantities of lead when tested under the special conditions described.

A large number of specimens was therefore analysed in order to ascertain, if possible, to what variations in chemical composition these differences of behaviour were due.

The condition on which the insolubility of the lead depends was found to be, primarily, the existence of a certain ratio between the whole of the base-oxides on the one hand, and the whole of the acid-oxides on the other. This becomes eventually referable to the hypothetical silicic acids from which the silicates may be considered to be derived. For working purposes, the relation may be more simply expressed as—

sum of percentages of base-oxides, expressed as PbO
sum of percentages of acid-oxides, expressed as SiO_2'

or, alternatively, as—

number of acid molecules
number of base molecules'

the latter ratio being obtained by dividing the percentage of each oxide by its molecular weight, and then dividing the sum of the quotients for the acid-oxides by the sum of the quotients for the base-oxides.

Provided the ratio falls within certain definite limits, the amount of lead extracted under the prescribed conditions is always small. It does not depend upon the quantity of lead in the silicate, which may have any value up to 50 or 55 per cent. The other bases usually present (lime, alumina, and alkalis) may also vary considerably, replacing one another, and also the lead oxide, within very wide limits without prejudice to the insolubility of the lead.

Analyses and formulæ of a number of silicates were given, together with tables showing the dependence of the solubility of the lead in the silicates upon the ratios mentioned above.

Discussion.

Mr. F. J. Lloyd asked whether experiments had been made using smaller quantities of solution than 1000 parts to 1 part of substance. The acid present in 1000 c.c. would be about seven times as much as that required to dissolve 1 grm. of lead oxide. The conditions which influenced the solubility of substances in dilute acid solutions were of especial interest to agricultural chemists. He had found in some experiments that the volume of solution employed appeared to materially affect the solubility, and wished to know whether the authors had had a similar experience during their investigation.

Prof. Tilden enquired whether the authors had paid special attention to the degree of fineness of the powders submitted to the action of the acid. Some facts had already been published which seemed to show that the apparent solubility of a frit was seriously influenced by the amount of trituration to which the substance had been subjected before bringing it into contact with the acid.

Prof. Clowes said it would be of interest to know if the solvent action of acids other than hydrochloric acid had been tried, and with what results. He also asked whether the method of testing finished articles purporting to be covered with leadless glaze, by exposing them to the action of dilute hydrochloric acid for some time, and examining the solution for the presence of lead, was satisfactory, and what were the best conditions for applying such a test.

Mr. Elworthy asked whether the authors had estimated the solubility of the frits or glazes in salt solutions, as they were much more likely to come into contact with salt solution than with free hydrochloric acid, especially during the preparation of food, and whether the lead dissolved from the frit existed in the solution as chloride or as a soluble silicate.

Prof. Carmody asked whether any comparisons had been made between the amount of lead oxide soluble in the frits before and after their application.

Mr. Simmonds, in reply, stated that an excess of acid was necessary, for otherwise misleading results were obtained; this was due to the curious fact that certain kinds of lead silicate reacted with a neutral solution of lead chloride, and removed the lead from solution, probably as an insoluble oxychloride. The volume of acid selected must be sufficiently great to ensure that there should be no very considerable weakening of its strength by the action of the various acid-neutralising constituents, of which, it should be borne in mind, there might be several besides the lead.

As regards fineness of subdivision, some of the specimens were sent ready ground, and were stated by the manufacturers to be in the condition in which they were to be used for glazing pottery ware; these were tested as received. The other specimens were ground to an impalpable powder in an agate mortar. Various solvents had been experimented with—for example, lactic and acetic acids—but the results threw no greater light on the subject than those obtained with hydrochloric acid; consequently, the experiments were not persisted in. Salt solution had not been tried. He did not know whether testing the glaze on table ware with hydrochloric acid had been suggested, but in Germany there was a provision that such ware should not give up lead when boiled for half an hour with 4 per cent acetic acid.

With reference to the state in which the lead existed when dissolved from a silicate, whether as a lead silicate or as a lead chloride, complete analyses of several of the solutions had been made, and some small quantity of silica was always present. The lead, or a part of it, may therefore, perhaps, have dissolved as a basic silicate.

76. "*The Preparation and Properties of* 2 : 6-*Dibromo-*4-*nitrosophenol.*" By M. O. Forster and W. Robertson.

2 : 6-Dibromo-4-nitrosophenol is produced by the action of potassium hypobromite on *p*-nitrosophenol dissolved in potassium hydroxide solution (compare Fischer and Hepp, *Ber.*, 1888, xxi., 674); the *potassium*, *acetyl*, and *benzoyl* derivatives are well defined. Dilute nitric acid oxidises the substance to 2 : 6-dibromo-4-nitrophenol, but the concentrated acid converts it into 2-bromo-4 : 6-dinitrophenol. Tin and hydrochloric acid reduce 2 : 6-dibromo-4-nitrosophenol to 2 : 6-dibromo-4-aminophenol, of which the *benzoyl* derivative is well defined.

77. "*The Chlorination of Toluene.*" By W. P. Wynne.

In consequence of the publication of an abstract of a paper by Cohen and Dakin (*Proc.*, 1901, 91), the author wishes to state that he has been, and is, engaged in a study of the chloro-derivatives obtained in chlorinating toluene under Seelig's conditions (*Trans.*, 1892, lxi., 1051). The six dichlorotoluenes, and their sulphonic acids, chlorides, and amides, to which Cohen and Dakin refer, were prepared and examined in this connection (*loc. cit.*, p. 1042; Wynne and Greeves, *Proc.*, 1895, xi., 151). Moreover, the 2 : 5-dichlorotoluene, which these authors state is very probably formed in presence of the mercury-aluminium couple, has been recognised as present in considerable quantity in the mixture of dichlorotoluenes obtained by Seelig's method.

PHYSICAL SOCIETY.

Ordinary Meeting, May 10th, 1901.

Prof. S. P. Thompson, President in the Chair.

A paper on "*Applications of Elastic Solids to Metrology*" was read by Dr. Chree.

The ordinary conception of a solid is apt to be that of a body whose shape and volume are variable only with temperature. Elastic changes in dimensions are necessarily small in most bodies of limited size, and they are often negligible even in exact work. The object of the present paper is to exemplify the bearing of elasticity on physical measurements. Many of the results depend ultimately on a previous paper by the author in which expressions were obtained for the mean strains, and for the change in total volume of any homogeneous elastic solid acted on by any given system of forces throughout its mass or over its surface. The formula is first applied to the case of a right circular cylinder, and it is shown that the action of gravity can be eliminated by taking for the length and volume the means of the results obtained when the cylinder is suspended by a string, and when it stands upon its base on a flat surface. The effect of the pressure of a surrounding medium of constant density upon the shape and volume of an isotropic solid is considered, and the theory is extended to the case of an

œolotropic solid in a medium of varying density. If a standard kilogrm. of platinum-iridium were suspended instead of being supported on its base, the alteration in volume would be 66×10^{-8} c.c., and if it were transferred from air at atmospheric pressure to a vacuum the alteration would be 24×10^{-8} c.c. The change in volume of the material of the walls of a flask containing liquid is next investigated, and it is shown that the change is independent of the thickness of the walls, the mean expansion per unit of volume being inversely proportional to the whole volume. Whether the alteration consists of an increase or a decrease depends upon the dimensions of the vessel. Theoretically a flask whose inner surface is a cone of any solid angle, vertex downwards, would have the property that the volume of the material of its walls would be unaffected by the pressure of any liquid it might contain. We cannot in general determine the effect on the internal capacity of a vessel due to the pressure of contained liquid, but if the walls are coaxial right circular cylinders, the common axis being vertical, the solution is possible. The increase in volume per unit of volume inside a thin walled circular tube varies directly as the density of the liquid, the height of the mark, and the radius of the tube, while it varies inversely as the thickness of the walls. As a numerical example, a glass-tube 12·7 c.m. high, 10 c.m. internal diameter, and 1·5 m.m. thick, would hold 0·11 grm. more mercury than it would if inelastic. The solution is possible in the case of a spherical shell, and this problem is also investigated in the paper. The author next considers the application of the theory of elasticity to standards of length, and to give a more exact idea of the problems actually occurring in metrology he deals particularly with five forms:—The standard yard, the international prototype metre of × section, a working standard belonging to the Bureau International, and two deflection bars used in magnetometers. The shapes of these bars are devised partly with the object of facilitating equalisation of temperature throughout the bar. Most modern standards are supported not over the whole lower surface, but either on two symmetrical rollers or on three points. An exact solution of the elastic problem presented by a heavy bar supported on points or rollers has not yet been obtained, but the Bernoulli-Euler solution is very accurate except near the supports. In using standards of length it is the horizontal projection of the graduated surface that usually concerns us, and it is proved that unless we deal with a very long bar the difference between the chord and the arc is very small. This difference increases as the supports are moved outwards, from their most favourable position, towards the end of the bar. The standard yard in this respect compares unfavourably with more modern types. The curvatures and lengths of bars supported in various ways, both loaded and unloaded, are treated at length, and it is shown that by a proper arrangement of supports the alteration in length between two points due to bending can be rendered so small as to be of no practical importance. In the metre prototypes of × section the divisions occur on the neutral surface, and their distance apart is unaffected by stretching of the material. In the case of magnetometer deflection bars it is advisable to have the magnet as near to the bar as possible. Increasing the distance between them is equivalent to having the scale a long way from the neutral surface. Increasing the weight of the magnet and carriage, or decreasing the distance between the two points of support by reducing the size of the graduated circle, produce errors on account of bending.

Prof. Everett congratulated the author upon the practical application of a difficult theory to the measurements of lengths and volumes.

Mr. Watson said that it was usual in deducing the radius of a coil from the measurement of its circumference with a steel tape to diminish the result by half the thickness of the tape. He would like to know if this was the right correction to apply. In measuring the circumference of a cylinder it is necessary to wind the tape in a spiral so as to bring the divisions side by side. This gives a result which is too great and not too small, as might at first sight be imagined.

Mr. Campbell asked if any special experiments had been performed to determine directly the bending of standards at different points of their length.

Dr. Lehfeldt asked if the work of the author could be used to determine the pressure corrections of thermometers. He would like to ask why it was necessary to use supports instead of allowing a standard to rest on a flat surface.

The Chairman said that the paper was important because of its bearing on the question of the relation between the units of different nations. He drew attention to the alteration of the factor converting metres into inches, and asked if it was due to alterations in the properties of matter or to errors of observation. The two legal definitions of the gallon differ by an appreciable amount, and it would be interesting to know if this discrepancy could be due to changes in the volume of measures due to the liquids contained by them.

Dr. Chree, in reply to Mr. Watson, said the correction would depend upon the diameter measured, because that determined the curvature of the tape, and therefore the stretching produced. In reply to Mr. Campbell the author stated that experiments had been made upon the bending of bars, and they agreed well with theory. The correction formula obtained for a thermometer is similar to the ordinary one used. A bar is usually supported so as to remove the uncertainty of the distribution of surface pressure when it rests on a flat surface, not a true plane. In reply to the President, Dr. Chree said that the alteration of the factor converting metres into inches was probably due to errors of observation on account of the width of the divisions of the standard yard, and on account of the difficulty of obtaining the bar at the standard temperature of 62° F.

A paper, by J. Rose-Innes and Prof. S. Young, on "*The Thermal Properties of Isopentane compared with those of Normal Pentane*" was read by Mr. Rose-Innes.

In previous papers the authors have investigated experimentally the thermal properties of isopentane and normal pentane, and have stated certain conclusions from their observations. The present paper gives the conclusions reached after a more exhaustive examination of the experimental results of the former papers. The quantity $RT - pv$ at any volume and temperature is called the departure from Boyle's law at that point, and it is found that there is a constant ratio between the departures from Boyle's law of isopentane and normal pentane at the same volume and temperature. To test the law, a probable value of the ratio was determined, and by means of it a large number of values of pv for isopentane were calculated from results for normal pentane. These calculated values fall upon the same curve as the observed values, and agree with them to within about 1 per cent. The authors are confirmed in their previous conclusion, that the difference of pressure between two isomeric substances at the same temperature and volume involves the same power of the density as the first deviation from Boyle's law, *i.e.*, the second power.

Mr. J. M. Gray said the numbers obtained would be valuable to him, and he would make use of them in his calculations. He was sorry, however, that the authors had dealt with empirical formulæ instead of rational formulæ deducible from the theory of gases.

Dr. Chree asked how the temperatures were measured.

Mr. Rose-Innes said recourse had been had to empirical formulæ because they found theoretical formulæ useless. He gave examples of the failure of well-known equations to satisfy experimental results. The temperatures were measured with a constant volume air thermometer, a small correction—less than the errors of experiment—being employed to reduce the readings to the thermodynamic scale.

The Society then adjourned until May 31st.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Note.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. cxxxii., No. 16, April 22, 1901.

Estimation of Nitric Acid in Natural Waters by means of Stannous Chloride.—H. Henriet.—An acid solution of stannous chloride is known to transform nitric acid into hydroxylamine if the stannous chloride is present in excess and if there is enough water present to prevent the hydrochloric and nitric acids from reacting upon one another. The author investigates this reaction, and finds that, at boiling-point, the nitric acid is transformed quantitatively into hydroxylamine; the reaction apparently taking place according to the following equation:—

$$3SnCl_2+NO_3K+8HCl=$$
$$=3SnCl_4+NH_2OHHCl+KCl+2H_2O.$$

This reaction can be utilised for the estimation of the nitrates, if an iodine solution is used for the estimation of the excess of stannous chloride, $SnCl_2+2I+4HCl=SnCl_4+2HI$. From these equations, it will be seen that six atoms of iodine correspond to one atom of nitrogen.

Action of various Alcohols on some Acetals of Monovalent Alcohols.—Marcel Delépine.—If methylal is heated with amyl alcohol or diamylic formal with methyl alcohol the same products result, a distillation of the mixture resulting in methylal, methyl alcohol, amylic alcohol of mixed formal (resulting from a partial substitution), and diamylic formal. The reactions may be represented by the following equations:—

$$CH_2(OCH_3)_2+2C_5H_{11}OH\rightleftarrows CH_2(OC_5H_{11})_2+2CH_3OH\ ;$$
$$CH_2(OCH_3)_2+C_5H_{11}OH\rightleftarrows CH_2(OCH_3)(OC_5H_{11})+CH_3OH\ ;$$
$$CH_2(OC_5H_{11})_2+CH_3OH\rightleftarrows CH_2(OCH_3)(OC_5H_{11})+C_5H_{11}OH.$$

A similar reaction occurs when ethyl alcohol reacts with diamyl formal, methyl alcohol with dipropyl formal, and propylic alcohol with methylal. Five substances are produced which are very difficult to separate.

Three New Alkaloids from Tobacco.—A. Piçet and A. Rotschy.—By submitting the nicotine obtained from tobacco to a series of fractional distillations, two well-defined fractions are obtained: one boiling at 256—268°; and the other, smaller fraction, boiling at between 300° and 310°. This latter solidifies partially on cooling. The first fraction contains a liquid alkaloid of formula $C_{10}H_{12}N_2$, and has been given the name nicoteine. The solid alkaloid, after crystallisation from dilute alcohol, can be obtained in little prismatic needles melting at 147—148°; this has been called nicotelline, and it apparently corresponds to the formula $C_{10}H_8N_2$. A third alkaloid is found in crude nicotine. By treating the nicotine with nitrous acid and distilling the product *in vacuo*, a small quantity of an oily nitrosamine is obtained, from which the base can be produced by boiling with hydrochloric acid; for this the name of nicotimine was adopted. This latter substance is an isomer of nicotine. The proportion of the new alkaloids in tobacco is very small as compared with nicotine; it can be approximately expressed as follows:—Nicotine, 1000; nicoteine, 20; nicotimine, 5; nicotelline, 1.

Action of Phenylhydrazine and Hydrazine on the two Isomeric Methylbutyrylacetylacetates. — M. Bongert.—The author describes the results obtained when hydrazine and phenylhydrazine react on the two isomers of methylbutyrylacetylacetate, and the preparation of a new body having the empirical formula $C_{12}H_{13}N_2O$. This latter differs from the corresponding pyrazolone by a single atom of hydrogen. This fact seems to indicate that the formula should be doubled, and that the substance is a bispyrazolone. This assumption has been verified.

Paraoxyhydratropic Acid.—J. Bougault.—This paper describes the properties and preparation of paraoxyhydratropic acid, $OH—C_6H_4—CH<^{CO_2H}_{CH_3}$.

New Reactions of Cyano-metallic Derivatives. (III.). Non-substituted β-Ketonic Ethers. — E. E. Blaise.—By the method described in a previous paper, the author prepares ethyl propionylacetate and ethyl butyrylacetate. The first of these bodies being separated from the products of the reaction by means of sodium bisulphite, and the second by transformation into the magnesium derivative.

A New derived Base from Glucose.—L. Maquenne and E. Roux.—The authors obtained, starting from the aldose oximes $C_nH_{2n}O_n$, a whole series of primary bases of the form $C_nH_{n+2}(OH)_{n-1}(NH_2)$. These are practically distinguished by their great stability and the absence of any action on cupro-potassium solutions. The authors also describe the base derived from ordinary glucose, which is in some measure the type of this new class of compounds, and which they designate by the name of glucamine.

Action of Alcoylcyanacetic Ethers on Diazoic Chlorides.—G. Favrel.—This paper gives an account of the action of alcoylcyanacetic ether on the chloride of diazobenzene, diazoparatoluene, and diazo-orthotoluene.

Reduction of Nitrated Azo-colouring Matters.—A. Rosenstiehl.—When nitramine is set free in a sulphonated azo-combination, it is much more soluble than when it is in a free state. This fact facilitates all reactions of reducing agents where the action takes place only on the nitramine, without the intervention of sulphonaphthol.

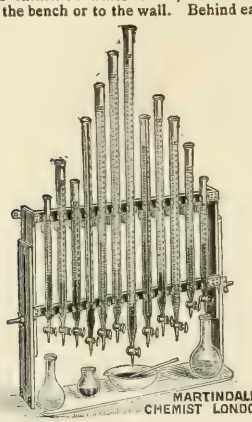
Two New Acetylenic Acids. Synthesis of Caprylic and Pelargonic Acids.—Ch. Moureu and R. Delange.—The authors prepare two new acetylenic acids and some of their immediate derivatives. Each of these acids, hydrogenated by sodium and boiling absolute alcohol, is converted into the corresponding saturated fatty acid—a transformation which allows of a new synthesis of two natural acids, caprylic and pelargonic acids.

MISCELLANEOUS.

Tannoform in Veterinary Practice.—Tannoform was first prepared by Merck about six years ago. It is the condensation product of tannic acid and formic aldehyde, and possesses simultaneously both the astringent action of the former and the antiseptic properties of the latter. Its composition corresponds to the formula $CH_2<^{C_{14}H_9O_9}_{C_{14}H_9O_9}$. In appearance it is a light, reddish-white, odourless, and almost tasteless powder, insoluble in water, but soluble in alcohol. Owing to the specific anhydrodic action of tannoform it was at first employed as a remedy against excessive perspiration of the feet, hands, and other parts of the body, and met with a hearty welcome from tourists, military, and sporting men. It is absolutely non-poisonous, and is tolerated in large doses without objection; it checks secretion, and destroys bacteria. Tannoform can be employed internally as a very active intestinal astringent, and has been found most effective in a large number of cases of intestinal catarrh. Very remarkable cures of infectious diarrhœas in young cattle are reported. Its applications to cuts and sores has given very good results owing to its antiseptic action, and it has been welcomed by veterinary surgeons as a valuable adjunct to their medicaments.

Tin Solder.—A useful form of tin solder has been placed upon the market by the Patent Solder Co , Limited, of 47, Old Street, E.C. The novelty consists in the rods of solder being "cored" with resin ; they are made in various sizes, from the thickness of a lead pencil downwards, and are very convenient to use. For little odd jobs in the laboratory its employment is a luxury, and if the price is reasonable this form of solder is likely to come into general use in the workshop, especially in the electrical trades.

New Burette Stand.—We have received from Mr. W. Martindale, of 10, Cavendish Street, W., a "common-sense" burette stand; the sketch shows the apparatus filled with tubes, and sufficiently explains the design. It is made in varnished white wood, and can either be screwed to the bench or to the wall. Behind each tube is



a little hook to hold a small bone memorandum tablet. Where titrations have to be frequently made it will be found very convenient; it also makes a useful store for burettes when not in use, as it takes up little room, and being fixed cannot get upset. The stand is made in two sizes to take six or twelve burettes.

The Higher Peroxides of Hydrogen.—A. Bach.—The author has already shown (*Comptes Rendus*, vol. cxxiv., p. 951), that the products of the oxidation of nascent hydrogen derived from hydride of palladium, oxidise a solution of indigo much more rapidly than does ordinary peroxide of hydrogen containing the same quantity of active oxygen. He was therefore obliged to admit the existence of peroxides of hydrogen more oxygenated than H_2O_2; to verify this he took a certain quantity of peroxide of hydrogen or other oxidising liquid, and simultaneously estimated its action on permanganate, and the volume of oxygen set free. The apparatus consists of a burette, a stoppered flask, a measuring tube, and a manometric tube, and is illustrated in the original paper; the flask and the measuring tube are kept immersed in water at a constant temperature. With peroxide of hydrogen, H_2O_2, the reaction is:—

$$5H_2O_2+2MnO_4K+3SO_4H_2 = 5O_2+SO_4K_2+2SO_4Mn+8H_2O.$$

But if the peroxide of hydrogen was H_2O_4, corresponding to K_2O_4, the reaction would give a double volume of oxygen (changing $5H_2O_2$ into $5H_2O_4$, and $5O_2$ into $10O_2$). Operating comparatively with commercial peroxide of hydrogen, the author has examined successively the products of oxidation of nascent hydrogen from palladium, peroxide of hydrogen obtained from dilute acids at very low temperatures, of tetroxide of potassium, and binoxide of sodium, and of "Caro's acid" (a mixture of concentrated SO_4H_2 with persulphate of potassium or even with H_2O_2). He arrived at the following results with regard to the oxygen liberated, taking that given off by ordinary peroxide of hydrogen as unity, for equal weights of $KMnO_4$ reduced:—

Ordinary peroxide of hydrogen from BaO_2 ..	1·00
Products of oxidation of nascent hydrogen ..	1·07
Peroxide of hydrogen from Na_2O_2	1·17
" " " K_2O_4	1·28
"Caro's acid"	1·65

M. Bach acknowledges that this increase of the oxygen set at liberty arises from the presence of *tetroxide of hydrogen*, H_2O_4; that is HO.O.O.OH, corresponding to the tetroxide of potassium. The trioxide, H_2O_3, does not appear to have any oxidising power.—*Berichte*, vol. xxxiii., p. 1506.

NOTES AND QUERIES.

Lactic Acid.—Could any of your reader give any information as to the "lactic acid" which is now becoming so largely used in tanning, and also to some extent in dyeing. Someone has informed the enquirer that it is obtained directly from potatoes through the action of some bacillus.—A Very Old Reader.

MEETINGS FOR THE WEEK.

Tuesday, 21st.—Royal Institution, 3. "On Cellular Physiology, with special reference to Enzymes and Ferments," by Allan Macfadyen, M.D., B.Sc.
—— Society of Arts, 8. "The Rise and Development of Egyptian Art," by Prof. W. M. Flinders Petrie, D.C.L.
Wednesday, 22nd.—Society of Arts, 8. "Testing and Training Distant Vision, with Special Reference to Military Requirements," by R. Brudenell Carter, F.R.C.S.
Thursday, 23rd.—Royal Institution, 3. "The Chemistry of Carbon," by Prof. Dewar, F.R.S., &c.
Friday, 24th.—Royal Institution, 9. "The Aims of the National Physical Laboratory," by Richard T. Glazebrook, M.A., D.Sc., F.R.S.
Saturday, 25th.—Royal Institution, 3. "The Rise of Civilisation in Egypt," by Prof. W. M. Flinders Petrie, D.C.L.

AMMONIUM BROMIDE AND THE ATOMIC WEIGHT OF NITROGEN.*

By ALEXANDER SCOTT.

Although the whole of the recent work on the ratio of the atomic weights of hydrogen and oxygen relatively to one another seems to establish that ratio as 1 : 15·88 or 1·0075 : 16, I thought it would be not only of great interest, but of the highest importance if this ratio could be determined in some manner totally different from any that had been previously attempted, and depending in no way on determinations of the composition of water.

The ideal method was to find some atom or group of atoms which unites with hydrogen and with oxygen to produce compounds of sufficient stability for their equivalent weights to be accurately determined. We seem to have this in the three bases—hydrazine, ammonia, and hydroxylamine, which for this purpose may be regarded as having the formulæ NH_2, NH_3, NH_3O, hydrazine having one hydrogen atom less, and hydroxylamine one oxygen atom more than ammonia.

The hydrobromides of these bases seem from their general properties admirably adapted for comparison with one another by determining in each case the equivalent amount of pure silver.

Although the preparation and purification of the substances and the necessary careful study of their adaptability for the end in view has occupied rather more than two years, it was not anticipitated that any serious difficulty would occur in the case of the central member of the group, ammonium bromide. Nevertheless, such is the case, and the explanation of the discrepancies which exist between the classical work of Stas and my own is by no means easy.

Stas (*Œuvres*, i., 812), gives the ratio of ammonium bromide to silver as 98·032 : 107·93, whereas I find only 97·995 : 107·93; the corresponding values for ammonium are 18·077 and 18·040, and for the atomic weight of nitrogen 14·047 and 14·010.

Stas deduced the value above stated from seven experiments on samples of ammonium bromide prepared in different ways and apparently always against the same sample of silver.

He states (*Œuvres*, i., 790) :—"On le sait, le bromure d'ammonium peut être volatilisé sans décomposition dans un courant de gaz ammoniac sec. Dans le but de me procurer ce sel à l'état compacte et partant facile à peser et à manier, j'ai essayé d'avoir recours à cette volatilisation, mais après plusieurs tentatives infructueuses, j'ai été obligé d'y renoncer. En effet, à une température très-peu supérieure à sa volatilisation, il se dissocie, du brome même devient parfois libre. On constate aisément la présence de ce corps par la coloration de la vapeur du bromure, et *par la coloration en jaune du sel condensé*, qui a produit des fumées lorsqu'on l'a chauffé dans de l'ammoniaque seche."

The italics are those of Stas himself. He further remarks that his bromide, which was brilliantly white, and remained so indefinitely at the ordinary temperature under a bell-jar over potash, lost its whiteness, and became greyish (*grisâtre*) when heated in air at temperatures above 100°, that this greyness increased as the salt was heated from 115° to 180°, and that the whiteness was only partially restored by heating it in a current of ammonia.

All my samples were also brilliantly white, and showed no greyness when heated in air to 180°, although they lost their sparkling whiteness; this was due, however, to a change in the surface of the crystals owing to the slight sublimation which takes place when the salt, imperfectly dried, is heated to that temperature. No difficulty was experienced in subliming the salt either in a vacuum, in a mixture of ammonia and hydrogen, or in pure ammonia itself, and no trace of yellow colouration was observed in any instance, the condensed salt being a somewhat horny, translucent mass.

The silver employed was prepared from the pure silver of commerce by dissolving it in nitric acid, evaporating the solution to dryness, and fusing the salt for twenty minutes; the fused mass was then dissolved in water, filtered, and kept gently boiling for several hours with 10 to 15 grms. of freshly precipitated silver oxide, the oxides of lead, copper, and iron being thus precipitated and apparently completely removed.

After filtration, the solution of silver nitrate thus purified was added in small quantities at a time to a solution of equivalent quantities of ammonium formate and acetate sufficient to reduce rather more than the total silver nitrate added. The solution of ammonium formate and acetate was made by distilling pure formic and pure acetic acids into a solution of ammonia (which had been prepared by passing well washed ammonia into pure redistilled water in a porcelain beaker), until the solution was strongly acid; everything of a nature not very easily volatile was thus completely excluded from the reducing agent. It was suitably diluted and raised to the boiling-point in a flask of special non-attackable glass, and the silver nitrate solution added. The reaction which takes place is :—

$$HCO_2NH_4 + 2AgNO_3 = NH_4NO_3 + HNO_3 + 2Ag + CO_2$$

and

$$CH_3.CO_2NH_4 + HNO_3 = NH_4NO_3 + CH_3.CO_2H,$$

the use of the ammonium acetate being merely to exchange the liberated nitric for acetic acid. After being thoroughly washed and dried, the silver was fused with a little pure sodium and potassium carbonates along with a little nitre, granulated, and the above process repeated, the re-precipitated and thoroughly washed silver being raised to a low red heat in a muffle, and kept in the easily divided form thus obtained. Only 2 or 3 milligrms. of ferric oxide were separated by the second treatment from a kilogrm. of silver.

This silver was notably better than a sample prepared with the utmost care by the cuprous ammonium sulphite method so much employed for the purification of silver.

The hydrobromic acid employed was made in two ways: —(1). By distilling potassium bromide with somewhat diluted sulphuric acid, and frequent re-distillation (Squibb's process), and (2) by the reduction of bromine to hydrobromic acid by means of sulphurous acid, as I have described (*Trans.*, 1900, lxxvii., 649).

The ammonia was also from two sources :—(1). From ammonium sulphate drastically treated with nitric and sulphuric acids, and (2) from potassium nitrite reduced by means of zinc which had been fused with lead oxide. In both cases, all the precautions given by Stas were rigorously adhered to, and in some cases even exceeded.

The balance chiefly employed in the weighings was an excellent one by Bunge, and the weights were of platinum-iridium made by Messrs. Johnson, Matthey, and Co., and adjusted with great accuracy by Oertling.

The silver, after being heated over a spirit burner in pure hydrogen and weighed, was dissolved in a carefully stoppered bottle in pure nitric acid (sp. gr. 1·42), the bottle standing on the water-bath for an hour. After complete cooling, the pressure inside the bottle was almost always considerably less than that of the atmosphere, so that water could be drawn in when the stopper was carefully removed, and all possible loss of silver thus avoided.

The silver nitrate solution was then diluted and kept on the water-bath until both the solution and the atmosphere above it were quite colourless.

* From the *Transactions of the Chemical Society*, 1901, lxxix., p. 147.

The ammonium bromide, heated in almost every case to 180° for some hours in a current of hydrogen which had been bubbled through pure ammonia solution, and dried by passing over solid soda and metallic sodium, was weighed after being cooled in a vacuum, then dissolved and added to the silver solution in a room lit with red light only, the whole vigorously shaken, and this shaking frequently repeated. The excess of silver or bromide remaining in solution was determined (usually after two days) by means of standard solutions (which were in all cases weighed).

In the following summary all the weights given are reduced to vacuum weighings, and corrected for all errors in the face values of the weights. The atomic weight of silver is taken as 107·93.

To test the effect of sublimation on the salt, the third crop of crystals obtained by evaporating to dryness the mother-liquors from the ammonium bromide used in series IV. and V. below was employed. Obtained in this way, it was likely to be abnormally acid, and therefore would tend to give a low equivalent.

(*a*). Not sublimed, dried in hydrogen and ammonia at 180°.

4·89631 NH_4Br = 5·39380 Ag ∴ NH_4Br = 97·975.

(*b*). Sublimed once in Sprengel vacuum, but not dried or treated further.

2·45925 NH_4Br = 2·70914 Ag ∴ NH_4Br = 97·972.

(*c*) Sublimed twice in Sprengel vacuum, and dried in hydrogen and ammonia at 180°.

3·29478 NH_4Br = 3·62928 Ag ∴ NH_4Br = 97·982.

(*d*) Sublimed in hydrogen and ammonia and heated in the same at 180° for some hours.

4·46957 NH_4Br = 4·92273 Ag ∴ NH_4Br = 97·994.

(*a*), (*b*), and (*c*) show by their low equivalents that they were distinctly acid, which acidity was only overcome by sublimation in a strongly ammoniacal atmosphere.

The other samples of ammonium bromide were crystallised from *alkaline* solutions. The solutions of the dried bromide, like those of Stas, were all strongly acid to litmus.

I. Ammonia from ammonium sulphate. Hydrobromic acid from potassium bromide. Silver reduced by formate.

(*a*). 4·20661 NH_4Br = 4·63303 Ag ∴ NH_4Br = 97·996.
(*b*). 4·23664 NH_4Br = 4·66644 Ag ∴ NH_4Br = 97·989.

II. Ammonia from potassium nitrite. Hydrobromic acid from potassium bromide. Silver reduced by formate.

(*a*). 4·31464 NH_4Br = 4·75175 Ag ∴ NH_4Br = 98 001.
(*b*). 6·19233 NH_4Br = 6·82047 Ag ∴ NH_4Br = 97·990.

III. Same ammonium bromide as in I. Silver reduced by cuprous ammonium sulphite.

8·77664 NH_4Br = 9·66788 Ag ∴ NH_4Br = 97·981.

This silver was found to contain 0·0018 grm. of ferric oxide, hence the true equivalent weights are—

8·77664 NH_4Br = 9·66608 Ag ∴ NH_4Br = 97 999.

IV. Ammonia from ammonium sulphate. Hydrobromic acid from pure bromine. *First* crop of crystals. Silver reduced by formate *unfused*.

(*a*). 10·47233 NH_4Br = 11·53416 Ag ∴ NH_4Br = 97·994.

Same, but the silver *fused* on pure calcium phosphate cupel.

(*b*). 4·91997 NH_4Br = 5·41834 Ag ∴ NH_4Br = 98·0028.

V. Ammonia from ammonium sulphate. Hydrobromic acid from pure bromine. *Second* crop of crystals. Silver reduced by formate.

The ammonium bromide was sublimed in a current of pure ammonia, and allowed to cool for 4 hours in it at the atmospheric pressure, then left in a vacuum for 36 hours over sulphuric acid. It was then divided into two portions, one of which was left 54 hours longer over sulphuric acid in a vacuum, when—

(*a*). 5·00442 NH_4Br = 5·51164 Ag ∴ NH_4Br = 97·997.

The other portion was dried as usual in hydrogen and ammonia at 180°, when—

(*b*). 5·17914 NH_4Br = 5·70390 Ag ∴ NH_4Br = 98·000.

VI. In order to test in the severest manner possible the quality of the silver employed, at the suggestion of Prof. Dewar I reduced the silver bromide obtained in Series IV. (*a*) by pure hydrogen; one part of this was fused on a pure calcium phosphate cupel by means of a mouth blowpipe of glass fed by pure hydrogen, and cooled in hydrogen, then thoroughly cleaned by treatment first with pure hydrochloric acid and then with ammonia, and heated for some time in hydrogen. When compared with the ammonium bromide of Series IV. it was found—

(*a*). 4·84099 NH_4Br = 5·33177 Ag ∴ NH_4Br = 97·995.

The other portion was fused on a cupel of pure lime made as Richards recommends by igniting a mixture of 3 parts of pure lime and 1 part of pure calcium nitrate, and treated as above. It was weighed and then heated for nearly an hour in a Sprengel vacuum at the boiling point of sulphur, and afterwards to as high a temperature as the combustion tube would stand, and cooled in the vacuum. Its weight was unchanged, and no gas was extracted from it.

(*b*). 5·10677 NH_4Br = 5·62515 Ag ∴ NH_4Br = 97·984.

This seems to corroborate the statement of Stas that the silver fused on calcium phosphate is purer than that fused on pure calcium oxide. It also looked more brilliant, although the dulness of that fused on the lime was due partly to a small quantity of lime dust floating on the surface.

The silver bromide precipitated was collected after several of the titrations, in order to determine whether the silver and the bromine were strictly comparable with those of Stas. To ensure the whole of the silver being precipitated, a few drops of pure hydrobromic acid were always added. The silver bromide was collected in a porcelain Gooch crucible on a filter of the finest asbestos, which had been very carefully purified by means of sulphuric and nitric acids. It was then heated to 180°, and after an hour or so at this temperature was dried perfectly, even with the largest quantities collected. Fusion of the bromide resulted in the loss of a few tenths of a milligramme only, which by blank experiments was shown to be due to the asbestos filter. No difficulty was encountered in getting both the crucible and filter, and these together with the silver bromide and chloride, to give weights constant to one-tenth of a milligramme.

The whole of the filtrate was evaporated to dryness in each case to see if any foreign matter could be detected, or if any silver bromide had passed through. In only one case was anything weighable found, and that was in the case of the silver reduced by means of cuprous ammonium sulphite (Series III.) when 0·0018 grm. of ferric oxide was obtained. The weights of silver bromide are obviously more likely to be too low than too high from experimental errors.

II. (*b*). 6·82315 Ag gave 11·87733 AgBr.
∴ 100 Ag = 174·074 AgBr.
Stas found 174·080.

III. 9·66809 Ag gave 16·82816 AgBr.
∴ 100 Ag = 174·059 AgBr.
corr. for Fe_2O_3 174·090.

IV. (*b*). 5·41906 Ag gave 9·43315 AgBr.
∴ 100 Ag = 174·0735 AgBr.

V. (*a*). 5·51258 Ag gave 9·59596 AgBr.
∴ 100 Ag = 174 074 AgBr.

(*b*). 5·70686 Ag gave 9·93346 AgBr.
∴ 100 Ag = 174·062 AgBr.

VI. (*a*). 5·33191 Ag gave 9·28093 AgBr.
∴ 100 Ag = 174·064 AgBr.

(*b*). 5·62572 Ag gave 9·79254 AgBr.
∴ 100 Ag = 174·007 AgBr.

A further interesting corroboration of the value found above for ammonium bromide as it involves different samples of ammonia, hydrobromic acid, and silver, as well as personal equation, is that in August, 1882, Mr. C. T. Heycock and the author prepared ammonium bromide which was titrated as above against silver prepared by the cuprous ammonium sulphite method, the titration being done by Mr. Heycock. The mean of two experiments, in each of which over 7 grms. were used, was 97·993.

As Mr. Heycock was working at the time on the atomic weight of rubidium, and along with Prof. Dewar I was working at the atomic weight of manganese, our object in then preparing ammonium bromide was to have a salt which we thought could be prepared easily at any time and used as a standard substance to determine the purity of any sample either of hydrobromic acid or of silver, but as our value differed from that of Stas, only these two determinations were made, and the salt condemned as unsuitable for our purpose.

Two determinations were made with ammonium chloride; the ammonia was from the purified ammonium sulphate used in the experiments on the bromide, and the hydrochloric acid was the pure acid of commerce diluted till just under constant boiling-point strength and boiled gently for some hours, a few crystals of potassium chlorate being added at intervals, all chlorine and chlorine oxides were then expelled by boiling, and the acid distilled first through a glass and then through a platinum condenser.

(*a*). 4·78257 NH_4Cl = 9·64484 Ag ∴ NH_4Cl = 53·519.
(*b*). 5·51744 NH_4Cl = 11·12810 Ag ∴ NH_4Cl = 53·513.

The silver chloride was collected from (*a*), when with the standard ammonium chloride solution added, it was found that—

4·7830 NH_4Cl gave 12·82048 AgCl.
If AgCl = 143·387 then NH_4Cl = 53·5165,

which is the mean of the two titration values. The value given by Stas is 53·532.

The situation may be thus summed up:—

The values obtained by Stas for the equivalents of ammonium bromide and chloride are 98·032 and 53·532, whereas mine are 97·995 and 53·516 respectively. That is to say, my results are in the first case 1/2650, and in the second 1/3350 lower than those of Stas, so that if I admit 1/3000 impurity in my silver this would explain the discrepancy, especially as the value for ammonium, and therefore for the atomic weight of nitrogen deduced by Stas from the bromide and from the chloride, agree so well:—

(18·075 from the chloride),
(18·077 „ bromide),

whilst my values for ammonium do not, but are 18·040 from the bromide, and 18·059 from the chloride.

But my silver and my bromine agree exactly with those of Stas as shown by the weight of silver bromide produced from a given weight of silver. Moreover, the ammonium bromide of Stas seems to have contained some foreign matter, most probably platinum, in vessels of which he largely made his preparations. I found that I could use platinum vessels *for hydrochloric* acid and chlorides, but *not for hydrobromic* acid, as the latter attacks platinum when warmed in presence of air in vessels of this material

The value for ammonium chloride calculated from the data given by Marignac (*Bibl. Univ. Geneve*, 1843, xlvi., 367), is 53·486, but I have been unable to find how he purified his silver; but it is obvious that it must have been very pure, as he found that 100 parts of silver were equivalent to 110·343 of potassium bromide, whilst Stas found (as the mean of 14 experiments) 110·345. A further proof of the purity of my silver is given in the paper on the preparation of pure hydrobromic acid above referred to, where my value for this ratio is shown to be 110·349.

I gave some of my silver to Sir W. Crookes when I had no reasons for suspecting any impurity, and he informed me that it was the purest silver he had ever tested spectroscopically, giving fewer lines than a specimen which he had until then regarded as pure, but which on comparison with mine was shown to contain traces of copper.

Every titration performed has been given above as well as every gravimetric determination with the exception of two in which some of the precipitated silver salt was unfortunately lost during transference from the bottle to the filter, these being the silver bromide in IV. (*a*) and the silver chloride in (*b*). No two determinations were made in exactly the same way throughout, even with those in the same series, but the extreme values differ very little, and in no case has any value approached that of Stas.

It is obvious that further determinations of ammonium chloride and also some of ammonium iodide must be made in order to clear up the discrepancies indicated above. Until this has been done it would be premature to discuss the value for the atomic weight of nitrogen as deduced from the equivalent weights of ammonium haloid salts.

RELATIONS BETWEEN ATOMIC WEIGHT, ATOMIC VOLUME, AND MELTING-POINT.

By THOMAS BAYLEY, Assoc.R.C.Sc

It is known that a definite connection exists between the atomic weight of an element and its specific gravity and melting-point (Chem. News, vol. lxxx., p. 282). It can further be shown that a definite connection exists between these physical properties of an element and the atomic weights of other elements, which is equivalent to saying that a definite law connects the atomic weights and physical properties of all elements.

The accompanying table exhibits a connection between the A.V. (expressed by $\{\ \}$) and the absolute M.P. (expressed by $[\ ]$) of various pairs of elements and the "critical points" considered by the author (Chem. News, vol. lxxvii., p. 157) to indicate the commencement of the various cycles, or the points of temperature, on the hypothesis of atomic condensation from cooling protyle, at which the tide of evolution underwent periodic change. The A.W.'s in the table are printed without brackets, and the A.V.'s are all multiplied by 10. It may be observed with regard to those pairs between the M.P. of one element with the A.V. of another element, that when the M.P. is a measurement obtained by experiment, although connected with the A.W. by a definite law, the A.V. $\left(\frac{\text{S.G.}}{\text{A.W.}}\right)$ necessarily varies with the scale on which A.W. is expressed. For example, in the expression—

$$\frac{[M']}{\{M'\}} = A$$

$$\frac{[M'']}{\{M''\}} = A',$$

when the value of the upper term of the pair is changed to $\frac{[M'M]}{M'e}$ by alteration of scale, the value of the lower term is not proportionately altered, because—

$$\frac{\text{A.V.}}{\text{A.W.}} = \frac{\text{S.G.}}{\frac{\text{A.W.}}{\text{A.W.}}} = \frac{\text{S.G.}}{(\text{A.W.})^2}.$$

Such an alteration from A.W. to A.W.^{x} occurs in the passage from H = 1 to O = 16; and although the identity between

* Dewar's result.

the two terms of the pair is not, owing to several causes,* sufficiently exact to be disturbed by so small a change as this, it is clear that a larger change (such as expression in terms of a possible element of lower atomic weight than H) would upset the identities. There is here a suggestion of necessity for an *absolute* scale of A.W., since the system of analogous pairs cannot be accidental.

The gaps in the columns in the accompanying tables are doubtless due to the want of the necessary data for so many of the known elements, and for the—as yet—undiscovered elements of the atomic system. A relation between S.G. and M.P. might be presumed to exist, because S.G. is a function of the attractive force between atoms, and M.P. is an expression for the intensity of thermal vibration which overcomes this attraction. The relations here shown are only instances, among others; thus there is a series conforming to the general expression—

$$\frac{\text{M.P. of } M_{x'}}{\text{A.W. of } M_{y'} - \text{A.W. of } M_{z'}} = A$$

for several values of A.

DETECTION OF SELENIUM IN SULPHURIC ACID.

By AD. JOUVE.

ALL ordinary sulphuric acid contains selenium, or, to be more precise, oxidised compounds of selenium. They can even, nearly always, be detected in the pure acid supplied to laboratories, or for pharmaceutical purposes.

Among the methods for detecting selenium two are fairly sensitive. One of these consists in the use of codein, which gives an intensely blue colouration to the sulphuric solution of selenious acid. Let us remark in passing that this reaction, which is said to be characteristic of codein, is also produced by morphine. In each case its sensitiveness reaches 1/200th at the most.

The second method consists in using sulphurous acid gas passed through the sulphuric acid diluted with four times its volume of water; this must be done warm. Under these conditions the selenious acid is reduced by the sulphurous acid, and the selenium is precipitated in the red form. In this case the sensitiveness reaches a maximum of 1/10,000th.

Now in what state does the selenium exist in the sulphuric acid? It exists in the forms of selenious and selenic acids. Selenic acid is only acted on with great difficulty by sulphurous acid gas, and not at all by the codein reagent, from which facts errors may frequently arise.

In a research on the composition of certain gases from carbides I had occasion to pass raw acetylene over sulphuric acid, and I observed the almost constant formation of a more or less intense red colouration. This colouration can be observed when only 1/100,000th part of selenium is present.

This colouration may be due to the formation of sulphonised compounds of the carbides, or to the setting free of selenium. To make certain which, two methods can be used:—

1. Sulphuric acid containing free selenium in suspension, dissolves it when heated, taking a green colour.

2. The red liquor is diluted with water after passing C_2H_2; it is then oxidised by permanganate until the rose-colour remains constant; the excess of $KMnO_4$ is then decomposed by means of sulphite of soda in excess, and the whole then heated; through the action of the permanganate the selenium is changed to selenious acid, which is again converted into selenium by the sulphite of soda, and, as a matter of fact, on heating we obtain a slight flocculent red precipitate of selenium, which can be collected on a filter, and identified by the odour it gives on burning, or by its solubility in the alkalis; or again by suspending it in sulphuric acid, and heating, when it dissolves with a beautiful green colour.

The reduction of the compounds of selenium is not due to the sulphonised compounds, for if we cause pure acetylene to be absorbed by sulphuric acid not giving any selenium reaction, and if we then add this solution to sulphuric acid containing as much as 1/1000th part of selenium added in the form of selenious acid, we are unable to obtain the colour reaction.

The reducing action is partly due to impurities in the

* Such as irregularity in the temperatures at which the determination of S.G. are made, allotropism, and errors of experiment.

raw acetylene gas; this gas containing, amongst other impurities, sulphide, phosphide, and silicide of hydrogen, which are all reducing agents, and which also give the colour reaction. However, when used pure these gases are not of much service; further, one of them, the most easy to obtain, viz., sulphuretted hydrogen, immediately reduces sulphuric acid with a deposit of sulphur so abundant that the selenium is entirely hidden. Pure acetylene also takes a considerable part in the precipitation of selenium, and that can be proved in two ways:—

1. The acetylene after having passed through five flasks containing pumice-stone soaked in sulphuric acid, alternated with potash tubes, gives the colour reaction when passed through a final flask containing impure acid.

2. Pure acetylene prepared from acetylide of copper gives the reaction.

It should be remarked that the sensitiveness is increased from the point of view of the rapidity of the colouration if the acetylene gas contains hydrochloric fumes.

The detection of selenium in sulphuric acid is of some interest, assuming that this acid is used in the free state, either from the pharmaceutical point of view, or under other circumstances in which it might be introduced in small quantities, for selenium compounds are far from being harmless to the human organism.—*Bull. Soc. Chim.*, Series 3, vol. xxv., No. 9.

SOME PRINCIPLES AND METHODS OF ROCK ANALYSIS.*

By W. F. HILLEBRAND.

(Continued from p. 235).

XXIII. *Fluorine.*

FLUORINE can only be estimated by the method of Rose, care being taken to use sodium-potassium carbonate as a flux, and to avoid use of the blast if possible. For minerals rich in fluorine and low in silica it may be necessary to add pure silica before the fusion in order to effect complete decomposition of the fluoride just as with the alkaline-earth phosphates. To the hot aqueous extract several grms. of ammonium carbonate are added, and more on cooling. After twelve hours the solution is filtered, ammonium carbonate is expelled, and an ammoniacal solution of zinc oxide added, whereupon evaporation is carried on till the odour of ammonia is entirely gone. After filtering, add nitric acid in insufficient quantity to fully neutralise.

The use of ammonium nitrate or chloride, instead of carbonate, for throwing out the silica and alumina is not to be recommended, because of loss of fluorine on evaporation (Rose). If the rocks are very basic it may happen that the amount of silica in the alkaline solution is so small that ammonium carbonate may be dispensed with, and the ammoniacal zinc oxide solution added at once.

By whatever modification of the method the silica and alumina may have been separated, the alkali carbonate must be converted into nitrate, and not chloride if phosphorus or chromium, or both, are present. To remove the chromium and the last of the phosphorus, silver nitrate in excess is added to the solution containing still enough alkali carbonate to cause a copious precipitate of silver carbonate, which shall take up the acid set free, and thus insure a neutral solution, and consequent complete precipitation of phosphorus and chromium. After heating and filtering, the excess of silver is to be removed by sodium or potassium chloride, and sodium carbonate is to be added, in order to furnish by addition of calcium chloride in excess to the hot solution a sufficient admixture of calcium carbonate with the fluoride. At this stage there must be no ammoniacal salts in solution, otherwise calcium fluoride may be held up.

The next operation is perhaps best conducted as recommended by Penfield and Minor (*Amer. Journ. Sci.*, 1894, Third Series, vol. xlvii., p. 389). To the gently ignited precipitate of carbonate and fluoride of calcium at most 1—2 c.m.³ of acetic acid are added in the crucible, which is then placed for a time on the water-bath, and afterwards its contents are evaporated to dryness. They are then taken up with hot water, the solution is decanted through a small filter, likewise the washings. The filter is burned in the same crucible, more acetic acid is added, and the various operations are repeated until all calcium oxide and carbonate have been extracted. The above authors find that if a great excess of acetic acid is used at the start, the results are low. While their experiments related to the determination of fluorine in a mineral rich in that element—topaz—their precautions are probably not needless with the small amounts of fluorine met with in rocks.

The well-washed and gently ignited calcium fluoride finally obtained in the course of this method should be converted to sulphate as a check upon its purity, and at the same time as a qualitative test to ascertain if it really is calcium fluoride by the characteristic odour of the gas given off. Should fluorine be found, and the weight of sulphate not correspond to that of the fluoride, the former should be dissolved in hot nitric acid, and tested for phosphorus by ammonium molybdate solution. If phosphate is absent the impurity may have been silica or calcium silicate—which of these it would be difficult to decide. In the former case the fluorine might be safely deduced from that of the sulphate, but not in the latter. If the rock were rich in sulphur it might happen that calcium sulphate would be thrown down with the fluoride, but this should be removed by thorough washing. If not, and it were certainly the only impurity present, the fluorine could be calculated, after conversion of the fluoride into sulphate, by the formula:—

$$CaSO_4—CaF_2 . 2F :: \text{Diff. between impure } CaSO_4 \text{ and } CaF_2 : x.$$

It is an exceptional case when there is exact agreement between the weight of fluoride and sulphate, and with the small amounts usually met in rocks the error may be an appreciable one in percentage of fluorine, though of no great significance otherwise.

There is no qualitative test which will reveal with certainty the presence of fluorine in rocks. Heating the powder before the blowpipe with sodium metaphosphate on a piece of curved platinum foil inserted into one end of a glass tube, or in a bulb tube, is not to be relied on in all cases. While as little as one-tenth of 1 per cent of fluorine can sometimes be thus detected with ease, much larger amounts in another class of rocks may fail to show.

XXIV. *Sulphur.*

Before proceeding to the estimation of sulphur, its condition, if present, should be ascertained.

Evolution of hydrogen sulphide on boiling with hydrochloric acid is evidence of a soluble sulphide, usually pyrrhotite, but possibly lazurite. Extraction of magnetic particles reacting for sulphur shows pyrrhotite to have been in part at least the source of the hydrogen sulphide. A reaction for sulphuric acid in the filtered solution indicates a soluble sulphate, usually noselite or hauynite. If the residue, when well washed and treated with aqua regia or hydrochloric acid and bromine, gives more sulphuric acid, the probable presence of pyrite is shown. Should this solution likewise show arsenic, the sulphide may be arsenopyrite, which, however, is of very rare occurrence in igneous rocks, if, indeed, it is ever found there.

For the quantitative extraction of the sulphur of soluble sulphates, simple boiling with hydrochloric acid suffices, which should be done in an atmosphere of carbonic acid if pyrites or other oxidisable sulphides are present, and

* *Bulletin of the United States Geological Survey*, No. 176.

should be finished as quickly as possible in order to minimise the error resulting from oxidation to sulphuric acid of the sulphur of sulphides, if present, by any ferric salts that may have been dissolved.

The sulphur of sulphides may sometimes be correctly determined by extraction with aqua regia or some other powerful oxidiser, but not always; so that it is better by far to fuse with sulphur-free sodium carbonate and a little nitre over the Bunsen burner, and for a few moments over the blast, fitting the crucible into a hole in asbestos board (Lunge) to prevent access of sulphur from the flame. After thorough disintegration of the fusion in water, to which a drop or two of alcohol has been added for the purpose of reducing manganese, the solution is filtered, and the residue washed with a dilute solution of sodium carbonate. In the filtrate (100—250 c.m.³ in bulk) the sulphur is precipitated at boiling heat by barium chloride in excess after slightly acidifying by hydrochloric acid. Evaporation to dryness first with acid, in order to eliminate silica, is needless, for in the above bulk of solution there will almost never be the least separation of silica with the barium sulphate. It is well that this is so, for evaporation on the water-bath heated by gas to remove silica would in many cases involve an error fully equal to the sulphur present by contamination from the sulphur of the gas burned.

Owing to the small amount of sulphur in rocks, special purification of the barium sulphate obtained is hardly ever needful, especially as it has been precipitated in absence of iron. Should there be fear of a trace of silica being present, it can be removed by a drop of hydrofluoric and sulphuric acids before weighing the barium sulphate.

This, of course, gives the total sulphur in the rock. If soluble sulphates and sulphides as well as insoluble sulphates and sulphides are present together, the sulphur of the first is found in solution after extraction by hydrochloric acid in a carbon-dioxide atmosphere, and that of the decomposable sulphides by collecting the hydrogen sulphide evolved.* In the residue the sulphur of the insoluble sulphides can be estimated, or from the total sulphur found in another portion its amount can be calculated. The error involved in the above estimation of the sulphur of soluble sulphides, due to the possible reducing effect of hydrogen sulphide on ferric salts, is probably negligible. Most of the hydrogen sulphide would be expelled before any such action could take place, and probably before the ferric salts were largely attacked, but of course the small proportion of sulphur set free as such from pyrrhotite would escape estimation, and introduce further uncertainty. In general, it would be safe enough to assume the composition Fe_7S_8 for pyrrhotite. However carefully all these separate determinations may be carried out, the final figures for ferrous and ferric oxides can hardly be regarded as more than approximations when much sulphide is present. (See p. 220).

(To be continued).

THE VOLUMETRIC ESTIMATION OF COPPER AS THE OXALATE, WITH SEPARATION FROM CADMIUM, ARSENIC, TIN, AND ZINC.†

By CHARLES A. PETERS.

(Concluded from p. 231).

Separation from Cadmium.

BOURNEMANN (*Chem. Zeit.*, xxiii., 565) has used nitric acid for a rough separation of copper from cadmium. This method was tried for a quantitative separation in the presence of 6 to 10 per cent strong nitric acid. The results are found in Section F of Table III. Experiments 33 to 35 stood six hours before filtering. Experiments 36 and 37 stood over night. Copper is separated from more than twice its weight of cadmium, and the results are accurate.

Separation from Arsenic in both Conditions of Oxidation.

For the separation from arsenic, arsenious oxide dissolved in sodium carbonate, and di-hydrogen sodium arseniate were the forms of arsenic used. The results are accurate, and are given in Sections G and H (Table III.). In Experiments 38 to 40 and 44 and 45 no nitric acid was added. While the presence of the nitric acid is not necessary for the separation of the copper from the arsenic, still the filtration in the absence of the nitric acid is so slow as to be objectionable. The presence of the nitric acid causes the precipitate to come down in a coarser condition, and in such condition it filters easily and is capable of being washed quickly.

Separation from Tin, in both Conditions of Oxidation.

For the separation of copper from tin, a preparation of stannous chloride (20 c.m.³ giving 0·3746 grm. metallic tin by the battery), containing sufficient hydrochloric acid to prevent deposition of oxy-salts, was used. The solution of stannic chloride contained 1·0 grm. metallic tin to every 10 c.m.³, and was used without hydrochloric acid. The results of the work are found in Sections I and K of the Table. The experiments go to show that while copper may be separated from small amounts of tin as stannous chloride, yet there is a limit to the amount of tin which may be present. One-tenth of a grm. of metallic tin is the largest amount that can be present, with 0·15 grm. copper oxide taken as the sulphate, without significant error. Practically the same statement can be made of the separation of copper from tin taken as stannic chloride. Experiment 57 shows a greater loss of copper when the nitric acid is omitted.

Separation of Copper from Iron.

A solution of ferric nitrate was used for the work on the separation of copper from iron. Low results were obtained when a solution of ferrous or ferric sulphate was used as the source of iron. The results of the experiments are recorded in Section L of the table, and show that 0·20 grm. copper oxide, as the sulphate, may be separated from 0·2 to 0·3 grm. iron oxide taken as the nitrate. In Experiment 64 a good result was obtained when no nitric acid was present, save that added in combination with the iron. A comparison of Experiments 63 and 65 shows that it is best to avoid the use of large amounts of nitric acid when the larger amounts of ferric nitrate are present.

For a practical application of the above separation of copper from iron, a convenient amount of finely-ground chalcopyrite (0·5 grm.) was roasted two to three hours in a porcelain crucible until all sulphur was driven off, washed into a beaker, strong nitric acid about 5 c.m.³ was added, and, with the beaker covered, allowed to evaporate slowly on a hot plate nearly to dryness. A little dilute nitric acid was added, the solution was filtered, the residue was washed with water containing dilute nitric acid, the filtrate (about 50 c.m.³ in volume) was precipitated with 2·0 grms. oxalic acid, and the precipitate was estimated after standing twelve to sixteen hours, as previously described. The washing with water acidified with nitric acid is important, because the finely-ground ferric oxide remaining undissolved passes through the filter when washed with water alone, but gives no trouble if the water be acidic. The results of two estimations are here given.

Chalcopyrite. Grm.	Copper found by battery. Per cent.	Copper found by oxalate method. Per cent.	Difference. Per cent
0·5000	31·00	30·92	−0·08
1·0000	31·00	31·25	+0·25

Separation of Copper from Zinc.

The separation of copper from zinc was not altogether successful, owing to the tendency of the zinc oxalate to

* With pyrrhotite a small fraction of its sulphur—one-eighth if the formula Fe_7S_8 is adopted—is liberated as free sulphur, and not as hydrogen sulphide.

come down with the copper oxalate. Some experiments are given in Section M of the table.

The separations of copper from bismuth and antimony were unsuccessful.

The work may be briefly summarised as follows:—Copper, exceeding in amount the equivalent of 0·0128 grm. of the oxide to 50 c.m.³ of solution as the sulphate, may be separated completely, even in the presence of a moderate amount of strong nitric, by the addition of sufficient amount of oxalic acid.

Copper may be separated from cadmium, arsenic, iron, and small amounts of tin, when precipitated by oxalic acid in a volume of 50·0 c.m.³ containing 5 c.m.³ strong nitric acid. Inasmuch as the completeness of precipitation of the copper depends upon the presence of a certain minimum amount of the copper salt, this method is not applicable when the amount of copper falls below 0·0128 grm. of the oxide to 50 c.m.³ of solution.

The author wishes to thank Professor F. A. Gooch for much kind help given in the preparation of this paper.

ON THE RESULTS OF A SEARCH FOR OTHER SUGARS THAN XYLOSE AND DEXTROSE IN THE PRODUCTS OF THE HYDROLYSIS OF WOOD FROM THE TRUNKS OF TREES.*

By F. H. STORER, Professor of Agricultural Chemistry.

SEVERAL years ago I had occasion (*Bull. Bussey Inst.*, 1897, ii., 386) to call attention to the fact that not infrequently undue prominence has been given to the opinion somewhat widely held by botanists, and by chemists also, that an abundance of starch is stored in winter as a "reserve matter" in the wood of many kinds of trees. In reality, there is much less starch in the trunk-wood of trees growing in temperate or northern climates than has ordinarily been supposed. Hence the need of studying anew the general question:—What are the reserve matters in trees? As well as the specific question:—Whence comes the sugar which is found in the spring in the sap of many kinds of trees?

It is to be remarked that the false impression as to the presence of much starch in woods depended primarily on the use of improper methods of analysis for estimating the starch (*Bull. Bussey Inst.*, 1897, ii., 391); though it is not improbable that too much importance may sometimes have been accorded to the microscopical observations of botanists on the presence of starch in the twigs of trees. In so far as the life of the whole tree is concerned, it may perhaps be true that the reserve starch stored in twigs should be regarded in some sort as a matter of merely local significance.

It is true of course that the wood of the trunks of trees often or even usually contains in store some starch, and that in the bark also there can be found small quantities of sugars and of substances, such as glucosides, which may be capable of reducing cupric oxide after they have been subjected to the action of water, diastase, and a dilute acid, as happens in the process of analysis which depends on the application of malt. But inasmuch as the visible effect produced by matters held in store in trees is often out of all proportion greater than can be credited to the small quantities of starch and glucosides exhibited by analysis, it seems probable that there must be other carbohydrates stored habitually in trees as reserve matters, and that some of them are equally important with starch, or possibly more important, as a means of carrying forward the life of the tree from one year to another.

It has been suggested not infrequently that the cellulose or, better still, some of the hemicellulose in plants should be regarded as capable of supplying matters for the sustenance of the plant, and this idea is supported by the fact that cellulose yields dextrose when subjected to the action of strong acids, and that several observers have noticed that it is often acted upon by enzymes of one kind or another. (J. R. Green, "The Soluble Ferments and Fermentation," Cambridge, 1899, pp. 84—103).

It would be a matter of no little interest to determine what other substances (if any) beside cellulose that are capable of yielding sugars by hydrolysis could be detected in woods, and the motive of the research here described was to ascertain if possible whether any suggestions as to the presence in woods of substances hitherto undetected could be got by testing roughly though methodically the reducing power and the rotatory power of various products obtained by hydrolysing woods with acids.

It was found by preliminary trials that after xylan had been removed (in some part) by boiling the powdered woods in dilute acids, it is easy to obtain no inconsiderable quantities of sugar by treating the residual wood with strong acids, and subsequently diluting and boiling the mixture. On neutralising and decolorising (if need were) these solutions, after the hydrolysis, they were tested quantitatively for sugar, by means of Fehling's liquor, and their rotatory power was observed with a Schmidt and Haensch polariscope.

Inasmuch as the solutions necessarily contained, beside sugar, extractive matters of one kind or another, it would have been impracticable to determine the specific rotation in each case by the usual and conventional method; for, in order to do that, we need to know the quantity of sugar that is contained in a determined weight of the solution, while in the method here employed we can find only the quantity of sugar in a measured *volume* of the solution. But it is still possible to compare these determinations one with another, and to obtain an approximation to the true specific rotation by making use of the formula—

$$[\alpha]_D = \frac{a \times s}{l \times g}, \text{ in which}$$

a = the observed angle;
l = the length of tube;
g = the number of grm. of dextrose in s, as determined by Fehling's liquor;
s = the number of c.c. of the saccharine solution taken.

I have designated these approximate rotations as "quasi-$[\alpha]_D$," and it is to be observed that the results set forth in this article have all been obtained in this way, unless otherwise expressly stated.

It should be observed that although the figures of the quasi-rotations are always somewhat higher than those of the true specific rotations, they must nevertheless depend upon definite relations which subsist between the quantities of sugar detected in the solutions and the angles of rotation actually observed in the polariscope.

For the sake of illustration a sample of pure dextrose was tested in the manner and by the formula above stated, and there was obtained as the approximate specific rotation of this substance, quasi-$[\alpha]_D = 56{\cdot}84°$; while pure galactose (from Merck and Co) treated in the same way, gave quasi-$[\alpha]_D = 86°$.

Whereas, the true specific rotations $[\alpha]_D = 53{\cdot}40°$ (for dextrose), and $[\alpha]_D = 79{\cdot}94°$ (galactose), were obtained on testing these very samples in the conventional way, and calculating from the observed data by means of the proper formula, viz.:—

$$[\alpha]_D = \frac{a(p+q) \times 1{\cdot}00125}{p \times d \times l}, \text{ in which}$$

a = the observed angle;
p = the number of grm. of sugar;
q = the number of grm. of water;
l = length of the tube;
d = sp. gr. of the solution at 17·5°;
1·00125 = factor for reducing the sp. gr. to 4° C.

In the preliminary trials above mentioned, it appeared as a rule that the rotatory power exhibited by the products of hydrolysis was appreciably higher than could have been the case if only dextrose had been present. Thus, several specimens of maple wood, hydrolysed as above described, after the action of strong acid, and tested in the manner indicated, gave the results which here follow:—Quasi-$[\alpha]_D = 63°$, 65°, 66°, 68°, 69°, and 73·5°, respectively. Birch wood, similarly treated, gave quasi-$[\alpha]_D = 64{\cdot}5°$; and pine wood gave quasi-$[\alpha]_D = 71°$.

It was with the hope of explaining this matter that systematic experiments upon maple and birch woods, and upon cotton cloth also, were made, as is described on the following pages:—

A. *An Examination of the Products of the Acid Hydrolysis of Wood from the Trunk of a Sugar Maple Tree (Acer saccharinum).*—10 grms. of maple wood in fine powder taken from the outer part (wholly free from bark) of the trunk of a tree four inches in diameter, felled on May 30th in the West Newfield, Maine, were soaked during twenty-four hours in 200 c.c. of strong ammonia water, to remove colouring matter and albumenoids, and were then thrown upon a filter, and washed with water. Enough dilute hydrochloric acid, of 3 per cent, was poured

* *Bulletin of the Bussey Institution*, 1900, vol. ii., Part 9.

into the filter to displace the moisture retained by the wood, and the latter was then boiled in a flask, with reflux condenser, over a free flame, with 200 c.c. of hydrochloric acid of 3 per cent during 3·5 hours. The undissolved wood was removed by filtration, and one half the product of the hydrolysis was neutralised with sodium hydroxide, and decolorised with bone-black. On testing the solution with Fehling's liquor it appeared that 100 c.c. of it reduced as much cupric oxide as would have been reduced if the solution had contained 0·5669 grm. of dextrose. This quantity would be equal to 16·21 per cent of dextrose in the dry wood. On observing in the polariscope through a 2 dm. tube a rotation of 0·5° was noted, *i.e.*, quasi-$[\alpha]_D = 44·09$.

The other half of the liquid that had been removed from the wood was boiled 3·5 hours longer over a free flame, and was then neutralised and decolorised as before. The specific rotation in this case was quasi-$[\alpha]_D = 68·17°$, and Fehling's liquor showed "sugar" (calculated as dextrose) equal to 10·43 per cent of the dry wood.

Due allowance being made for the possibility of the presence in the solution of matters other than sugars, which might have some influence on the rotatory power, it is to be presumed that the sugar observed in the product of the first hydrolysis probably consisted of a mixture of xylose and dextrose, and that some of the latter was made to "revert" to compounds of higher rotatory and lower reducing powers by the second boiling, after the removal of the wood. Such reversion has repeatedly been noticed by chemists,* and there are researches by Grimaux and Lefèvre (*Comptes Rendus*, 1886, ciii., 146), by Gautier (*Bull. de la Soc. Chim. de Paris*, 1874, xxii., 145), and by Fischer (*Ber. der Deut. Chem. Gesell.*, xxiii., 3687; xxvi., 2400; xxvii., 2478; xxviii., 1145, 1167, 3024), which help to explain what kinds of products are formed.

The residual wood, taken from the acid liquor of these first trials with dilute acid, was soaked in strong hydrochloric acid of 35 per cent, during twenty-four hours, and the mixture was then poured into boiling water, taken in such quantity that the final strength of the acid in the mixture should be 3 per cent. In the 3 per cent acid thus obtained, the residual wood was boiled over a free flame during six hours. The liquid was then neutralised with sodium hydroxide, evaporated, and decolorised with bone-black. The specific rotation was found to be quasi-$[\alpha]_D = 70·84°$, and Fehling's liquor showed 3·79 per cent of "dextrose" calculated on the material operated upon or to 3·17 per cent of the dry wood.

The wood left after the foregoing treatments with hydrochloric acid was rubbed up with 10 c.c. of concentrated sulphuric acid (of 92·5 per cent H_2SO_4), and the dark brown mixture was left to itself during twenty-four hours: it was then poured into enough boiling water to yield an acid containing 3 per cent of H_2SO_4, and was boiled therein during 3·5 hours. After filtration a part of the liquid was neutralised with sodium hydroxide. It was clear enough to be examined without the use of decolorising agents. It gave quasi-$[\alpha]_D = 66·16°$ and "dextrose" amounting to 33·50 per cent of the dry residue or to 27·04 per cent of the dry wood. This solution may be called "A." Another portion of the filtered acid liquid was boiled 3·5 hours longer, without any further addition of acid, and was then neutralised with calcium carbonate, filtered, and evaporated. The solution was clear enough to be examined without decolorising it. The approximate specific rotation was quasi-$[\alpha]_D = 64·82°$, and the "sugar," as shown by Fehling's liquor, and calculated as dextrose, amounted to 35·08 per cent of the dry residue. This solution may be called "B."

The high rotatory power exhibited by these products of the hydrolysis of wood, taken in connection with other results of similar import which had been obtained previously while studying other specimens of woods, pointed most distinctly to the presence of some other reducing substance beside dextrose and xylose; for the true specific rotation of xylose is $[\alpha]_D = 19·2°$, and that of dextrose is $[\alpha]_D = 52·6°$ (Tollens, "Handbuch der Kohlenhydrate," 1895, ii., 5). Efforts were made at once to isolate this additional substance. To this end a part of each of the sulphuric acid solutions "A" and "B" were allowed, after neutralisation, to evaporate spontaneously (in mid-winter) at the ordinary temperature of the laboratory. From "A" crystals of sodium sulphate separated, and were removed. The brown residues from the evaporation were rubbed up with three successive portions of strong alcohol. A part of the matter dissolved, while there was left a sticky, stringy, dextrin-like mass, insoluble in strong alcohol, though readily soluble in cold water. The aqueous solution of this substance had a flattish, sweetish taste, as was noticed in other instances. That from "A" gave quasi-$[\alpha]_D = 89·69°$. Meanwhile, the matter soluble in alcohol, obtained from "A," was taken up with water after the alcohol had been driven off, and this solution gave quasi-$[\alpha]_D = 66·18°$, calculated as dextrose, as was the preceding.

From the solution "B," which was boiled in the dilute acid longer than "A" had been boiled, a somewhat different result was obtained. The matter left undissolved by strong alcohol in this case was not wholly soluble in water. The insoluble residue was granular rather than gummy, and the solution obtained by means of water had practically no reducing action on Fehling's liquor.

The matter soluble in alcohol in this case gave quasi-$[\alpha]_D = 69·57°$, when examined in aqueous solution, and calculated as dextrose. It is evident from the foregoing that that product of the hydrolysis which fails to dissolve in strong alcohol (as in "A") is apt to suffer decomposition when boiled for a long time in dilute acids. It will be noticed that in all these experiments no wood was left in contact with the acid during the second boilings; the acid then had nothing to act upon but the products formed by the first boiling. The nature of this decomposable substance will be discussed in subsequent paragraphs.

(To be continued).

* Compare for example, the memoir of Wohl in *Ber. der Deut Chem. Gesell.*, 1890, xxiii., 2095, and Wohl's list (on p. 2084) of the names of chemists who have worked upon the subject.

LONDON WATER SUPPLY.

REPORT ON THE COMPOSITION AND QUALITY OF DAILY SAMPLES OF THE WATER SUPPLIED TO LONDON FOR THE MONTH ENDING APRIL 30TH, 1901.

By SIR WILLIAM CROOKES, F.R.S.,
and
PROFESSOR DEWAR, F.R.S.

To CHARLES PERRIN, Esq., M.Inst.C.E.,
Water Examiner, Metropolis Water Act, 1871.

London, May 10th, 1901.

SIR,—We submit herewith, at the request of the Directors, the results of our analyses of the 192 samples of water collected by us during the past month, at the several places and on the several days indicated, from the mains of the London Water Companies taking their supply from the Thames and Lea.

In Table I. we have recorded the analyses in detail of samples, one taken daily, from April 1st to April 30th inclusive. The purity of the water, in respect to organic matter, has been determined by the Oxygen and Combustion processes; and the results of our analyses by these methods are stated in Columns XIV. to XVIII.

We have recorded in Table II. the tint of the several samples of water, as determined by the colour-meter described in previous reports.

In Table III. we have recorded the oxygen required to oxidise the organic matter in all the samples submitted to analysis.

Of the 192 samples examined by us during the month, all were found to be clear, bright, and well filtered.

For the first time in the present year, the monthly rainfall at Oxford shows an excess, the amount of rain measured during April was 1·96 inches; the average fall is 1·61 inches, giving an excess of 0·35 inch, and reducing the deficit for the year to 1·21 inches, or 17·3 per cent on the thirty-five years' average.

Our bacteriological examinations of 483 samples have given the results recorded in the following table; we have also examined 36 other samples, from special stand-pipes, &c., making a total of 519 samples in all:—

	Microbes per c.c.
New River, unfiltered (mean of 24 samples) ..	176
New River, filtered (mean of 122 samples) ..	6
Thames, unfiltered (mean of 23 samples) ..	2076
Thames-derived water, from the clear-water wells of eight Thames-derived supplies (mean of 257 samples)	15
Ditto ditto .. .. highest	196
Ditto ditto .. .. lowest	0
River Lea, unfiltered (mean of 24 samples) ..	177
River Lea, from the East London Company's clear-water wells (mean of 33 samples) ..	15

Of the 412 samples of impounded and filtered water supplied to London, examined bacteriologically during the past month, twenty-six samples, or 6·3 per cent, were sterile. Only one sample out of the total number examined contained more than 150 microbes, and only six, or 1·4 per cent, contained more than 100 microbes per c.c. The mean of the microbes in the excess samples was 126, against a corresponding mean last month of 162. These bacterial results can only be characterised as excellent.

We are, Sir,
Your obedient Servants,
William Crookes.
James Dewar.

NOTICES OF BOOKS.

Atoms and Energies. By D. A. Murray. New York: A. S. Barnes and Co. 1901.

This remarkable book is written by a some time instructor in the Government Shogyo Gakko, Kyoto, Japan, who is now pastor of a Presbyterian church in the State of Iowa; it is endorsed in an introduction by an anthropologist, well known through his archæological investigations in Mexico.

Physicists and chemists seekling novel ideas will find in this essay food for thought and reflection; they are told that chemical affinity is the result of the *shapes* of atoms, that atoms are in actual contact, that the number of points of contact determines the state of aggregation; thus, "when the atoms are not in contact we have the gaseous state, when but a single point of contact the liquid state, when so many points of contact there is rigidity the solid state, when face to face contact chemical combination." All atoms are identical in essence; they are influenced by two simple energies, gravitation or attraction, and heat or expansion; "both are distinct entities articulated to, but not a quality or attribute of, atoms."

The author's definition of an atom is interesting:—"An impenetrable expanse of the ability to modify and be moved by energy." B.

Annual Report of the Smithsonian Institution for 1899.

One of the functions of the Smithsonian Institution, at Washington, is the diffusion of knowledge in language "understanded of the people;" so that, while most of its works are intended primarily for the specialist, the Secretary publishes an Appendix to his Annual Report which is addressed to the large body of the public, which has a general interest in scientific matters though without special knowledge of them.

The Report for 1899, just issued by the Institution, contains thirty articles, covering a wide range of information, given in such terms as must interest the general reader. They mainly refer to the scientific novelties of the year, and are selected because they are interesting as well as sound expositions of the most important scientific results that the year has brought. We have, for instance, an account by Professor Dewar, of the Royal Institution of Great Britain, of the recent liquefaction of hydrogen and of work on temperatures as low as 250 degrees centigrade below zero. There is a most curious and interesting paper by Johnstone Stoney on the range of Nature's operations. The volume contains two papers by Sir William Crookes, at once President of the British Association for the Advancement of Science, and of the Society for Psychical Research. In the one he presents the startling idea that there may be means of communication between human minds without the intervention of any of the ordinary channels of sense. In the other there is an interesting discussion of the effects which a simple change of scale would make on our understanding of Nature. He imagines our full human intelligence to exist in a body so small in size that to it the world of Lilliput would be a world of giants, and indicates conclusions which are altogether surprising and unexpected. The paper first mentioned is a departure from the usual rule of the Smithsonian publications, and is prefaced by a special note by Secretary Langley to the effect that while these commonly set forth known and admitted scientific facts, and not speculations, these articles are so weighty that an exception is made in their favour, though it is added that they are not presented as demonstrated. Their reprinting here may be taken as a curious sign of the times, illustrating the fact that men of science now hold an open mind toward speculations which a generation ago would have been scoffed at in the same circles.

A very comprehensive review of nineteenth century science, by Sir Michael Foster, the friend of Huxley and editor of his works; a most interesting paper on the extinct mammoth, by Mr. Lucas; a review of the subject of the date of the Calaveras skull, by Mr. Holmes, who leans to the opinion that it is of a modern Californian and not of a prehistoric man; two well illustrated papers on the peopling of the Philippines, by Virchow, and a list of native tribes of the Philippines, and of the languages spoken by them, by Blumentritt, the greatest living authority on the ethnology of the Philippines; an account by Professor Lester F. Ward of the petrified forest of Arizona, and other papers not only instructive, but entertaining, which cannot be more especially mentioned, are contained in this volume, which is profusely illustrated with plates and maps.

The Smithsonian Reports are distributed by the Institution to libraries throughout the world, may be had by purchase at cost from the Superintendent of Documents, Washington City, and may generally be obtained free of charge, also from the applicant's Member of Congress.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. cxxxii., No. 17, April 29, 1901.

Variation in the Composition of Mineral Waters.—P. Th. Muller.—For a complete study of a water, a chemical analysis is indispensable, and nothing can take its place. The composition of a natural water is not necessarily invariable. It varies with the season of the year, and from year to year, and also permanently alters during several years. The author's experiments were carried out on the dissolved matter in certain waters. He

measured in all cases the electrical conductivity by the method of alternating currents and the telephone, operating always at the same temperature (about 25°). The conductivity depends on the nature and the quantity of the dissolved substances, and its measurement should precede a chemical analysis of a mineral water. The author's researches, which extended over a year, were taken upon the conductivity of the water from one of the sources of the Vosges.

Myrcenol and its Constitution.—Ph. Barbier.—By the hydratation of myrcene an alcohol of formula $C_{10}H_{18}O$ is obtained, to which the name myrcenol has been given. This substance is an oily liquid, colourless, and having a powerful smell; its boiling-point is 99—100° at 10 m.m. pressure, and its density at 14·5° is 0·9012. The author's experiments on this substance satisfactorily establish its constitution, which may be represented by the formula $CH_3-C=CH-CH_2-CH_2-C(OH)-CH=CH_2$ (with CH_3 and CH_3). This formula shows that the substance is of the tertiary alcoholic nature. A knowledge of the constitution of myrcenol easily leads to that of myrcene, which can be obtained by dehydratation of the former, and so has the constitution $CH_3-C=CH-CH_2-CH=C-CH=CH_2$ (with CH_3 and CH_3).

Ethyl Nitroacetate.—A. Wahl.—The potassium and sodium salts of ethyl nitromalonate, $C_7H_{10}NO_6K$ and $C_7H_{10}NO_6Na$, can be obtained in the form of large yellow needles, soluble in water. When heated on platinum, these crystals first melt and then explode with extreme violence. Either of these salts, when treated with dilute acids, gives ethyl nitromalonate, which can be purified by distillation under reduced pressure. The substance thus prepared is a colourless liquid, analysis showing it to have the formula $C_4H_{10}N_2C_4$.

Preparation of Isomeric Ortho-, Meta-, and Para-nitrobenzoylcyanacetic Ethers and Crystallised Ortho-nitro-benzoyl Chloride.—M. Mavrojannis.—When nitrated benzoyl chlorides react on sodium cyan-acetic ether, the author succeeded in preparing the ortho-, meta-, and para-nitrobenzoylcyanacetic ethers. These bodies are formed during a reaction represented by the equation—

$$C_6H_4(COCl)(NO_2) + NaCH(CN)(COOC_2H_5) = C_6H_4(CO-CH(CN)(COOC_2H_5))(NO_2) + NaCl.$$

New Reaction of Saccharine (Benzoic Sulphimide).—Alex. Leys.—The presence of saccharine in a solution can be detected when the product of the ether extraction, taken up once again by means of water, gives a sweet taste and is limpid and not coloured after the addition of iron perchloride, but which gives a violet colouration on the addition of very dilute peroxide of hydrogen.

Contribution to Micro-chemical Researches on Alkaloids.—E. Pozzi-Escot.—The author obtains several interesting reactions, but these do not allow of a rigorous toxicological research. With strychnine, chloroplatinic acid gives prismatic plates of a peach colour. Auric chloride gives an abundant crystallisation of prisms grouped in colonies. Potassium iodide and iodine give abundant crops of crystals of a dark olive-green colour and great sharpness. With brucine, platinic chloride gives very small star-like crystals; with quinine, platinic chloride gives little grains which strongly polarise light. Iodine, dissolved in potassium iodide, gives little prisms. Platinic chloride gives, with cocaine, large toothed crystals; gold chloride gives similar crystals. With codeine, mercuric iodide dissolved in potassium iodide gives clusters of almost black crystals. Iodine in iodide of potassium with atropine gives pointed crystals, grouped in two's and crossed, of a black colour. Morphine, with the same reagent, gives crystallisations in the form of a thistle head.

MISCELLANEOUS.

Appointment.—Mr. William French, M.A. (Cantab), F.I.C., F.C.S., for the past nine years Senior Science Master of the Bury Grammar School, and of the Bury and Ramsbottom Technical Schools, was on Tuesday elected Principal of the Stevey Institute and Municipal Technical School, Lancaster. There were 135 applicants. Mr. French, who has been a frequent contributor to the Chemical News, was for twelve years Assistsnt to Prof. Liveing, F.R.S., and Prof. Dewar, F.R.S., at Cambridge, being for some time assistant to the former in private research.

The Double Nitrates of Tetratomic Cerium and of Thorium.—R. J. Meyer and R. Jacoby.—While comparing them with the double nitrates of gold examined by M. Schottländer which were regarded as the salts of a nitro-auric acid $(NO_3)_4AuH$, the authors have examined ceric nitrate and its double salts. Ceric nitrate, which was obtained by Berzelius as a syrupy yellow mass, can be prepared in the form of beautiful orange crystals, if to the solution of CeO_2 in concentrated NO_3H we add nitrate of calcium, and then leave the whole to stand in a desiccator. However, the salt obtained in this manner is a basic salt, $(NO_3)_3CeOH+3H_2O$. The ammonio-ceric nitrate, which occurs in beautiful deep red crystals, has been examined by various authors, but it has not been decided by them whether or no the salt is anhydrous; as a matter of fact it is, the formula being $(NO_3)_6Ce(NH_4)_2$. We also get salts of cæsium, rubidium, and potassium; this latter is the most difficult to obtain. All four are of the type $(NO_3)_6CeR_2$. The double salts of the magnesian series (magnesium, zinc, nickel, cobalt, manganese), belong to the same type with about the same water of crystallisation, viz., $(NO_3)_6CeM+8H_2O$; they are only slightly stable, the nickel salt appears in dark yellowish-brown crystals. The authors next directed their attention to the double nitrates of thorium, which have not yet been described; they take their rise in a mixture of two nitrates in concentrated solution; water decomposes them into their constituent parts. One of the double ammoniacal salts is $(NO_3)_5Th(NH_4)+5H_2O$; under other conditions of concentration we obtain another salt, $(NO_3)_6Th(NH_4)_2$, corresponding to the cerium salt; similar results are obtained with the anhydrous salts of cæsium and rubidium, $(NO_3)_6ThR_2$. With magnesium, zinc, nickel, cobalt, manganese, and strontium we also obtain salts corresponding with the ceric compounds, $(NO_3)_6ThM+8H_2O$. With potassium a very acid salt was obtained having a great tendency to crystallise. Beautiful crystals are formed with brilliant facets, rapidly becoming dull on exposure to the air, with loss of water and nitric acid; their composition is $(NO_3)_{10}ThK_3H_3+5H_2O$.—*Berichte*, vol. xxxiii., p. 2135.

MEETINGS FOR THE WEEK.

Tuesday, 28th.—Royal Institution, 3. (The Tyndall Lectures). "The Philosophical Undertones of Modern Poetry," by Prof. William Knight, LL.D.

Thursday, 30th.—Royal Institution, 3. "The Chemistry of Carbon," by Prof. Dewar, F.R.S., &c

Friday, 31st.—Royal Institution, 9. "With the Allies in China," by A. Henry Savage Landor.

—— Physical, 5. "On a Model which Imitates the Behaviour of Dielectrics," by Prof. Fleming, F.R.S., and A. W. Ashton, B.Sc. "On the Resistance of Dielectrics and the Effect of an Alternating Electromotive Force on the Insulating Properties of Indiarubber" and "Note on the Electrification of Dielectrics by Mechanical Means," by Mr. Ashton.

Saturday, June 1st.—Royal Institution, 3. "The Biological Characters of Epiphytic Plants." by Prof. J. B. Farmer, M.A., F.R.S.

THE CHEMICAL NEWS.

Vol. LXXXIII., No. 2166.

ANALYSIS OF THE RED RAIN DEPOSIT WHICH FELL IN VICTORIA, AUSTRALIA, ON DECEMBER 26, 1896, AND WHICH IS SIMILAR IN APPEARANCE TO THAT WHICH FELL IN ITALY IN MARCH, 1813, AND AGAIN IN MARCH OF THE PRESENT YEAR.

(Second Note).

By Dr. T. L. PHIPSON.

The very minute quantity of this deposit which was forwarded to me by Captain C. J. Gray, F.R.G.S., who collected it with great care near Melbourne, and of which I gave some account in April last (Chemical News, vol. lxxxiii., p. 159), did not permit of an exhaustive chemical examination. That gentleman, however, has kindly given me a little more, which has enabled me to throw some light on its true nature, though the analysis in this case was made on less than half a grm.

I need not repeat here what I have said in my first note of its physical properties and microscopic appearance, but will merely add that it is very slightly, if at all, magnetic.

It should be stated that the analysis given in a note in the *Comptes Rendus* (April, 1901), by M. Stanislas Meunier, of a specimen collected this year at Palermo, appears to show that some white-wash of the window-sills was scraped up with the red deposit, and that the author of that note has taken for quartz or sand what is really glassy felspar.

The deposit which was collected from the rain in Italy in March, 1813, was analysed by Sementini, then Professor of Chemistry at Naples. This analysis is also rather unsatisfactory, but it shows nothing to indicate that the red rain deposit was "sand from the Sahara Desert," as suggested in the *Comptes Rendus*. He believed it was not of volcanic, but perhaps of meteoric, origin.

This fall of red rain in 1813 was accompanied by noise compared to the dashing of waves at a distance, and some meteoric stones fell at the same time at Cutro, in Calabria.

On November 15th, 1755, *rain of a red colour* fell around Lake Constance and at Ulm, also, on the same day, in Russia and Sweden. The deposit on this occasion was stated to be *magnetic*. No analysis was made of it, as far as I know.

The general aspect and physical properties of these curious falls of mineral matter along with rain correspond very closely with each other; they are all described as a very fine dust, very soft or unctuous to the touch, of a reddish yellow or fawn colour when dry, becoming rather redder when wet and darker on being heated. I found the dimensions of the grains of which it is composed exceedingly small, a great many being flat or tabular, with irregular edges, and of various colours (see my first Note).

My analysis of the red rain deposit which fell in Australia has given the results here shown. The substance does not effervesce when HCl is poured upon it, neither does it give off chlorine.

The portion insoluble in HCl has, in 100 parts, the composition of felspar (and also the blowpipe characters) —a substance which forms part of volcanic rocks and of meteoric stones. The portion soluble in acid may be labradorite or peridot, or a mixture of both, to which the same remark applies.

It was impossible with the very small quantity of substance at my disposal to make the analysis more complete.

Water	9·09	14·30
Organic matter	5·21	
Soluble in HCl—		
Oxide of iron, alumina, silica, and titanic acid	4·61	8·00
Lime, magnesia, and alkalis, with traces of Ni and Co	3 39	
Insoluble in HCl—		
Silica	50·99	77·70
Alumina and oxide of iron (without any titanium)	16·40	
Lime..	0·21	
Magnesia..	Minute quantity	
Potash and soda, with indication of lithia	10·10	
	100·00	

I am decidedly of opinion, after a due discussion of this subject, that this dust brought down in the rain is of volcanic origin. The composition, *as a whole*, corresponds closely with that of the Puzzolana of Naples and Rome. Such volcanic dust, shot up to immense heights, may remain for years suspended in the atmosphere, and is liable at any time to be attracted by storm clouds and precipitated with the rain they yield.

Casa Mia, Putney, S.W.,
May 27, 1901.

THE ESTIMATION OF CYANIDES IN LAMING'S MIXTURE.

By A. O. NAUSS.

In view of the increasing importance of compounds of cyanogen in different branches of industry, gas works which now supply the raw material for these products are constrained to utilise this by-product as completely as possible, and, thanks to exact analytical methods, we are now able to determine its proportion in Laming's mixture with rapidity.

Among the methods of estimating cyanides there are three which may be recommended; those of Knublauch (*Journ. fur Gasbeleuchtung*, 1889, p. 450); Zulkowski (*Chem. Tech. Unters-Meth. von Lunge*, i., 492), modified; and Drehschmidt (*Journ. fur Gasbeleuchtung*, 1892, pp. 221 and 268).

Although the two former methods are very widely used and have the advantage of simplicity, they both have the inconvenience of being touch methods, in which the exact end of the reaction can only be judged with difficulty, or through long practice.

Drehschmidt's method, especially as modified by Buschell (*Journ. fur Gasbeleuchtung*, 1893, p. 8), may be looked upon as very exact, as is also the method due to Lubberger (*Journ. fur Gasbeleuchtung*, 1878, p. 124). It requires, however, a considerable amount of time, on account of the numerous operations entailed, and further, it is necessary to scrupulously remove all trace of chlorine from the reagents.

In a works laboratory the principal characteristics of an analytical method should be simplicity and exactness.

Keeping this in view, I have devised a new method of which the starting point is the decomposition of the Prussian blue by alkalis, according to the equation :—

$$Fe_7Cy_{18} + 12NaOH = 4Fe(OH)_3 + 3FeCy_6Na_4.$$

The Prussian blue is treated with a warm solution of soda of known strength until it is decolorised. Before the colour has entirely disappeared the liquid takes a

green tint. It is as well to use an excess of alkali which can be neutralised afterwards with a titrated acid solution. On the addition of an excess of acid the yellow tint of the liquid changes to greenish by reason of the re-formation of the Prussian blue.

It is not necessary to use any special indicator, as the compounds in solution take its place. It is only necessary to operate with boiling solutions; in this case the end of the reaction is very distinct and sharp. When we make use of N/50 soda the factor for obtaining the Prussian blue is 0·001431.

The method of carrying out the analysis is as follows:—

Into a flask, marked at half a litre, we place 10 grms. of Laming's mixture, and 50 c.c. of 10 per cent soda; this is frequently shaken, and the reaction allowed to proceed at the ordinary temperature. According to Knublauch (*Journ. fur Gasbeleuchtung*, 1889, p. 453), this operation requires fifteen hours. By using dilute soda we prevent the formation of alkaline sulphides. The flask is then filled up to the mark, and a further 5 c.c. of water are added, corresponding to the volume of the mixture employed, and, after having thoroughly shaken, we filter about 50 c.c.

This liquid is run into 10 or 15 c.c. of a warm acid solution of iron-alum (200 grms. of alum and 100 grms. H_2SO_4 per litre), so as to transform the ferrocyanide into Prussian blue; it is then heated on the water-bath until the characteristic sweetish odour which is produced ceases to be apparent. We then filter hot through a folded paper, and wash the precipitate with hot water until the washings no longer contain any sulphuric acid.

The filter and the precipitate are then placed in a flask, water is added, and the whole brought to boiling point with constant shaking.

We next gradually add N/50 soda until all the Prussian blue is decomposed, which does not require a very long time. The excess of soda is then titrated with N/50 acid, keeping the solution warm and agitating. It is indispensable to heat the solution, for even in the presence of an alkali, the Prussian blue will be re-formed, giving a green tint, which lasts some considerable time. When the green tint remains permanent the operation is finished.

Comparative analyses with the Drehschmidt-Burschell method and mine have given the following results:—

No.	Proportion of Prussian blue.	
	Drehschmidt.	New method.
	Per cent.	Per cent.
1.	8·11	8·08 and 8·15
2.	7·3	7·02
3.	8·86	8·65
4.	8·11	8·29
5.	7·65	7·63
6.	7·51	7·34
7.	7·63	7·72 and 7·65

I have, further, made comparative analyses after adding a known weight of ferrocyanide of potassium to Laming's mixture; there again the results were the same.

This method can be extended to the determination of cyanogen in gas.

The following method of working has given very good results:—

One hundred litres of gas are passed through two wash bottles, each containing 10 c.c. of a solution of sulphate of iron at 10 per cent, and 10 c.c. of caustic potash at 33 per cent. The length of time for this operation should be from one to two hours. The contents of the wash-bottles are then poured into a half litre flask, and potash and sulphate of iron are further added until there is no more precipitate of sulphide of iron formed. It is as well to add 1 grm. of carbonate of lead to remove all the sulphuretted hydrogen.

After boiling for a few minutes the liquid is cooled, and the flask filled up to the half litre mark; 5 c.c. more water are added to make up for the volume of the precipitate, and the whole is then filtered on a dry filter.

Fifty c.c. of the filtrate are taken, so as not to have too voluminous a precipitate; this is poured into an excess of a warm solution of iron-alum (20 or 30 c.c.); then after having heated for some time on the water-bath, sulphuric acid is added to precipitate the Prussian blue. The rest of the analysis is the same as in the case of Laming's mixture.

One c.c. of N/50 alkali corresponds to 0·0007794 grm. of cyanogen.—*Journ. f. Gasbeleuchtung und Wasser versorgung*, xliii.

SOME PRINCIPLES AND METHODS OF ROCK ANALYSIS.*

By W. F. HILLEBRAND.

(Concluded from p. 247).

XXV. *Boron.*

To the best of the writer's belief, it has never been found necessary in this laboratory to estimate boron in a silicate rock. Should the determination be required, since most silico-borates are insoluble minerals, it would probably be necessary to fuse with sodium carbonate, extract with water, faintly acidify with nitric or acetic acid, expel the boron by distillation with methyl alcohol, and collect the boric ether in a suitable manner. For simple borates, artificial or native, this method,† first devised by Rosenbladt and Gooch independently, gives entire satisfaction when all needful precautions are carefully observed, but its application to boro-silicates yet needs investigation, in view of the as yet unexplained very discordant results obtained some years ago by J. E. Whitfield in this laboratory on the mineral warwickite, a boro titanate of magnesium and iron.

It is also quite possible that the accurate estimation of but a few milligrms. or even less of boric oxide by the use of a large excess of lime as a retainer would not be feasible. Fluorine would have to be first removed by calcium nitrate or acetate before freeing the boron.

XXVI. *Nitrogen.*

Nitrogen has been found in igneous rocks or the minerals occurring in them by several observers. Thus, H. Rose ("Quantitative Analyse," p. 673, Finkener Edition), says that pitchstone gives off ammoniacal water on heating; Silvestri (*Gazz. Chim. Ital.*, 1875, vol. v., p. 303), mentions a nitride of iron in lavas from Etna; Sandberger finds ammonium carbonate to be given off from certain rocks of Pribram; the writer has shown nitrogen to exist in uraninite; Ramsay and others have noted it in traces with or without helium, &c., in numerous minerals; and later Erdmann (*Ber. Deut. Chem. Gesell.*, 1896, vol. xxix., p. 1710), found it to be given off as ammonia on treating various minerals of "ancient igneous rocks" with a caustic alkali. Luedeking also found ammonium sulphate in a barite from Missouri, the presence of which the writer was able to confirm.

It has been noted in this laboratory on three separate occasions, when series of ores, roofing slates, and eruptive rocks were analysed, that ammonia, either in the form of

* *Bulletin of the United States Geological Survey*, No. 176.

† Rosenbladt (*Zeit. fur Anal. Chem.*, 1887, vol. xxvi., p. 21), used magnesia for binding the boron, while Gooch (*Proc. Amer. Acad. Arts and Sci.*, 1886, p. 167; *Bull. U.S. Geol. Survey*, No. 42. p. 64; CHEMICAL NEWS, 1887, vol. lv., p. 7), preferred lime, as more active and reliable. Gooch and Jones have later (*Amer. Journ. Sci.*, 1899, Fourth Series, vol. vii., p. 34; CHEMICAL NEWS, 1899, vol. lxxix., pp. 99, 111), upheld the use of lime, and proposed, as a convenient though perhaps not quite so perfect substitute, sodium tungstate containing an excess of tungstic oxide. In this article they likewise indicate the precautions now used to ensure complete collection and retention of the boron. For a useful modification in the way of collecting the boric ether in ammonia before bringing in contact with the lime, see Penfield and Sperry (*Amer. Journ. Sci.*, 1887, Third Series, vol. xxxiv., p. 222); also Moissan (*Comptes Rendus*, 1893, vol. cxvi., p. 1087, and *Bull. Soc. Chim.*, 1894, vol. xii., p. 955), who modifies the Gooch distilling apparatus in certain respects.

chloride or sulphate, or even as free ammonia, was given off on heating. Its appearance was not limited to one or a few specimens of a series, but seemed to be characteristic of all, and to be afforded by the unbroken rock as well as by the powdered sample. The precise conditions under which the specimens were collected not being known, it is impossible to affirm positively that the ammonia may not have been due to recent organic contamination of some sort, especially in the case of the slates, but it is believed that a more critical collection of material will not alter the general result. Its amount was sometimes readily determinable by Nesslerisation, being as high as 0·04 per cent in some slates. Carbonaceous organic matter was absent from most of these, but doubtless existed in them in their early history. In their case the ammonia was, in part at least, evolved as such, imparting a strong alkaline reaction to the water in the upper part of the tube. The presence of sulphides, fluorides, or chlorides in the rock might cause the ammonia to appear as a sublimate of sulphate, fluoride, or chloride. Speculation on this matter would be altogether premature, but attention is called to it in the hope that other observers may be led to look for and investigate similar appearances. It should be borne in mind that the nitrogen present would not necessarily appear as ammonia or ammonium salts, since it might be given off in the elemental condition, as with the gases obtained from uraninite.

XXVII. *Special Operations.*

The problem often presents itself of ascertaining the composition of that portion of a rock powder which is soluble in special reagents or in a reagent of a particular concentration. No precise directions can be formulated to meet such cases. The procedure must vary with the character of the constituents of the rock, and with the object which it is sought to attain, and only in exceptional cases can a separation of this kind be sharp. Much depends on the degree of fineness of the powder, and on the length of time it is exposed to the action of the reagent.

Detection of Nepheline in presence of Olivine.

For confirmation of the microscopic diagnosis, Prof. L. V. Pirsson (*Amer. Journ. Sci.*, 1896, Fourth Series, vol. ii., p. 142), has indicated a means of detecting nepheline in presence of olivine, as in nepheline basalts, based on the very ready solubility of nepheline, as compared with olivine, when boiled for but one minute with a sufficiency of very dilute nitric acid (1:40). Gelatinisation of the filtrate on evaporation is taken as evidence of the presence of nepheline. If olivine is present in quantity, however, this test must not be accepted at once as final, for some, if not all, olivines are much more soluble in nitric acid of the above strength than Professor Pirsson was led to believe from his original tests. If, therefore, on evaporation of the filtrate, much iron is indicated, the gelatinisation may well be due to olivine alone or in part, and then the quantitative relation of silica to iron plus magnesium should be ascertained. It must also be borne in mind that any other very soluble silicates present will be more or less affected, and that apatite is largely or wholly dissolved. It is possible that still more dilute nitric, or perhaps some other, acid may exert a slighter solvent action on olivine without being appreciably less effective in dissolving nepheline, &c. In combination with a quantitative analysis of the extract the method is perhaps susceptible of a wider application than the particular case for which it was first used. It is well worth further study.

Estimation of Soluble Silica.

Very often in treatment by acids silica is separated in gelatinous or granular form mixed with the unattacked minerals, and it becomes necessary to remove or estimate this silica, or else to discriminate between soluble and insoluble silica already existing together. Usually a boiling solution of sodium carbonate has been employed for this purpose, though the caustic alkalis have found advocates. Lunge and Millberg (*Zeit. fur Angewandte Chem.*, 1897, pp. 393, 425), have lately conclusively shown that quartz is not nearly so insoluble in solutions of the caustic alkalis as has been supposed, but that, given a sufficient degree of subdivision, it can be brought wholly into solution; that it is impossible to secure correct separation of quartz and opaline silica by the use of either caustic or carbonated alkalis; and that digestion on the water-bath for fifteen minutes with 5 per cent solution of sodium carbonate is the only way to secure exact separation of unignited precipitated silica from quartz, and then only when the finest flour has been removed by levigation. The authors say:—

If, however, no more of such flour is present than is produced in the ordinary operations of powdering and sifting through cloth of the finest mesh, the error arising from the above mentioned treatment is so slight that it can generally be neglected; it reaches 0·1 to at the most 0·2 per cent of the total silica, by which amount the quartz will appear too low, the amorphous silica too high.

The above authors also show, however, that the solvent action of the caustic alkalis on quartz becomes very apparent only when the material has been reduced to such an utterly impalpable degree of fineness as is practically never reached in the preparation of samples for rock analysis. For this reason I have no hesitation in recommending the employment of a dilute solution of sodium hydroxide when the silica separated by acid from one of several mineral constituents of a rock is to be estimated. Even when dilution is considerable, solution is almost immediate, and as soon as this is accomplished—the point being known by the change in appearance of the residue—the solution should be diluted with cold water, and filtered at once. The difficulty met with in filtration may often be overcome by faintly acidifying, which has the added advantage of at once arresting any further action of the alkali. If the dilution is sufficient no separation of silica results from so doing. Very dilute acid should also be used for washing. Lunge, when using sodium carbonate, washes with hot carbonate solution to which alcohol has been added, thus obtaining clear filtrates.

XXVIII. *Estimation of Minute Traces of certain Constituents.*

If, as sometimes may happen, the problem is presented of examining rocks for traces of gold, silver, and other elements which are not ordinarily looked for, as in Sandberger's investigations bearing on the origin of the metalliferous contents of veins, large weights of material must be taken, up to 50 grms. or more. This involves the use, also, of large quantities of reagents, the purity of which must then be looked to with the utmost care. Special directions to meet such cases can not now be given, nor even a complete reference list of the scanty and scattered literature on this subject. Sandberger's own writings deal but little with its analytical side, and from its inaccessibility in the Washington libraries the writer is as yet unacquainted with the report by Von Foullon, "Ueber den Gang und die Ausführung der Chemischen Untersuchung." (*Jahrbuch der Bergakademie, Leoben u. Pribram*, 1887, p. 363), following Sandberger's own paper in the general report, "Untersuchungen der Nebengesteine der Pribramer Gänge."

(From Sandberger's report it appears that the rocks were treated successively with water, acetic acid, boiling dilute hydrochloric acid for two days, and finally hydrofluoric acid, the several extracts, and final residue of fluorides, and pyrite, being separately examined for heavy metals. The products of distillation were also examined. A striking fact observed in all cases was the complete insolubility of the pyrite, even after the severe treatment mentioned. This speaks strongly in favour of the correctness of ferrous iron estimations in silicates by the hydrofluoric and sulphuric acid method when pyrite is present unaccompanied by other sulphides). (See p. 220).

The present writer has published a few data as to gold,

silver, lead, zinc, &c. (*Mon. U.S. Geol. Survey*, 1886, Appendix B. vol. xii., pp. 592—596), in Mr. S. F. Emmons's report on "The Geology and Mining Industry of Leadville"; and Mr. J. S. Curtis (*Mon. U.S. Geol. Survey*, 1884, vol. viii., pp. 120—138), in his report on "The Silver-Lead Deposits of Eureka, Neveda," has given his method of assaying rocks for traces of gold and silver.

To Prof. F. W. Clarke and Dr. H. N. Stokes the writer's thanks are due for friendly suggestions in the preparation of the foregoing work.

ON THE RESULTS OF A SEARCH FOR OTHER SUGARS THAN XYLOSE AND DEXTROSE IN THE PRODUCTS OF THE HYDROLYSIS OF WOOD FROM THE TRUNKS OF TREES.*

By F. H. STORER, Professor of Agricultural Chemistry.

(Continued from p. 250).

B. *Acid Hydrolysis of Wood from the Root of a Sugar Maple Tree.*—A root, from an inch to an inch and a half in thickness, was dug up in November at West Newfield, Maine. The bark was stripped off, and the wood ground to powder. A quantity of the powdered wood was soaked in strong ammonia water during twenty-four hours, and then thrown upon a filter, and washed with water. The wood thus leached with ammonia was dried at 100°, and subjected to hydrolysis as follows:—Seven grms. of the dry residue were boiled for three hours in 200 c.c. of hydrochloric acid of 3 per cent, and the undissolved residue was separated by filtration. One half of the liquid was neutralised with sodium hydroxide, evaporated, and decolorised with bone-black. It gave quasi-$[\alpha]_D = 59{\cdot}26°$, and there was shown by Fehling's liquor 23·04 per cent of "sugar" (calculated as dextrose) in the dry root wood that had been leached with ammonia.

The other half of the acid filtrate was boiled three hours longer, and then neutralised with sodium hydroxide, and decolorised with bone-black. The approximate specific rotation in this case was quasi-$[\alpha]_D = 68{\cdot}21°$, and the "dextrose" shown by Fehling's liquor was equal to 16·30 per cent of the dry wood that had been leached with ammonia.

Both the higher rotation observed in these two trials of root wood and the larger percentage of dextrose, as compared with the corresponding experiments with trunk wood, are explained by the fact that the wood of the maple root contained much more starch than the trunk wood did. While the latter was well nigh absolutely devoid of starch, the root wood, when tested with barley malt, showed as much as from 5 to 7 per cent of "starch and sugar," *i.e.*, matters capable of reducing copper from Fehling's liquor. Indeed, on merely boiling some of the powdered root with successive portions of water, enough reducing matter was dissolved to indicate 4·12 per cent of sugar ("dextrose") when tested with Fehling's liquor, while the trunk wood gave no indication of starch when thus tested. Under the microscope also much more starch was found in the root wood than in the trunk wood. (See *Note*). All of which consists with the view, not infrequently enunciated, that appreciable quantities of starch are stored in the winter in the roots of trees.

(NOTE.—My colleague, Mr. E. W. Morse, who was good enough to examine specimens, noticed much blue colouration on testing the maple root wood with iodine, although he obtained no reaction for starch, either in the outer or inner wood, or in the bark of the trunk of a maple tree that had been felled on May 1st. A hardly visible reaction with iodine was got, along the medullary rays, on testing the outer and inner wood of a maple tree felled on May 30th. On examining wood and bark from the trunk of a sugar maple tree, felled in October, he got no reaction for starch in the bark; and the outer wood gave the starch reaction only in the medullary rays, excepting a few cases where scattering starch grains were detected in the wood fibre, usually not far from the medullary rays. Some starch grains were observed in the medullary rays of the inner wood also, but they were few in number, *i.e.*, they were still less numerous than those observed in the outer wood of the same tree. Pith from a stem of an elder bush (*Sambucus*) cut in July gave no reaction with iodine. Wood cut from the stem of a red maple tree in June gave a decided reaction along the medullary rays, while wood cut on the same day from a grey birch tree showed only a slight colouration with iodine; indeed, there were so few of the blue coloured granules lying in the medullary rays that they could readily be counted).

As was the case in the experiment described on page 249, so here, the long continued boiling appeared to have produced reversion (or destruction?) of a part of the dextrose that had been formed at first. On mixing what remained of the two solutions from the hydrolysis with 3 per cent hydrochloric acid, they were evaporated nearly to dryness, and the residue was treated with strong alcohol. The matter insoluble in alcohol gave quasi-$[\alpha]_D = 84{\cdot}69°$, and the matter soluble in alcohol gave quasi-$[\alpha]_D = 39{\cdot}41$.

The residual wood left after hydrolysing with hydrochloric acid of 3 per cent was soaked in 80 c.c. of strong hydrochloric acid of 35 per cent during twenty-four hours in the cold, and the mixture was poured into enough boiling water to dilute the acid to a strength of 3 per cent. The diluted mixture was boiled during three hours, and then filtered. One half the filtrate, neutralised with sodium hydroxide, evaporated, and decolorised with bone-black, gave quasi-$[\alpha]_D = 76{\cdot}78°$, and "dextrose" to the amount of 7·33 per cent of the dry material operated upon, or to 5·64 per cent of the dry wood that had been leached with ammonia.

The other half of the acid filtrate, after having been boiled three hours longer, gave anomalous results, as to rotatory power, while Fehling's liquor showed only 2·94 per cent of "dextrose" calculated on the dry wood that had been leached with ammonia. To all appearance much of the sugar produced in the first hydrolysis had been destroyed by the second boiling.

The residual wood, from the foregoing hydrolysis with strong hydrochloric acid, was treated with 10 c.c. of concentrated sulphuric acid (of 92·5 per cent of H_2SO_4), and left to stand in the cold during twenty-four hours. It was then poured into enough boiling water to bring the mixture to a strength of 3 per cent H_2SO_4, and the whole was boiled for three hours. The filtered liquid was divided into two parts. One part was neutralised with calcium carbonate, and evaporated. It did not need to be decolorised. The solution gave quasi-$[\alpha]_D = 73{\cdot}48°$, and "sugar" enough to amount to 32·12 per cent of dextrose in the dry matter operated upon, or to 29·91 per cent in the dry wood that had been leached with ammonia.

The rest of the neutralised solution was evaporated to dryness, and the residue was treated with hot, strong alcohol. The light brown, sticky mass insoluble in alcohol did not need to be decolorised when taken up with water. It gave quasi-$[\alpha]_D = 79{\cdot}34°$, and Fehling's liquor indicated 19·29 per cent of sugar calculated as dextrose on the dry wood that had been leached with ammonia.

The matter soluble in alcohol, on being dissolved in water, after the expulsion of the alcohol, gave quasi-$[\alpha]_D = 54{\cdot}60°$, and Fehling's liquor showed dextrose enough to amount to 13·93 per cent of the dry wood that had been leached with ammonia.

The second portion of the acid filtrate from the hydrolysis with 3 per cent sulphuric acid (after the action of strong sulphuric acid) was boiled three hours longer, after it had been removed from the wood. It was then neutralised with calcium carbonate, and evaporated. The

* *Bulletin of the Bussey Institution*, 1900, vol. ii., Part 9.

solution did not need to be decolorised. It gave quasi-$[\alpha]_D = 68{\cdot}58°$, and Fehling's liquor showed 33·16 per cent of "dextrose" calculated on the dry substance operated upon. On being again evaporated, it was treated with hot, strong alcohol. The matter insoluble in alcohol on being dissolved in water gave quasi-$[\alpha]_D = 58{\cdot}33°$, and Fehling's liquor showed 22·92 per cent of "dextrose." The matter soluble in alcohol gave quasi-$[\alpha]_D = 66{\cdot}30°$, and Fehling's liquor showed 9·45 per cent of dextrose.

It will be noticed that, as indicated by Fehling's test, the total amount of sugar obtained from the three prime hydrolyses of the maple root was by no means inconsiderable. After the first action of the 3 per cent hydrochloric acid on the wood that had been leached with ammonia the tests indicated 23·04 per cent of sugar; after the second action (3 per cent HCl, after soaking in strong, cold HCl), the tests showed 5·64 per cent, and after the treatment with strong sulphuric acid they showed 23 per cent. That is to say, the indications were that nearly 52 per cent of sugar, all told, had been got from the root wood which had been leached with ammonia, and dried at 100°.

In the case of the trunk wood the tests showed, respectively, 16·21 per cent, 3·17 per cent, and 27·04 per cent of "dextrose." In all 46·42 per cent of the dry wood. These figures (as indicated by Fehling's liquor) depend of course solely on the presumption that the observed reductions were due to the presence of sugars properly so-called. As will be shown directly, this presumption is not justifiable; but at this stage of the investigation it was regarded as a not wholly improbable hypothesis, and many efforts were made to isolate in visible, tangible form the substance whatever it might be that exhibited a rotatory power higher than dextrose. For example, rather more than 50 grms. of powdered maple root were boiled over a free flame in a flask with reflux condenser for three hours with 1000 c.c. of dilute sulphuric acid (of 3·5 per cent) to remove starch and some of the xylan. The filtrate obtained in this way was neutralised with calcium carbonate, evaporated, and examined. It showed quasi-$[\alpha]_D = 47{\cdot}87°$, and "dextrose" (in some part xylose), enough to amount to 14·35 per cent of the dry wood.

The undissolved residue from this first treatment was left over night to dry out somewhat in the air, and 30 c.c. of strong sulphuric acid, of 90 per cent H_2SO_4, were added to it. The mixture was left to itself during twenty-four hours, and was then poured into enough boiling water to reduce the acid to the strength of 3·5 per cent. After this dilution the mixture was boiled over a free flame for three hours, and the filtrate was set aside to be added to the product of the next hydrolysis.

In this particular instance the treatment with strong sulphuric acid was not wholly satisfactory, because in the course of it evidence presented itself that the residue from the treatment with 3·5 per cent acid had not been adequately dried. It had, in fact, retained so much moisture that the strong acid added to it was at once diluted to such an extent that it had no proper opportunity to act upon the cellulose in the wood. It was noticed, for example, that even 30 c.c. of the strong acid made a pasty mass with the residue, and that only a small part of the residue was blackened. Hence, the residue from this treatment with strong acid was dried carefully, and again mixed with a new portion of the strong sulphuric acid. In this case the residue blackened instantly and throughout when the strong acid was added to it, and 70 c.c. of the acid were required to bring about the desired pasty condition.

After standing during twenty-four hours the mixture was poured into enough boiling water to reduce the acid to the strength of 3·5 per cent, and boiled over a free flame for three hours. The filtrate from this treatment was added to that previously obtained, as above stated, after the first application of the strong acid, calcium carbonate was added to neutralise the acidity, and the filtered liquid was evaporated to a syrupy condition. After decolorising with bone-black, this solut on showed quasi-$[\alpha]_D = 63{\cdot}42°$, and "sugar" enough to amount to 9·65 per cent of the dry wood.

It is worthy of remark that in this trial where 50 grms. of wood were boiled directly in an acid of 3·5 per cent, and the residue was treated with sulphuric acid of 90 per cent H_2SO_4, and where a 3·5 per cent acid was used again in the final hydrolysis, less sugar (14·35+9·65=24 per cent) was obtained than had been got previously where a smaller quantity of wood (10 grms.), a slightly weaker dilute acid (3 per cent), and a more concentrated strong acid (92·5 per cent H_2SO_4) were employed; for in that case the yield of "sugar" was 23·04 + 5·64 + 23 = nearly 52 per cent. So, too, in subsequent trials, less sugar was got from 50 grm. portions of wood after treatment with acid of 90 per cent than had been got in the earlier trials.

In respect to the action of strong sulphuric acid, it may here be said that (after the wood had soaked in strong acid), the 10 grm. portions were boiled in 464 c.c. of acid of 3·5 per cent, while the 50 grms. portion were boiled in 3250 c.c. of acid of 3 per cent.

Another difference of treatment in the two particular instances above cited was that the 10 grm. portion had been leached first of all with ammonia, then boiled with dilute hydrochloric acid, and afterwards soaked in strong hydrochloric acid, and again boiled in this acid, after dilution, before they were soaked in strong sulphuric acid; while neither ammonia nor hydrochloric acid were used upon the 50 grm. portions of wood. Here the powdered wood was boiled at once in dilute sulphuric acid of 3·5 per cent, and afterwards soaked in the strong sulphuric acid of 90 per cent, and again boiled, after dilution to 3·5 per cent.

In the hope of obtaining crystals 15 grms. of the thick syrup, left on evaporating the neutralised liquor from the hydrolysis by dilute acid after treatment with strong sulphuric acid, were warmed in a dish together with 10 c.c. of water, and 20 c.c. of strong alcohol were added. After three days it was found that a slimy mass had settled at the bottom of the dish. Sixty c.c. of strong alcohol were poured upon it, and the dish was left to itself in an exsiccator. No perceptible change occurred in the course of a fortnight; the clear brown solution was then filtered off, and the stringy, brown residue was washed with a little dilute alcohol. It became white under this treatment. On attempting to dry it on a watch-glass in an air-bath, it began to melt at 70°; when it was immediately taken from the bath, and set aside in an exsiccator. Next morning the contents of the watch-glass were found to be solid, and numerous needle-like crystals were visible upon and in the midst of the mass. Under the microscope the crystals were well defined, and it could be seen that many of them had pyramidal terminations. After a time these crystals effloresced in dry air. The whole of the crystalline mass was tested for mucic acid by treating it with nitric acid of 1·15 sp. gr. It was oxidised completely by this acid, and a clear solution was obtained from which after a while a white powder was deposited. This precipitate was so white and of such excellent appearance that the treatment with ammonium carbonate, ordinarily employed for separating mucic acid from insoluble contaminations, was omitted, and the precipitate was collected directly, and weighed. Dried at 100°it amounted to 11·36 per cent of the weight of the crystalline mass, supposed to contain sugar, which had been subjected to the action of the nitric acid; on examination, however, the precipitate turned out to be not mucic acid, but mere inorganic matter. On dissolving it in ammonium carbonate, evaporating to dryness, and treating anew with nitric acid, only a very small precipitate appeared, and this also was found to consist wholly of inorganic matter, the source of which will be suggested later on.

In order to determine whether the matter insoluble in alcohol, obtained as above, is always contaminated with inorganic substances, another portion of the powdered maple root (more than 50 grms.) was hydrolysed as before;

first with dilute sulphuric acid of 3·5 per cent, to remove starch and xylan, and subsequently after treatment with strong sulphuric acid of 90 per cent H_2SO_4, with acid that had been diluted to 3·5 per cent. In the treatment of this sample care was taken to dry thoroughly the residual cellulose left after the action of the first acid of 3·5 per cent, before adding to it 70 c.c. of strong sulphuric acid. This strong acid was left in contact with the cellulose during twenty-four hours, and was then diluted to 3·5 per cent, and boiled and examined as before.

In this instance the liquor obtained from the first hydrolysis was 3·5 per cent acid, and supposed to contain a mixture of xylose and dextrose, showed quasi-$[\alpha]_D = 42·87°$, and enough "sugar" to amount to 15·48 per cent dextrose, calculated on the dry wood. On the other hand, the product of the hydrolysis after the action of strong sulphuric acid gave quasi-$[\alpha]_D = 63·75°$, and "sugar" enough to amount to 1·07 per cent of the dry wood.

The syrup left on evaporating most of the liquor from the hydrolysis after the strong acid was a brown molasses. Strong alcohol was added to it in three successive portions, the last portion being left over night in contact with the insoluble matter. This precipitate, which was lighter coloured than the syrup from which it came, was dissolved in a very small quantity of water, and heated carefully upon an oil-bath to 65° C., and then set aside in a desiccator to cool. After twenty-four hours the dish was found to contain a solid crystalline mass, in and upon which, as in the previous instance, were to be seen numerous acicular crystals. Under the microscope these needles seemed to be hexagonal prisms, many of which had well-defined terminations. After a day or two these crystals effloresced in dry air, while preserving their original shape. They were found to consist for the most part of inorganic matter.

The solution obtained on dissolving this crystalline mass in water showed no disposition to form a syrup on being evaporated. On the contrary, it left a dark brown, somewhat granular residue, which remained unchanged in appearance on the addition of strong alcohol. After driving off the alcohol, dissolving in water, decolorising with bone-black, and again evaporating to dryness, a very small quantity of water was added, the mixture was heated to 60°, and set aside in an exsiccator; it dried out to a solid mass in which no crystals were visible. Six weeks later, on treating the dry residue with alcohol of 75 per cent, a very small portion of it dissolved; but most of it dissolved in alcohol of 60 per cent. The alcohol solutions, mixed one with the other, showed no indications of crystallising, but dried down to an amorphous mass which was taken up with four-fifths its weight of water. On adding to this solution twice its volume of alcohol of 93 per cent, an apparently gelatinous precipitate began to form, and increased on standing. This precipitate was found to consist of fine crystals of inorganic matter. Moreover, the residue which was left undissolved at the time of treating with alcohol of 60 per cent was seen to consist of white crystals of inorganic matter.

For the moment it was a matter of uncertainty whether this inorganic matter consisted merely of ash-ingredients proper to the wood, or whether it might not have been derived from acids, produced in the process of hydrolysis, that were capable of forming soluble calcium salts. In the hope of avoiding the inorganic substances which had thus far contaminated the "matter insoluble in alcohol," various experiments were now made with carbonic acid; and with lead carbonate as the neutralising agent, instead of calcium carbonate or barium hydroxide, and with cotton also instead of wood. For the conclusions to be drawn from the results of these trials, see *prox.*

The unusually small quantity of sugar (1·07 per cent) obtained in the experiment, described above, led to a repetition of it.

Some 54 grms. of powdered maple root were boiled for three hours in 1000 c.c. of dilute sulphuric acid of 3·5 per cent, to get rid of xylan and starch; the residue was dried in the air, and treated with 70 c.c. of strong sulphuric acid of 90 per cent H_2SO_4, then poured into 3247 c.c. of boiling water to reduce the acid to a strength of 3·5 per cent, and boiled for three hours. The filtrate was neutralised with calcium carbonate, and, after the precipitated calcium sulphate had been removed by filtration, carbonic acid gas was passed into the clear liquor, which was subsequently boiled. The slight precipitate which formed was filtered off, and the liquid was evaporated to the bulk of 428 c.c. It did not need to be decolorised. It gave quasi-$[\alpha]_D = 79·89°$, and 13·61 per cent dextrose, calculated on the dry root wood. On being evaporated to dryness and treated with strong alcohol, a large portion of the residue failed to dissolve.

In still another experiment rather more than 50 grms. of powdered maple root were boiled for three hours in 1000 c.c. of 3·5 per cent sulphuric acid; the undissolved wood was filtered off, dried thoroughly, and left to soak during twenty-four hours with 70 c.c. of sulphuric acid of 90 per cent H_2SO_4. The mixture was poured into 3250 c.c. of boiling water, and the boiling was continued during three hours. The filtrate was neutralised with lead carbonate, and, after the removal of the lead sulphate, sulphuretted hydrogen was passed through the filtrate to remove any lead which might be held in solution. After removing the lead sulphide and the excess of sulphuretted hydrogen, the solution tested with Fehling's liquor showed 0·84 per cent of dextrose, calculated on the dry wood, and gave quasi-$[\alpha]_D = 82·15°$. The low percentage of dextrose is remarkable.

(To be continued).

THE SULPHOCYANIDES OF COPPER AND SILVER IN GRAVIMETRIC ANALYSIS.

By R. G. VAN NAME.

Cuprous Sulphocyanide.

As early as 1854 attention was drawn by Rivot (*Comptes Rendus*, xxxviii., 868) to the possibility of estimating copper gravimetrically by weighing as cuprous sulphocyanide, and to the advantages which the process afforded in separating copper from other metals. Rivot's method of procedure consisted in dissolving the substance to be analysed in hydrochloric acid, reducing the copper with hypophosphorous or sulphurous acid, and precipitating with potassium sulphocyanide. The precipitate dried at a moderate temperature was weighed as cuprous sulphocyanide and then as a control converted by ignition with sulphur into cuprous sulphide and weighed in that condition.

In his well-known work upon Quantitative Analysis Fresenius in one place (6th Aufl., i., 187) denies the practicability of the direct weighing of copper as cuprous sulphocyanide on account of the tendency of the latter to hold water even when heated to the temperature of incipient decomposition. As authority for this statement he cites Claus (Gmelin's "Handbook," iv., 472), who found 3 per cent of water in the precipitate after drying at 115°, and Meitzendorff, who gave the percentage of water under the same conditions as 1·54.

On a later page of the same volume, however (6th Aufl., i., p. 335), Fresenius, after a trial of the process which gave 99·66 per cent of the theory for copper, concludes that the method is practicable although apt to give low results, particularly in the presence of free acid.

The process was again recommended in 1878 by Busse (*Zeit. Anal. Chem.*, xvii., 53), who had employed it for the estimation of copper, both alone and in the presence of iron, nickel, zinc, and arsenic, obtaining results very near the theory and plainly comparable with the figures ob-

tained by afterwards igniting the cuprous sulphocyanide with sulphur in hydrogen.

In spite of the evident advantages for certain purposes of Rivot's method over other modes of determining copper, it has never come into general use. The chief reason for this has apparently been the difficulty and inaccuracy attendant upon the weighing of the precipitate upon dried paper filters, a process which can hardly be depended upon unless managed with extreme care.

In the experiments to be described this difficulty was avoided by performing the filtering and weighing upon asbestos in a perforated platinum crucible. The method of conducting a determination was as follows:—A suitable quantity of a standard copper sulphate solution was run from a burette, diluted to a convenient volume, a few cubic centimetres of a saturated solution of ammonium bisulphite added, and the copper precipitated by an excess of ammonium sulphocyanide. The precipitate was allowed to settle, collected upon asbestos in a weighed crucible, washed with cold water, and dried at 110° until no further loss of weight took place.

In Table I. are given the results of a number of determinations made in this way. The copper sulphate solution was made up exactly decinormal, and the standard confirmed electrolytically. As the ammonium sulphocyanide solution was slightly above decinormal, 13 c.m.³ represent a small excess (about 1 c.c.) above the amount theoretically required to precipitate 25 c.m.³ of the copper sulphate solution. The ammonium bisulphite, which had been recently prepared by saturating aqueous ammonia with sulphur dioxide, was always used in sufficient quantity to give the liquid a strong and permanent odour of the latter.

When there is no free acid present the time of standing

before filtration and the amount of the excess of ammonium sulphocyanide are practically without effect, as experiments 1 to 4 of the table show.

Experiments 5 to 10 were carried out in the presence of various amounts of free sulphuric acid up to 12 per cent of the total volume of liquid. The acid, at least within this limit, does not exert a sufficient solvent effect upon the cuprous sulphocyanide to interfere materially with the accuracy of the process, but it retards the precipitation, making it necessary to increase the time of standing before filtering in proportion to the amount of acid present. In several of these determinations the precipitation was visibly incomplete even after several hours standing. This effect of the acid, however, hardly shows in the results of the table, because the standing was always prolonged until the copper appeared to be all down before filtering.

The low results of No. 7 was probably due chiefly to incomplete precipitation, although No. 9 shows that even with a much larger amount of acid precipitation may be complete within three hours. In general, however, it is safer to allow ample time (twelve hours or more) for the precipitation when there is much free acid present.

Comparison of Nos. 5 and 6, for which only a bare excess of ammonium sulphocyanide was used, with Nos. 7 to 12 shows an apparent advantage in the larger excess in the presence of acid. Hydrochloric acid, judging from the results of Nos. 11 and 12, has no greater disturbing influence than sulphuric acid, although in No. 12, where the concentrated acid constituted one-fourth of the entire volume, there was apparently a slight solvent action. The filtrate from this determination when concentrated to about 25 c.m.³ and treated with potassium ferrocyanide gave a strong test for copper, as did also the filtrate from No. 6. Several of the other filtrates were tested in the same way, but none showed more than an insignificant trace of copper. No. 7, however, was not tested.

Table II. contains the results of a series of experiments conducted as before, except that larger amounts of copper were employed. The copper sulphate solution was approximately N/5 and standardised by the battery. The solution of ammonium sulphocyanide was the same previously used, and a considerable excess was employed in every determination. More than twice the amount theoretically required was used in every case where free acid was present, and at least twenty hours were allowed for the precipitation, which was made in cold, and, as the table shows, rather dilute solutions. If the solution is too concentrated the copper is apt to be thrown down in a finely divided condition, making it hard to filter.

The time required to dry the cuprous sulphocyanide at 110° is in general from two to three hours. Heating much longer than this is not to be recommended, as a gradual increase in weight begins to take place, as is shown by the following example, which gives a series of weights of the same precipitate at different stages.

	$Cu_2S_2(CN)_2$ Grm.	Calculated as Cu. Grm.
After 2 hours at 110° ..	0·6060	0·3167
,, 4 ,, ,, ..	0·6059	0·3167
,, 19 ,, ,, ..	0·6067	0·3171
,, 23 ,, ,, ..	0·6069	0·3172

This tendency to increase in weight is, however, usually less marked than in the above example, and in any case need not interfere materially with the accuracy of the process unless the drying is prolonged far beyond the necessary length of time.

The method is easily handled, and as the results of Tables I. and II. show, is capable of considerable accuracy. From the nature of the process it is evident that it is much less likely to be interfered with by the presence of other metals than the other gravimetric methods for copper, and may therefore be directly applied with good results in many cases where the use of the electrolytic or the oxide method would involve a previous separation.

Silver Sulphocyanide.

The sulphocyanide of silver, unlike that of copper, is soluble in an excess of ammonium or alkali sulphocyanides, and this fact prevents the use of the latter to precipitate silver for gravimetric estimation. The reverse process, however, the precipitation of a soluble sulphocyanide by an excess of silver nitrate, as will be shown by the experiments to be described, furnishes a convenient means of standardising sulphocyanide solutions and in general for estimating thiocyanic acid.

When freshly precipitated the sulphocyanide of silver resembles the chloride in appearance, but when allowed to stand a few hours becomes finely granular and is very easily filtered and washed. It may be safely dried to a constant weight upon an asbestos filter at 110°—120°, but at a somewhat higher temperature is decomposed, leaving a residue of silver sulphide.

The determinations which are shown in Table III. were made as follows:—Portions of 25 c.m.³ of an approximately decinormal solution of ammonium sulphocyanide were measured from a burette, diluted with 100 c.m.³ of water, and silver nitrate added in excess. The precipitate was collected upon asbestos in a platinum crucible, washed with cold water, and dried to a constant weight at 115°; the drying requiring usually between two and three hours.

The filtering is facilitated by allowing a few hours for the precipitate to settle; but this is by no means essential, as it is easy with a little care to obtain a clear filtrate even when the filtering is performed at once.

The solution of ammonium sulphocyanide was prepared from a pure salt, especially tested and found free from chloride. This point is of importance, as chlorine is a common impurity and its presence in any considerable quantity will vitiate the results.

In order that the effect of varying the excess of silver might be investigated, an approximately decinormal solution of silver nitrate was titrated against the ammonium sulphocyanide and the ratio between the two solutions determined. This silver nitrate solution was used for the first five determinations of Table III. For the rest the quantity of silver nitrate was not measured but regulated by the eye alone, thus making the conditions the same as would be the case in practical use of the method.

These results are as uniform as could be expected, considering the variations which would be produced by even very small errors in measuring out 25 c.m.³ of decinormal sulphocyanide solution. It is, moreover, clearly shown that there is no difference in the results whether a bare excess or a moderately large excess of the silver nitrate is used.

The mean of the values in the last column is 0·4374, which is equivalent to 0·2006 grm. of ammonium sulphocyanide for every 25 c.m.³ of the solution.

The standard of the sulphocyanide solution was also determined volumetrically by Volhard's process. The mean of four titrations carried out with great care against a standard silver nitrate solution gave as the standard 0·2003 grm. of ammonium sulphocyanide for 25 c.m.³ of solution. This difference between the standards as determined by the two methods (1 part in 670) is much less than the variations which frequently appear between successive determinations by Volhard's method, under like conditions as to strength of solutions and amounts used. It is about equal to the error that would be produced in a single volumetric determination by a mistake of one drop in measuring one of the solutions, or of one-half drop in the same direction on each.

It is therefore evident that the standard of a sulphocyanide solution obtained in the above way may be applied directly to the estimation of unknown amounts of silver by Volhard's method without sensible error.

To remove a possible doubt as to whether the silver sulphocyanide dried at 115° was entirely free from water, a number of electrolytic determinations of the silver contained in the previously weighed precipitates of Table III. were made in the following way:—

The perforated platinum crucible containing the silver sulphocyanide and asbestos was hung in a loop of heavy platinum wire and served as the anode. For the cathode a deep platinum dish of about 200 c.m.³ capacity was used. An ammoniacal solution of potassium cyanide was employed as the electrolyte, and gave the best results when made up by dissolving 2 grms. of potassium cyanide in 15 c.m.³ of strong ammonia and 15 c.m.³ of water. The crucible which served as the anode was filled with this solution in full strength, and the remainder was put into the platinum dish and diluted to the required volume with water. In this medium the silver sulphocyanide is slowly dissolved and diffuses through the asbestos felt into the space between the electrodes, where the silver is deposited in the usual way. This diffusion is, however, aided but little, if at all, by the current, and there is a tendency for traces of the silver to remain behind in the crucible. The current density employed was about 0·0012 ampère per square centimetre of cathode surface and the time about twelve hours. After weighing the silver deposited, it was dissolved in nitric acid, precipitated by hydrochloric acid, and weighed again as the chloride, giving a check upon the results.

Seven of the ten determinations of Table III. were thus treated, but, owing to the imperfections of the process, the results were all slightly low, the worst showing a deficiency of 0·0025 grm. of silver—an error of less than 0·9 per cent. The results of the two best of these determinations (Table IV.), are, however, sufficient to prove the point in question—namely, that the silver sulphocyanide dried at 115° has the theoretical constitution and contains no water. The numbers are those under which the determinations appear in Table III.

It is clear, therefore, that the estimation of sulphocyanides by precipitation with silver nitrate and direct weighing of the precipitate is wholly permissible. The method is extremely simple, and, as has been shown, the results are quite accurate.

In conclusion, I wish to thank Prof. F. A. Gooch for many valuable suggestions given during the course of this investigation.

THE LITERATURE OF ALCHEMY.*

By HENRY CARRINGTON BOLTON.

The acquisition of riches surpassing the most extravagant dreams of avarice, the indefinite prolongation of life with perfect enjoyment of unfailing health both in body and mind, the attainment of a saint-like, unselfish spirit with hopes of a blessed immortality, were the unparalleled prizes promised by the pseudo-science of alchemy to those successful in penetrating its secrets; these and other less lofty allurements induced conscientious but misguided men to spend life-times, and to waste fortunes in search of the "Philosophers' Stone" capable of conferring such inimitable benefits. To gain the knowledge needed to secure this miraculous substance, two methods were open to students; first, to form the acquaintance of men claiming to possess the treasure, and to wrest from them the secret of its preparation, and secondly, to peruse the literature in which the mystery was believed to be hidden. The first plan necessitated long journeys, often to the little known and distant Orient, the wanderings extending to many years; the second required the accumulation of precious manuscripts and rare books, their careful study, and repetition in the laboratory of the processes obscurely described therein.

In the interiors of alchemists' laboratories painted by the Flemish artist Teniers, besides furnaces and crucibles, stillatories, and alembics, vellum covered handbooks and huge folios fitted with brass clasps are always conspicuous; the smaller volumes being held in the hand of the bearded alchemist, and the folios lying on the floor within reach. Teniers' studies are true to life, and one examining them in earnest longs to know what sort of literature was accessible to mediæval students of transmutation, what were its characteristics, who were their favourite authors, and what doctrines were propounded in the well-thumbed tomes.

Alchemical manuscripts and books are coeval with the pseudo-science that gave them birth, which has existed more than two thousand years. Or longer, if the claims of China be taken into account, as scholars tell us that the Chinese practised transmutation of metals full six hundred years before Europeans; indeed the Arabians are said to have acquired their knowledge by contact with Chinese merchants at Bagdad, an important Eastern market and early a centre of alchemical activity. The claims of China, moreover, are supported by finding the germs of a belief in transmutation in the religion of Tao, a sect founded by a contemporary of Confucius who died 478 B.C.

The early Chinese treatises on alchemy are written in an archaic style, with obsolete words, and many unknown characters that makes the task of deciphering them almost impossible for even expert sinologues. One of the earliest is entitled "Ts'an T'ung Ch'i," of which I own a reprint issued during the reign of the late Emperor Kuang Hsü (1873—93). A few years ago I made an effort to get this translated, at least in part, and had it examined by some of the first Chinese scholars of the world, but they abandoned the undertaking.*

Dr. Martin has, however, published notes on the treatise called the "Uniting Bond," written about the first century A.D. by a Tauist named Wei Peh Yang; this contains an account of an Elixir Vitæ having gold as its chief ingredient. "Gold is imperishable, fire does not injure its lustre; like the sun and the moon it is not affected by time, wherefore the Elixir is called the Golden (*Kin Tan*). Life can be lengthened by eating the herb *ku ma*, how much more by taking the Elixir which is the essence of gold, the most imperishable of all things. When partaken its influence will extend to the four limbs, the countenance will become joyful, white hair will turn black, new teeth will grow, and youthful vigour will replace the infirmities of age."

This passage reads like a glorified advertisement of the Keeley Gold Cure.

Alchemical books are still sold in the shops of Shanghai; one of the commoner is that entitled "Wu-chen-pien," in two volumes, written by Chang Pih Tuan about 1075 A.D.

Many of the alchemists were eminent scholars, but most of the ardent workers with furnaces and coals, lead, and mercury, were unlettered men who could not have profited by Chinese literature had it been available; all those seeking the "Way to Bliss," studied Latin translations of ancient Syriac, Arabic, and Greek manuscripts purporting to explain the preparation of the "Victorious Stone." These Latin versions were but fragmentary, they abounded in errors, glosses, and interpolations made by copyists, but their supposed antiquity and the renown of their reputed authors caused them to be most highly prized. Some of the genuine originals of these are still preserved in the great libraries of Europe, and are of curious interest to both the philologist and the historian of science; those in Syriac are translations from the Greek made in the seventh to the ninth centuries. The "Doctrine of Democritus" contains two treatises, "The Preparation of Gold," and "The Philosophers' Stone"; the latter deals with processes on metals, and on sulphur, arsenic, and ores, and is illustrated with rude sketches of chemical apparatus.

The first Mohammedan writer on alchemy was Prince Omeyyade, who died in 708; he was the teacher of Djâber,

* From the *Pharmaceutical Review*, vol xix., Nos. 4 and 5.

* It was seen by Dr. W. A. Martin, of Peking; Dr. John Fryer, then of Shanghai, who procured my copy for me; by Mr. Herbert Giles, of Aberdeen; by Miss Adèle Field, of New York; and by Lord Kingsgeast, of Tseng, of the Chinese Legation at London.

but only the titles of his works have come down to us. The Arabian physician Djâber, the Geber of the Latin authors, was the great master of the "sacred art," and enjoyed the highest reputation throughout the Middle Ages; he is credited with having written 500 treatises, an Oriental exaggeration. Those known exhibit evidence of Moslem faith, and as he himself admits, are written in an allegorical, obscure language; he shows familiarity with many mineral substances, and discourses on the changes in volume produced by heat and cold, but makes no reference to the mineral acids, nor to nitrate of silver, that Geber is supposed to have known. Perhaps the most satisfactory passage in his writings is the following from the "Book of Mercy":—

"I saw that persons engaged in attempts to manufacture gold and silver were working ignorantly and by wrong methods; I then perceived that they were divided into two categories, the dupers and the duped. I had pity for them both."

Berthelot, the distinguished French chemist who first collected the Arabic treatises, in 1893, made the discovery that the supposititious originals of many Latin works have no existence, the writers fraudulently claiming for the latter an Oriental origin; he showed that the chemical books attributed to the much lauded Geber are fictitious, and that the reverence paid to him as a pioneer in chemistry has been misplaced. Thus the whole history of chemistry has been falsified by giving credit to the Arabians for knowledge which really belonged to a period five hundred years later.

If we disregard the Egyptian papyrus named after Georg Ebers, which deals with the medical art, and dates back to 1550 B.C., the most ancient writings on alchemy are certain Greco-Egyptian papyri preserved in Leyden; several of them contain magical formulas, incantations, love philtres, and dream secrets, but one known as "Papyrus X" is a treasury of information on metallurgical operations at so early a period as the third century of the Christian Era. It was found in a tomb at Thebes, and may have been one of those ancient Egyptian books on the preparation of gold and silver which escaped the destruction ordered by the Emperor Diocletian in the year 290: an order issued lest the people using them should grow rich by their art, and revolt against the Romans.

This precious document contains more than one hundred recipes for making alloys to be used in the manufacture of cups, vases, images, and other objects of the goldsmith's art; also processes for soldering metals, and superficially colouring them, besides formulas for making gold and silver inks. The text is full of ignorant spellings and grammatical errors, which show the writings to have been the work of an uneducated artisan; the whole papyrus, in short, is evidently the memorandum book of a goldsmith (or silversmith), engaged in attempts to imitate gold and silver. This and similar MSS. prove that the doctrines of alchemy concerning the transmutation of metals did not originate in philosophical views of the constitution of matter, as generally supposed, but in the practical experiments of workmen trying to find fraudulent substitutes for the precious metals.

(To be continued).

NOTICES OF BOOKS.

Veterinary Posology. By GEORGE A. BANHAM, F.R.C.V.S. Second Edition. London: Baillière, Tindall, and Cox. 1901. Pp. 192.

THESE tables are intended as an aid to the memory for the dose and pharmacopœial preparations of the drugs used in veterinary medicine.

The author considers it more convenient to arrange the agents alphabetically instead of under various groups, and we quite agree with him that such an arrangement will save the busy practitioner a good deal of time.

The doses given in the three columns are for the horse, pig, and dog respectively; those for cattle, sheep, goats, and cats can easily be calculated from the former by means of a few factors which are given.

Amongst other tables which are included in this handy little volume we may call attention to the table of the General Classification of Medicines, according to their influence on the organs and structures of the body; the table of agents arranged according to their therapeutical action; the table of diseases and their remedies, &c. The book is supplied with a good index.

CORRESPONDENCE.

PROUT'S HYPOTHESIS AND RADIO-ACTIVE ELEMENTS.

To the Editor of the Chemical News.

SIR,—A writer to the CHEMICAL NEWS of March 22nd suggests that the discoveries of the heavy radio-active elements, all closely resembling formerly well known elements, may have the effect of reviving Prout's hypothesis that atomic weights should be expressed in whole numbers. He says that the presence of a small amount of a heavier element occurring as an unrecognised impurity might easily make enough difference in atomic weights to account for many of the small fractional variations from whole numbers. Atomic weight comparisons and theories have been popular with chemists for the past century, and as such comparisons led to the discovery of the periodic law they certainly cannot be regarded as valueless. Hence it may not be useless to follow out the ideas of the above-mentioned correspondent.

The past few years have been prolific in new elements, and in the promise of more; and in nearly all cases the new ones resemble closely other elements already well known. Lord Rayleigh and Professor Ramsay found a whole series of elements so much like nitrogen that they had previously escaped detection; and the recent spectrum investigations of Professors Liveing and Dewar indicate the existence of an indefinite number of other similar elements yet to be isolated. The new radio-active elements are so similar to bismuth, barium, and titanium that many chemists still hesitate to believe them different. Victorium, the latest of the rare earth group, is another instance of the same kind, as it so closely resembles others of the same group that it was isolated only by a most laborious method. The original yttrium, thought by Gadolin a century ago to be a single element, has proved to be the parent of a large number of children all bearing a family resemblance, and the possibilities of a further increase in the family seems almost unlimited.

There can be little doubt of the existence of a large number of undiscovered elements, and equally little doubt that many of them will be found very similar to elements now known—so similar that they may now exist unsuspected with the known elements, and may affect their atomic weights to the fractional extent that has seemed to disprove Prout's very convenient whole number hypothesis. According to the latest international table of atomic weights, published by the Commission of the Deutschen Chemischen Gesellschaft, taking O=16, there are 76 elements, 35 of which have their atomic weights expressed in whole numbers. Of the 41 others 16 vary from whole numbers by not more than 0·1. If these 16 could be added to the 35 it would give a list of 51, nearly 70 per cent of the whole number.

It can easily be seen that the admixture of a very small amount of a material of different atomic weight might easily account for the minor differences in the table. Let us take, for example, the first on the list, aluminium, with an atomic weight of 27·1. If this 0·1 be conceived as due to admixture of some unknown element it must of course

be heavier than the aluminium. If it be supposed to have an atomic weight of 28, it would constitute one-tenth of the element we now call aluminium. If the atomic weight were greater the proportion would be correspondingly less. The atomic weight of radium is reported to be about 174, not far from 36 higher than barium, which it so closely resembles. If the same difference be imagined in the case of aluminium, the new undiscovered element need be in the proportion of 1 to 359, an amount that might easily escape detection if it as closely resembled aluminium as radium does barium, or as argon does nitrogen.

The case of hydrogen is even more interesting. It is given an atomic weight in the table of 1·01, which is a little too high. It it be supposed to contain as an impurity an element having an atomic weight as great as helium—the next in the scale—the new element would have to be present in the proportion of 1 to 300, while if it were as heavy as neon it would be there as 1 to 1900.

Of course it is not very probable that a sufficient number of these conveniently located elements will be discovered, and so it is hardly likely that the atomic weights will be corrected in this way. Still it can easily be seen from the above facts that such is within the range of possibility, if not of probability.—I am, &c.,

EDWARD BOOTH.

University of California,
Berkeley, California, April 25, 1901.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. cxxxii., No. 18, May 6, 1901.

Osmotic Pressure across a Membrane of Copper Ferrocyanide.—G. Flusin.—An examination of osmotic pressure across those membranes said to be semi-permeable, like copper ferrocyanide, presents certain experimental difficulties. For the author's experiments, the membrane was precipitated on the internal side of a porous vessel, and solutions of the following substances were used:—A 2 per cent sugar solution, 1 per cent sugar solution, 1 per cent amygdaline solution, 1 per cent antipyrine solution, and a 1 per cent urea solution. The agreement between the numbers is very satisfactory, except for urea; and a study of these numbers shows that, for the same vessel, the velocities of osmose are proportional to the osmotic pressures, and consequently inversely proportional to the molecular weights.

Alloys of Aluminium. Combinations of Aluminium and Tungsten.—Léon Guillet.—The author makes a systematic study of certain aluminium alloys. He prepares the compounds by mixing the oxide of the metal whose alloy is desired with powdered aluminium, and, to excite the reaction of these two, he uses the medium of a powder of barium dioxide and aluminium. The first experiments were performed on tungstic acid, molybdic acid, magnetic oxide of iron, manganese oxide, tin binoxide, and titanic acid.

Mercury Iodoantimonide.—Albert Granger.—The author has already shown that mercury, when heated in presence of phosphorus iodide, is transformed into iodide and phosphide of mercury. He now finds that, in generalising this reaction, he can isolate arsenide, antimonide, and bismuthide of mercury. The present paper gives an account of the results obtained when mercury acts on antimony tri-iodide; a body is apparently obtained having a formula $Hg_5Sb_4I_4$.

A Specimen of Crystallised Lime.—Ad. Jouve.—Lime can be obtained in a prismatic form by suddenly cooling the mass of lime and carbon, just at the moment when the calcium carbide is on the point of forming. The carbon and lime to form the carbide are found respectively, the one in the form of graphite, the other of melted lime, sometimes even in the form of lime vapour. It is the cooling of this vapour in a closed space which probably produces the lime in prismatic crystals.

The Chemistry of Methylene.—V. Thomas.—The author's experiments on methylene show—(1) That mercury reacts on iodide of methylene (quite free from iodoform), with simultaneous formation of $CH_2I.HgI$, $CH_2(HgI)_2$, and $CH(HgI)_3$; (2) that the iodide, $CH_2I.HgI$, is decomposed under the action of heat, giving the derivatives $CH_2(HgI)_2$ and $CH(HgI)_3$; (3) that methylene iodide is decomposed by certain metals, with formation of ethane and methane (*e.g.*, mercury), or by others into acetylenic carbides, with precipitation of ammoniacal cuprous chloride (*e.g.*, silver).

Hydratation of Amylpropiolic Acid. Caproylacetic Acid.—Ch. Moureu and R. Delange.—The authors show—(1) That fuming sulphuric acid decomposes amylpropiolic acid with production of the fatty acid having at least two atoms of carbon; (2) that when the same acetylenic acid is treated with alcoholic potash, a non-substituted β-ketonic acid is obtained and caproylacetic acid. They propose to generalise these two reactions. The second constitutes a method of synthesis of the β-ketonic acids and ethers entirely different from the two other methods already known, of which one has been noticed by M. Bouveault and the other quite recently by M. Blaise.

Dimethylpyruvic Acid.—A. Wahl.—In a former paper, the author describes the preparation of dimethylpyruvic acid, $\begin{matrix}CH_3\\CH_3\end{matrix}\!\!>\!CH\!-\!CO\!-\!COOH$, a substance unknown up to the present time. He now endeavours to prepare dimethylpyruvamide by acting upon dimethylpyruvic ether with a concentrated solution of ammonia. An unexpected reaction, however, occurs, resulting in crystals possessing the composition $C_9H_{18}N_2O_2$. By further experiments, he succeeds in transforming dimethylpyruvic acid into α-isovalerianic oxide, and to fix in a certain and definite manner the constitution which was originally suggested for the above acid.

The Anhydride of the pretended Binaphthalene Glycol.—R. Fosse.—The author's experiments show that Rousseau's binaphthylene anhydride is identical with dinaphthoxanthene, $CH_2\!<\!\begin{matrix}C_{10}H_6\\C_{10}H_6\end{matrix}\!\!>\!O$. In a future research, the author hopes to establish the true nature of binaphthalene glycol.

Action of Acid Chlorides on the Ether Oxides in presence of Chloride of Zinc.—Marcel Descude.—When acetyl chloride and ethyl oxide in molecular proportion are heated together for some hours, no trace of reaction can be observed. The same thing occurs if any other ether oxide is taken, whether simple or mixed. If, however, a certain quantity of anhydrous zinc chloride is added, an immediate action takes place, with evolution of heat. The author investigates this reaction, using ordinary ether; it apparently takes place according to the following very simple equation:—

$$CH_3\!-\!COCl+C_2H_5\!-\!O\!-\!C_2H_5=$$
$$=CH_3\!-\!COOC_2H_5+C_2H_5Cl.$$

Bulletin de la Société Chimique de Paris.
Series 3, Vol. xxv., No. 2.

Research on Solutions.—G. Wyrouboff.—A very long paper, not suitable for abstraction.

On the Nitrocelluloses.—Leo Vignon.—Already noticed.

Reduction of Nitrocellulose.—Leo Vignon.—Already noticed.

Oxycelluloses from Cotton, Flax, Hemp, and Rush Pulp.—Leo Vignon.—Already noticed.

Cellulose, Mercerised Cellulose, Precipitated Cellulose, and Hydrocellulose. — Leo Vignon. — Already noticed.

Acetyl Derivatives of Cellulose and of Oxycellulose.—Leo Vignon and F. Gerin.—Already noticed.

Note on the Examination of Butter and Fats.—A. Reychler.—The author's attention having been directed to the examination of coco butter, which is a product relatively rich in insoluble volatile acids, he thought it would be of interest to determine, besides the Reichert characteristic, a figure which would be in relation to the total volatile acids. For this purpose he saponified 5 grms. of fat and followed all the succeeding operations of distillation, &c., in the usual manner, but, instead of filtering the distillate, he transferred it directly to a conical flask and placed a layer of 50 c.c. of alcohol over it. The floating droplets immediately disappeared, and on shaking the whole he obtained a slightly opalescent homogeneous liquor. The acidimetric titration was most simple, and gave a perfectly sharp and distinct terminal reaction. The results obtained by the two methods are set out in a table in two parallel columns, and in a third column the relation between the two is shown. This relation varies considerably, according to the nature of the fat under examination. With butter it reaches 0·90; that is to say, that on 100 molecules of volatile fatty acids, there are 90 soluble in water. With coco butter, the proportion goes down to 0·32. With oleomargarine and neutral lard, it takes an intermediate position.

MISCELLANEOUS.

The Estimation of Cerium.—G. von Knorre.—This method depends on the reduction of the yellow ceric salts to the state of colourless cerous salts, by means of peroxide of hydrogen in acid solution:—$2(SO_4)_2Ce + H_2O_2 = (SO_4)_3Ce_2 + SO_4H_2 + O_2$. The following is the method of working:—The solution is acidulated with the smallest possible quantity of dilute sulphuric acid, and persulphate of ammonium added in the cold; it is then boiled for one or two minutes, and cooled down to 40—60°, when a further quantity of persulphate is added, and the whole again raised to boiling for a few minutes; this cooling and the addition of persulphate is repeated a third time, after which the boiling is continued for ten to fifteen minutes. Finally, a slight excess of dilute sulphuric acid is added to decompose the persulphate. About 3 grms. of this salt are required for 0·2 or 0·3 grm. of cerium. The metal being thus completely peroxidised, titrated peroxide of hydrogen is added by means of a burette to the well-cooled solution, the point of decolouration being slightly exceeded. The excess of H_2O_2 is estimated by means of permanganate. The author compares his method with the similar ones devised by M. Job (*Comptes Rendus*, vol. cxxviii., p. 101), and W. Gibbs (*Zeit. Anal. Chem.*, vol. iii., p. 395), in which PbO_2 is used instead of persulphate.—*Berichte*, vol. xxxiii., p. 1924.

Examination of Commercial Nitrate of Thorium, and on the Incandescent Bodies in the Auer Burner.—W. Muthmann and E. Baur.—Starting from the fact that impurities considerably diminish the illuminating power of the incandescent substance in the Auer burner, the authors took some commercial nitrate of thorium, and, to its solution brought to boiling-point, they added drop by drop a solution of bichromate of potassium so as to effect a fractional precipitation. The first portions which came down consisted of a beautiful deep yellow microcrystalline precipitate of pure chromate of thorium, $(CrO_4)_2Th + 3H_2O$; it is only the very last portions which gave a dirty olive-green precipitate, or even no precipitate at all; they either no longer contained any thorium or only foreign oxides containing perhaps 0·3 per cent of nitrate of thorium. The thorium thus purified was incorporated with 0·01 per cent of peroxide of cerium, and then used for impregnating mantles. These turned out to be much more brilliant than the ordinary commercial ones, with a more yellow and less green light; their illuminating power was 1·3 to 1·4, taking as unity the "metathor" mantles made by Drossbach, of Freiberg. Thus we find that in the manufacture of mantles with well purified thorium, as the cerium is only present in very small quantities, its preparation does not require such great care.—*Berichte*, vol. xxxiii. p. 2028.

MEETINGS FOR THE WEEK.

MONDAY, June 3rd.—Society of Chemical Industry, 8. "The Need of Greater Care in Introducing Gas-firing into small Gas Works," by G. Cecil Jones. "The Chemical Aspects of Bacteriology," by Dr. Walter C. C. Pakes.

—— Royal Institution, 5. General Monthly Meeting.

TUESDAY, 4th.—Royal Institution, 3. "The True Functions of Poetry, and Wordsworth as a Teacher," by Churton Collins, M.A.

WEDNESDAY, 5th.—Society of Public Analysts, 8. "Arsenic in Coal and Coke," by Alfred C. Chapman, F.I.C. "Public Analysts' Records," by J. F. Liverseege, F.I.C. "The Composition of Milk and Milk Products" and "The Use of Partially Sterilised Milk Cultures in Judging the Purity of Water," by H. Droop Richmond, F.I.C.

THURSDAY, 6th.—Royal Institution, 3. "The Chemistry of Carbon," by Prof. Dewar, F.R.S., &c.

—— Chemical, 8. "A Laboratory Method for the Preparation of Ethylene," by G. S. Newth. "Oroxylin," by W. A. H. Naylor and G. S. Dyer. THE CHEMICAL NEWS.

Vol. LXXXIII., No. 2167.

ON THE

CIRCULATION OF SALT AND ITS BEARING ON CHEMICO-GEOLOGICAL PROBLEMS, MORE PARTICULARLY THAT OF THE GEOLOGICAL AGE OF THE EARTH.*

By WILLIAM ACKROYD, F.I.C., Public Analyst for Halifax.

Introduction.

Common salt, or sodium chloride, is probably the most widely distributed of all sodium compounds, as it is one of the most soluble. During our investigation of the underground waters of North-West Yorkshire, a fruitful aspect of its solubility was presented to us in the disappearance of 3 tons of salt in a runnel of 19,800 gallons per day; it went down the Smelt Mill Water Sink and reappeared after ten days at Malham Cove, where the amount of combined chlorine in the water suddenly rose from 1 up to 6 parts per 100,000, and in the course of another eight days slowly fell to the normal unit (*Proc. Yorkshire Geol. and Poly. Soc.*, vol. xiv., Part 1., p. 17). We had a similar experience at Clapham. It is apparent, therefore, that any salt in the soil or in underground channels is carried quickly away by the water; and such soil or underground channels would be thenceforth free from the compound unless in the course of disintegration fresh quantities were exposed for solution. This, however, is so slow a process that it quite fails to account for the enormous amounts of chloride annually conveyed by rivers to the sea.

The position is perhaps better seen in the following statement of fact:—The Widdop reservoir, belonging to the Halifax Corporation, contains some 640·5 millions of gallons of water, and I estimate it to contain 55 tons of salt. The two thousand odd acres of gathering ground is moorland on millstone grit for the most part with a little of the Yoredale rocks. Needless to say, it is a saltless area; yet the 55 tons of salt is renewed probably more than once a year in the course of filling up to replace the Corporate demands on the reservoir. The chlorides come down in the rain-water. We may take it, then, as a working hypothesis, that rain has brought down the salt, which has been derived from the sea, and that to the sea it quickly returns. It will be convenient to speak of this salt as *sea-salt*, in contradistinction to such as may be derived from the earth by solvent denudation, which will be referred to as *earth-salt*, and the proportionate amount of the sodium compound will be indicated in this paper by the chlorine figure.

Circulation of Sea-salt.

The conditions obtaining in the Widdop area are of more than ordinary scientific interest, and I have made an experimental investigation of them during the winter 1900—01, which has been communicated to the Chemical Society of London (*Trans. Chem. Soc.*, lxxix., p. 673). It will suffice to recount here that from November 12 to February 18 weekly chlorine determinations were made of the reservoir water, of the water in a rain-gauge kept close by, and of rain-gauge water on four other gathering-grounds some miles to the east of Widdop—viz., Walshaw Dean, Midgley, Warley, and Ovenden Moors,—besides daily tests of rain-gauge water from Belle Vue in the town of Halifax.

The reservoir water was fairly constant with an average of 1·188 parts of chlorine per 100,000. This figure will be greater than that of the annual average rainfall, on account of evaporation, and if we deduct 10 per cent, it would still be equivalent to a fall of 172 lbs. of common salt per acre with the 1899 rainfall of 43·17 inches.

The rain-gauge figures fluctuated wildly; Widdop rain-gauge water reached 3·3 per 100,000 during a December week when a violent storm was blowing from the Irish Sea about 40 miles away, and on another occasion it got up to 6·5; the average for the fourteen weeks of observation was 1·53. That the winter average should be in excess of the yearly average is in keeping with the results obtained by other observers, and gives some idea of the activity of salt circulation during the stormy part of the year when gales are prevalent from the sea. The abnormally high figures obtained at Widdop synchronised with similarly high figures for the other gathering-grounds.

Observations on chlorine in rain-water have been made at Cirencester since 1870 by Professors Church, Prevost, and Kinch (*Trans. Chem. Soc.*, vol. lxxvii., p. 1271). An abnormal amount of chlorine has almost always been traced by them to salt spray from the Bristol Channel 35 miles away. On different occasions, immediately after a storm from the S.W., crystals of common salt have been found on the College windows facing west. The same kind of evidence has been furnished to me by Mr. J. H. Howarth respecting Malham, concerning Leeds by Mr. J. E. Bedford, and Mr. J. Denison calls my attention to the following references:—"The winds from the south-west have sometimes blown so strong that the pieces of cloth on the tenters in several parts of Halifax parish have been charged with a considerable number of saline particles brought from the sea" ("Watson's History of Halifax," 1775, p. 5); and, further,—"Sea-salts have been found deposited on the windows in West Park and York Place (Harrogate), thus giving practical evidence of the presence of the sea-breeze" ("The Use and Abuse of Harrogate Mineral Waters," by Arthur Roberts, p. 32).

Table I. is a synopsis of results up to date, the chlorides in the rainfall being calculated into annual downfall of salt per unit area.

As to the particular nature of this salt circulation, we may suppose—(1) That salt spray from the sea is carried to the land to distances varying with the force of the wind; (2) that when the salt is dried by evaporation it is carried further inland with the dust; and (3) that rains dissolve it and bring it down to the rivers by which it is carried back to the sea.

Of the carrying of the salt spray abundant evidence, as I have shown, has been obtained in times of storm, and of the presence of sodium in dust at all times the spectroscope yields never-failing proof, while in the examination of rain-water I have found the highest chlorine contents in light rain-falls.

The full extent inland of salt circulation has yet to be determined; it may not be entirely limited by mountain chains barring the direction of prevalent sea-winds, as finely divided sea-spray may possibly be carried nearly as far as the dust of Krakatoa. This much, however, we know, that the further one gets inland, the less the chlorine figure becomes for rain-water. Angus Smith has published some averages for rain ("Air and Rain," Longmans, London, 1872, p. 281), in terms of hydrochloric acid per million. The following are his figures converted to chlorine in parts per 100,000 of rain-water:—

Ireland, Valentia	4·72
Liverpool	3·49
English towns	0·84
Darmstadt	0·094

The Concentration of Sea-salt.

When rain-water reaches the earth its burden of salt necessarily becomes concentrated by evaporation. A sheet of water will in twelve months lower its level 20

* Read before the Yorkshire Geological and Polytechnic Society, at Leeds, April 25, 1901.

Table I.

	Distance from the sea. Miles.	Deposit of NaCl per acre per year.	Observers.
Cirencester	35	36 lbs. (average of twenty-six years)	Church, Prevost, and Kinch (*Trans. Chem. Soc.*, vol. lxxvii., p. 1773).
Rothamsted	—	24·59 lbs. (average of six years)	Lawes, Gilbert, and Warington (*Ibid.*).
Perugia	75	37·8 lbs.	Bellucci (*Ibid.*).
George Town, Demerara	—	186 lbs.	Harrison (*Ibid.*).
Widdop	40	172 lbs.	Ackroyd.

Table II.

„ 3 „	38	2·15	100	:	5·7

inches,* so that it follows if the original depth were 40 inches, the result of a year's evaporation would be to double the amount of salt in the residual water; much quicker must evaporation be from land surfaces, where capillary action may come into play, and consequently draw moisture upwards where it is exposed on a maximum of earth surface to the evaporative influence of the sun or of a higher atmospheric temperature.

The final result appears so apparent as to need no proof. I may, however, refer to peculiar cases of concentration I have come across in the course of this study. Well waters in the millstone grit show evidence of concentration in higher chlorine figures, and also that the salt is cyclic *sea-salt* from the fact that *it does not increase at the same rate as the other solids in solution*, whereas, it it were derived from the soil it ought to increase at a greater rate, because of its greater solubility than that of the other bodies. The data given in Table II. will illustrate the point.

The Caspian and Dead Seas.

This concentration of chlorides is an important geological factor. To return to our Pennine reservoir:—If there were no outlet, and a rate of evaporation equal to the inflow of water, it would, in 50,000 years, contain 2½ millions of tons of salt; or, if we halve the rate of accumulation, it would still be 1,375,000 tons of salt, collected from a gathering-ground of 2223 acres into a reservoir of 93 acres surface and of a depth of 65 feet. The water at this lesser estimate would contain 32 per cent of salt, as compared with the Dead Sea with its 24 per cent; and the accumulation, derived nearly entirely from rain-borne sea-salt, would have been amassed during a period which is comparatively trifling, as geological time is reckoned, being probably less than a seventh of the Pleistocene age.

We have here, then, a process at work which must be taken into account in framing theories of salt-lake and salt-deposit formations; hitherto it has been entirely overlooked, and only contributions of earth-salt derived by solvent denudation have been drawn upon for the purpose, with in many cases the added supposition that the first step in their formation was the disconnection of an arm of the sea—a supposition which is not always required. Thus, with regard to the salt deposits of Northern Africa, Prof. Zittel (*Nature*, vol. xxix., pp. 121 and 122) has shown, on what appears to be overwhelming evidence, that the popular idea of the Sahara having been the basin of a sea in Pleistocene times is without foundation, and —as the rainfall was heavier and the climate damper in those days than now—rain-borne sea-salt must have played an important part in the formation of the salt hills of the Sahara.

The usual theory of the cause of the saltness of the Caspian Sea appears also somewhat anomalous. The Mediterranean, Black Sea, Sea of Azof, and Caspian Sea decrease in saltness in this order, on which Ramsay (*Nature*, vol. vii., p. 313) has remarked:—"It will be seen that the Black Sea is fresher than the Mediterranean. The Caspian is still fresher, and its fauna and fossils in recent deposits in the neighbourhood prove it to have once had connection with the Black Sea, from which it has been separated by changes in physical geography; it was then salter than at present, but is now growing salter again every year, and the fauna now inhabiting its waters have likewise considerable affinities with North Sea types." Now I should think the whole physical facts of the case are comprised in the simple statements that the Caspian is an inland sea, of large volume and variable composition, fed by inland rivers rising in and flowing through regions where the sea-salt in the rainfall—not reckoning that derived from the lake itself—must have reached a minimum, where the chief source of the saltness must be the earth-salt from solvent denudation, and how small that may be expected to be will be presently shown in the case of the Aire at Malham Cove, where a large portion of the evaporated water must come down again to the sea itself, so large is its area; from all of which statements it follows that the Caspian must increase in saltness at so phenomenally slow a rate that one is not surprised to find it least salt of all the waters which have been mentioned. As an inland lake, without outlet, one would think that it can never have been salter than it is at present, and it will be well to revise the biological data upon which such an idea is based.

Let us next consider the Dead Sea from this point of view. Little further removed from the Mediterranean than Widdop is from the Irish sea, with a rain-fall in Palestine higher than that of the Pennine hills, and an intensity of meteorological conditions in the past of which we can at the present day form but a poor conception (Tristram, "The Land of Israel," p. 320), it is reasonable to suppose that the salts in the Dead Sea have been for the most part derived from the Mediterranean, carried by winds and brought down by rains, and barring the contributions of Jebel Usdum it will probably be found that over 90 per cent of the salts come from this source. On such a theory we look for some measure of likeness between the dissolved matters of the two waters, but an initial obstacle to comparison presents itself in the much greater concentration in one case than in the other, and in the variability of the Dead Sea itself from the north where the Jordan enters to the south, where the salt hill

* A four years' mean annual evaporation from the Torquay watershed, as kindly supplied to me by Mr. W. Ingham, C.E., is 20·88 inches, 1897—1900.

of Jebel Usdum overlooks it. In instituting a comparison I have therefore confined myself to the ratio of the related ions chlorine and bromine. Usiglio's figures for the Mediterranean at Cette give :—

Cl.		Br.
100	:	2·1

which are practically the same as Von-Bibra's for the Atlantic at the Equator :—

Cl.		Br.
100	:	2·09

The analyses of Dead Sea surface water made by Terreil give the following ratios :—

	Cl.		Br.
Near Rasdale	100	:	0·95
Lagune North of Sodom ..	100	:	2·7
Near island	100	:	3·6
Average	100	:	2·4

The closeness of this average to the Mediterranean and Atlantic Ocean figures is somewhat remarkable, and although it will not be taken as absolute proof that the Dead Sea has derived its salt from the Mediterranean, it at least destroys the contention that the dissolved constituents of the two seas are so dissimilar that one cannot have been derived from the other.

The Geological Age of the Earth as measured by the Rate of Solvent Denudation.

I now pass to the bearing of the foregoing facts, and others I shall adduce on Prof. Joly's way of deducing the age of the earth since the first ocean was formed. The method may be thus briefly put :—

$$\frac{NaCl + NaNO_3 + Na_2SO_4 \text{ in the seas}}{\text{Annual addition of } NaCl + NaNO_3 + Na_2SO_4 \text{ by rivers}} = \text{Age of the earth,}$$

or more particularly the sodium contents of the seas divided by the sum of the annual sodium increments furnished by the affluent rivers equals the geological age of the earth.

There can be no mathematical precision in any method for getting at the age of the earth, and notwithstanding the marked circumspection shown by Prof. Joly in dealing with the facts available to him, this latest method of attacking the problem appears no more precise than the rest.

If we take the numerator to be approximately correct, the degree of accuracy attainable will depend upon the reliability of the denominator, and to this question my attention will be solely directed.

It is assumed in the first place that the solvent denudation which yields the annual load of combined sodium to the seas has been uniform in its action from the first. Now as a chemist I have tried to picture to myself the condition of things immediately before and after the "consistentior status," when the cooling globe allowed of the condensation of aqueous vapour to form the first ocean.

Oxides of the alkalis and alkaline earths, silicated and otherwise, would exist among the first compounds; hydrochloric acid would admittedly be another, and as the temperature gradually lowered their incompatibility would result in the production of silica, aqueous vapour, and salts like sodium chloride.

There is no more remarkable fact than the thoroughness with which hot water takes up chlorides from a hot surface with which it is in contact or prevents their deposition. I need only instance the formation of boiler scale. The boiler water increases the amount of its chlorides in solution so regularly with the amount of evaporation that it has been made the basis of a technical method, now often used, for finding the evaporative power of coal; the boiler scale contains only the minutest trace of chlorides.

I imagine, then, that the seething Archæan Sea would dissolve all soluble chlorides from the ocean floor and rocks of those times; and as the deliquescent salts appeared on new land surface they would be washed away by every shower, so that to all intents and purposes "the sea was salt from the first." My ideas here run somewhat parallel to those of Prof. W. J. Sollas, who in his able address to the Geological Section of the British Association at Bradford, observes :—"The ocean when first formed would consist of highly heated water, and this, as is well known, is an energetic chemical reagent when brought into contact with silicates like those which formed the primitive crust. As a result of its action saline solutions and chemical deposits would be formed; the latter, however, would probably be of no great thickness, for the time occupied by the ocean in cooling to a temperature not far removed from the present would probably be included within a few hundreds of years" (*B. A. Report*, 1900, p. 716).

This view of things is opposed to uniformity of rate of solvent denudation, and leads to the direct inference that in the later age of the earth such changes are proceeding at a very much slower rate. I see no objection to a varying rate in the facts adduced by Dr. Joly as confirmation of his hypothesis of uniformity from the first. He points out that the sum of the soda now in the ocean and in the sedimentaries would nearly suffice to effect the full restoration of this constituent to the original igneous rock. Such facts are equally in keeping with an unequal distribution of the work of denudation over the period of the earth's age, that it was rapid at first and afterwards slower and slower with the flow of time, and the slower the rate at which one can prove it to be now proceeding, and the more prodigious must have been the initial rate to yield the final colossal sum of oceanic contents.

On the Ratio of Sea-salt to Earth-salt in River-Water.

It will be apparent that if we have to get an idea of the rate at which solvent denudation is now proceeding it will be necessary to find what proportion of earth-salt rivers are carrying to the sea along with the cyclic sea-salt. I have to offer the following attempt at a solution of the problem for the source of the Aire.

A gravimetric analysis of Craven limestone gave 0·01 per cent of chlorine. The water at Malham Cove is 10° of hardness, and contains a total 0·7 part of chlorine per gallon. It is included in that area of equal chlorine figures (Ackroyd, *British Association Report*, 1900, p. 695) where at least in one case, that of Widdop, I have proved all the combined chlorine comes from the rain. Therefore every gallon of water at the Cove contains :—

	Grains.
Calcium carbonate	10·000
Chlorine in earth-salt	0·001
Chlorine in sea-salt	0·699

or of the load of salt carried to the sea fully 99·8 per cent is sea-salt, and only less than 0·2 per cent earth-salt, or that part which is to be taken into account in ascertaining the rate of solvent denudation now in progress, and even this is cyclic in a sense as it comes from a carboniferous and goes back to a present day sea.

How does this result square with other facts? Lawes, Gilbert, and Warington (*Trans. Chem. Soc.*, vol. li., p. 94), have shown that the amount of chlorides in drainage from drain-gauges in unmanured land and uncropped soil is almost exactly equal to that contained in the rain. In other words, they were unable to estimate the amount of earth-salt, it was so small. Again, in chalk, granite, sandstone, and other rocks, the sodium chloride is so inconsiderable a trifle as to find no place in recorded analyses. It is improbable, then, that after extended investigations, an average of 1 per cent of the sodium carried to the sea as chlorides, &c., will ever be found as the result of solvent denudation, and consequently that Prof. Joly's 90 millions of years estimate of the age of the earth based on uniformity of action, and a deduction of 10 per cent for cyclic

sea-salt, would become 8000 millions of years, a quantity of time which I imagine will be too excessive even for the exorbitant demands of the biologists.

Seasonal Variation of Salt Circulation.

In all such problems again seasonal variation of fluviatile salt load must also be taken into account. It has a tendency to average itself where large volumes of water are concerned; thus, in the hundreds of samples analysed from the source of the Aire during our investigations of the underground waters, there has been no noticeable variation from normal; these, however, have only been summer experiments. There must be variations due to periods of excessive evaporation and of storm. The summation of such effects is shown strikingly in the case of the Nile. Wanklyn ("Water Analysis," Sixth Edition, p. 151), in 1874 and 1875 obtained the following chlorine figures for this river:—

	Parts per 100,000.
1874, June 8	2·5
July 9	1·3
August 12	0·4
September 20..	0·5
October 12	0·5
November 12	0·7
December 12	0·6
1875, April	1·4
May 13	1·7

Similar observations are wanted for all the rivers of the world.

Conclusion.

To sum up, then, salt circulation in nature forms an important and up to now inadequately realised phenomenon. In the solvent denudation method of arriving at the age of the earth too little allowance has been made for the mass of sodium chloride carried by the rivers which has been derived from the ocean by atmospheric transportation, and consequently too high a figure (viz., 5·73 parts per million, which is the equivalent of 0·88 part of chlorine per 100,000), has been adopted for the variable proportion of sodium derived from the earth. But although little satisfaction may be derived from numerical results obtained by this in common with other methods, they are at least welcome in that we are led to garner and make use of an abundance of facts which lie to hand and only need the trouble of reaping.

SATURATED LIME-WATER FOR THE PRESERVATION OF EGGS.

By FRANK T. SHUTT, M.A.,
Chemist, Dominion Experimental Farms.

THE solubility of lime in water at ordinary temperatures is 1 part in 700 parts of water. Such a solution would be termed saturated lime-water. Translated into pounds and gallons this means 1 lb. of lime is sufficient to saturate 70 gallons of water. However, owing to impurities in commercial lime, it is well to use more than is called for in this statement. It may not, however, be necessary if good, freshly burnt quicklime can be obtained, to employ as much as was at first recommended, namely, 2 to 3 lbs. to 5 gallons of water. With such lime as is here referred to one could rest assured that 1 lb. to 5 gallons (50 lbs.) would be ample, and that the resulting lime-water would be thoroughly saturated. The method of preparation is simply to slake the lime with a small quantity of water, and then stir the milk of lime so formed into the 5 gallons of water. After the mixture has been kept well stirred for a few hours it is allowed to settle. The supernatant liquid, which is now "saturated" lime-water, is drawn off, and poured over the eggs previously placed in a crock or water-tight barrel.

As exposure to the air tends to precipitate the lime (as carbonate), and thus to weaken the solution, the vessel containing the eggs should be kept covered. The air may be excluded by a covering of sweet oil, or by sacking upon which a paste of lime is spread. If after a time there is any noticeable precipitation of the lime the lime-water should be drawn or syphoned off and replaced with a further quantity newly prepared.

It is essential that attention be paid to the following points:—

1. That perfectly fresh eggs only be used.

2. That the eggs should throughout the whole period of preservation be completely immersed.

Although not necessary to the preservation of the eggs in a sound condition, a temperature of 40° to 45° F. will no doubt materially assist towards retaining good flavour, or rather in arresting that "stale" flavour so characteristic of packed eggs.

Respecting the addition of salt, it must be stated that our experiments—conducted now throughout three seasons—do not show any benefit to be derived therefrom; indeed, salt appears to impart a limey flavour to the egg, probably by inducing an interchange of the fluids within and without the egg.

Water-glass (sodium silicate), has been extensively experimented with, using solutions varying from 2 to 10 per cent. Although in the main the results have been fairly satisfactory, we are of the opinion that lime-water is fully its equal, if not its superior, as a preservative, and that this latter preservative is both cheaper and pleasanter to use there can be no doubt.

ON THE USE OF PERMANGANATE OF POTASH IN DYEING.

By G. SAGET.

PERMANGANATE of potash can be used in dyeing for obtaining light bistre or tawny tints. Its oxidising action is utilised for destroying any given background by the production of peroxide of manganese in the body of the fibre.

The backgrounds obtained with a tannin material and a metallic salt are very easily destroyed, and the bistre tint is obtained with great facility.

Tannins generally have a very good action on cotton fabrics, the final tint obtained being very regular; this latter varies according to the quantity of tannin used, and therefore an excess of permanganate need not be feared.

The reduction of the permanganate takes place very rapidly in the cold; any increase of temperature must be avoided or the permanganate will be reduced by the cellulose, and the tint will not be uniform, as it varies with the temperature.

Chestnut-brown and iron are particularly useful in obtaining unbleached tints. If, for example, we apply extract of chestnut, then pyrolignite of iron, and, after a sufficient time wash, and pass the material through a cold dilute solution of permanganate of potash, at the end of a quarter of an hour the brown colour will have entirely disappeared and given place to an unbleached tint, which will be the deeper as the original brown was the more intense.

Extract of yellow wood, cachou, &c., may be used instead of extract of chestnut, but the tints obtained will be practically the same.

Other metallic fixers of tannin may be used instead of iron; with antimony we obtain a less reddish tint than with iron. In the case of this latter, ferric oxide is formed, which adds its colour to that of the peroxide of manganese.

The tannates of lead, copper, chromium, alumina, manganese, &c., give the same results.

The salts of manganese and lead give deeper shades than those of the other metals. This is due to the fact

that peroxides of manganese and lead are formed, the deep colours of which are added to that of the manganic oxide resulting from the reduction of the permanganate.

The colourless, or slightly coloured oxides, like those of antimony, alumina, and chromium, give the palest tints; this, of course it must be understood, is when using the same quantities of tannin and permanganate, and equivalent amounts of the metallic salts.

The metallic salts which give the best results are those which most effectually fix the tannin, and among these are the acetates.

Putty-colour tints, obtained by the oxidation of the tannins by means of the bichromates alone or with the addition of salts of copper, also reduce permanganate; in this manner we obtain a light brown colour, appearing yellowish by reflected light.

Plumbite of lime fixed on the fibre also reduces permanganate of potash, a maroon colour looking red by reflected light is obtained; this is formed by a mixture of peroxides of lead and manganese.

The tints obtained as above strongly resist the action of hypochlorites. When immersed in "javelle" water the tint does not change. Boiling soap degrades and tarnishes the colour.

Sunlight has a very rapid action on these colours; after two hours' exposure to the summer sun the tint becomes decidedly paler; treatment with chlorine will revive it. Oxycellulose is not formed by this reduction in the sun. It is nevertheless possible to give greater permanence under the action of light to tints obtained as above described.

Treatment in a soda-salt at 60° for half an hour does not change the shade, but it will then resist the action of sunlight very well. When boiled, the soda-salt fades the tint to a slight extent, without making it any more permanent than when treated at 60°. The same can be said with regard to treatment in the cold by hypochlorite of lime at ½° Baumé, followed by thorough rinsing.

Ferric nitrate also gives greater permanence, under the action of light, to tints obtained with manganese, but the shade becomes a little more yellow. This last treatment also enables the colour to resist the action of soap better. Steaming, with or without pressure, degrades the tint considerably, and it cannot then be revived by chlorine.

Acids, even when dilute, soon cause the colour to disappear; when placed in citric acid at 1 per cent a sample became quite white in half an hour.

Bisulphite of soda instantly bleaches bistre, leaving the tissue perfectly white. The same is the case with mineral and organic reducing agents.

When applied to oiled tissues these neutral tints are much more permanent, especially if care be taken to treat them with soap at 60° after the washings which follow the treatment with permanganate of potash. Their resistance to light is good, and steaming, which has no effect on the colour, gives it more stability with acids.

Tissues may be prepared with oil for a reddish colour, or the oil may be added to the tannin material made alkaline with ammonia. In this case the pieces must be dried before passing them through the metallic bath.

With oil, the shade is greyer than with ordinary tissues, and approaches the colour of otter fur. Soap still slightly degrades the colour, but when once soaped and steamed without pressure, its resistance may be looked upon as sufficient.

Alumina increases the resistance of tints formed by tannate of iron oxidised by permanganate of potash to dilute acids; and in the same way a shade obtained with manganese and acetate of alumina, and then dried and steamed without pressure, hardly changes at all in a solution of 1 per cent citric acid. Its resistance to soap is fairly good, but in sunlight it fades rapidly.

The drying with an aluminium salt produces a yellowish tone, which disappears again on steaming.

On the other hand, the tint produced by fixing the tannin with an aluminium salt, and then, after oxidation in permanganate, treating with acetate of iron, drying, and steaming without pressure, does not resist the action of soap, hypochlorites, dilute acids, or light. It is just the same if, instead of using an aluminium salt for fixing the tannin, we use a salt of antimony.

Binoxide of manganese fixed on the tissue, as we have shown above, may serve as a mordant for various colouring materials, and at the same time as an oxidising agent for certain aromatic amines.—*Moniteur Scientifique*, Series 4, vol. xv., p. 319.

THE LITERATURE OF ALCHEMY.*

By HENRY CARRINGTON BOLTON.

(Continued from p. 262).

The Greek manuscripts of the eleventh to the fourteenth centuries, collected, translated, and edited by Berthelot, vary in length from fragments of a few lines to essays of many pages; all are written in an archaic, enigmatical style puzzling to decipher; names of mythical personages, chemical expressions of obscure meaning, magical formulas, astrological computations, are mixed in singular confusion with allusions to a long forgotten, mystical philosophy. Commentators on these writings of the "Sacred art" early felt the need of lexicons and compiled vocabularies professing to throw light on them, but their definitions are no clearer than the words defined; one word was used for a score of different articles, and a single object or process was known by a dozen different names. Of scientifically classified knowledge there is no trace, the alleged opinions of fabulous writers are given as authoritative, and information is imparted in the tedious form of dialogues. Many of the writings contain reverent acknowledgment of the Deity and other evidences of piety.

The titles of a few of these MSS. will give an idea of the nature of the literature at this period.

"The Chemistry of Moses."
"Letter of Isis to her son Horus."
"Cleopatra on the art of making Gold."
"The divine Zosimus on Virtue."
"Zosimus on Furnaces and Apparatus."
"The Whitening of Arsenic."
"The Practical Treatise of the Emperor Justinian."

The authors of these essays are unknown, and they are practically a farrago of nonsense.

The most ancient Latin treatises on alchemy date from the eighth to the tenth century; they are really collections of recipes for industrial processes and metallurgical operations, but include formulas for the manufacture of gold, and for "multiplying" the precious metal, resembling those of the Greco-Egyptian papyri. The readers are cautioned not to reveal the secrets and are instructed in the use of appropriate incantations. The manuscripts of these Latin writings are seldom met with, but they were printed in several great collections published in the seventeenth and eighteenth centuries; the most notable of these were the "Aureum Vellus" (Basel, 1599); "Artis Auriferæ" (Basel, 1572), containing 34 treatises; "Theatrum Chemicum," published by Lazarus Zetzner (Strassburg, 1613—22, 5 vols.; second edition, 1659—61, 6 vols., containing 149 titles); "Bibliotheca Chemica Curiosa," edited by J. J. Manget (Geneva, 1702), containing 133 titles.

More than half a century elapsed after the invention of printing before the subject of alchemy occupied the press, but in the sixteenth and seventeenth centuries thousands of works printed in every country of Europe supplied the universal demand for a literature that revealed secrets enriching and exalting its fortunate possessors. The most highly revered treatises were those ascribed to mythical Egyptians, to Old Testament Hebrews, to Arabian physicians, and to Greek philosophers; and at a later period the most popular works were those written by certain dignitaries of the Church. The genuineness of the trea-

* From the *Pharmaceutical Review*, vol. xix., Nos. 4 and 5.

tises was not questioned, and the fact that their teachings were contrary to reason did not diminish their popularity.

In the sixteenth century the favourite authors were Roger Bacon, an English Franciscan, Albertus Magnus, a German Dominican, Raymond Lully, a Spanish Minorite, and Basil Valentine, a German Benedictine; somewhat later the hermetical writings of that bombastic Swiss physician Paracelsus were much in demand, and following him there came a host of lesser lights whose names are quite unknown outside of this contracted field.

A prominent feature in alchemical literature is the bold claim of fabulous antiquity for the art; this has been referred to in speaking of fictitious authorship, and may well be illustrated by citing the famous "Tabula Smaragdina"; its story runs thus:—

Hermes Trismegistus, who is identified with Canaan, the grandson of Noah, was perfectly acquainted with the Philosophers' Stone, and wishing to transmit the knowledge to posterity had the secret of its preparation engraved on a tablet made of a huge emerald, and had it placed in his sarcophagus. Many years afterwards it was removed by Sarah, the wife of Abraham, and concealed in a cave near Hebron; there it remained until again discovered by Alexander the Great. The inscription reads as follows:—

"I speak not fictitious things but that which is most true and certain. Whatsoever is below is like that which is above, and that which is above is like that which is below, to accomplish the miracles of one thing. Also since all things were made from one by the help of one, so all things are made from one thing by conjunction.

"The Father thereof is the sun, and the Mother thereof is the moon; the wind carries it in its belly, and the nurse thereof is the earth. This is the foundation of all wisdom, and its power is perfect if it be changed into earth.

. . . . .

"This thing has more fortitude than fortitude itself; because it will overcome every subtile thing and penetrate every solid thing. By it this world was formed. Hence proceed wonderful things which in this wise were established.

"For this reason I am called HERMES TRISMEGISTUS, because I possess three parts of the philosophy of the whole world.

"What I had to say about the work of the sun is completed."

The first appearance of this phantasy is not certain; some claim it is found in a work by Albertus Magnus, others trace it back to Hortulanus in the eleventh century; it was certainly known to Raymond Lully.

Pretentions to even greater antiquity were made by the anonymous author of "Gloria Mundi," in which we find the chemical notions of Aristotle, Plato, and Socrates, interspersed with statements by Hermes and Morien, Lamech and Methuselah, Abel and Seth, and even of Adam himself.

The presence of Saccharose in Panama Wood.—G. Meilliere.—The presence of a hydrate of carbon has been observed several times in Panama wood (*Quillaja smegmadernos*). Up to the present it has been thought that this sugar was identical with the lactosine isolated from various caryophylls by A. Meyer. When the sugar from Panama wood is purified by means of a large number of crystallisations and by dialysis, it loses the property of frothing which was evidently due to the presence of a small quantity of saponine. The carbohydrate thus prepared has all the physical and chemical properties of saccharose. Without wishing to deny the possible existence of Meyer's lactosine in certain saponine plants, the author is of the opinion that the lactosine from Panama wood is nothing else but saccharose contaminated with saponine.—*Bull. Soc. Chim.*, Series 3, vol. xxv., No. 2.

ON THE RESULTS OF A SEARCH FOR OTHER SUGARS THAN XYLOSE AND DEXTROSE IN THE PRODUCTS OF THE HYDROLYSIS OF WOOD FROM THE TRUNKS OF TREES.*

By F. H. STORER, Professor of Agricultural Chemistry.

(Continued from p. 258).

C. *Acid Hydrolysis of Wood from the Trunk of a Birch Tree* (*Betula populifolia of Aiton*).—The wood submitted to examination was the outer part of the trunk of a grey birch tree four inches in diameter that had been felled in the month of October. After the outer and inner bark had been removed, that portion of the outer wood which lay between the bark and a circle drawn half an inch inward from the bark was split off, and ground to a fine powder. Ten grms. of this powder were soaked in 200 c.c. of strong ammonia water for twenty-four hours to remove colouring matters and albumenoids, and the excess of ammonia was removed by washing. The wood was then mixed with 200 c.c. of hydrochloric acid of 3 per cent, and boiled for three hours, over a free flame, in a flask provided with a reflux condenser. One half of the filtrate from the wood thus treated was neutralised with sodium hydroxide, evaporated, decolorised with bone-black, and tested. It gave quasi-$[\alpha]_D = 62{\cdot}85°$ and 19·8 per cent of "sugar," calculated as dextrose on the wood dried at 100° C.

On evaporating the solution to dryness, and treating the dry mass with cold, strong alcohol, there was obtained a residue which gave quasi-$[\alpha]_D = 76{\cdot}81°$, while the portion soluble in alcohol gave quasi-$[\alpha]_D = 24{\cdot}52°$; both observations being made, of course, upon aqueous solutions after the alcohol had been driven off—the references are to dextrose. It is evident that the matter insoluble in alcohol contains some substance of higher rotatory power than dextrose, while as regards the portion soluble in alcohol it is to be inferred that it contained much xylose, the true specific rotation of which is $[\alpha]_D = 19{\cdot}2°$. Calculated as dextrose, the matter insoluble in alcohol amounted to 4·65 per cent of the dry birch wood, and the sugar soluble in alcohol to 12·54 per cent.

The second half of the filtrate, from the three hours' boiling with hydrochloric acid of 3 per cent, was now boiled three hours longer, and neutralised and decolorised as before. It gave quasi-$[\alpha]_D = 40{\cdot}54°$, and "dextrose" amounting to 9·97 per cent of the dry wood, showing that in the absence of wood some of the products of the first hydrolysis were readily destroyed by the hot dilute acid.

On evaporating this solution to dryness and treating the residue with cold, strong alcohol, the matter less soluble in alcohol gave quasi-$[\alpha]_D = 42{\cdot}27°$, and the readily soluble portion gave quasi-$[\alpha]_D = 22{\cdot}17°$.

The residual cellulose from the wood which had been boiled with 3 per cent hydrochloric acid was washed and allowed to dry in the air; it was then left to soak for twenty-four hours in 100 c.c. of hydrochloric acid of 35 per cent, and the mixture was poured into enough boiling water to reduce the acid to the strength of 3 per cent. The mixture was boiled during three hours over a free flame, as before. Evidently the strong hydrochloric acid had but little action upon the wood.

One half of the filtrate was neutralised with sodium hydroxide, evaporated, and decolorised. It gave quasi-$[\alpha]_D = 85{\cdot}7°$, and dextrose equal to 0·98 per cent of the dry residue, or to 0·78 per cent of the dry wood. It is to be remarked, however, that this observation is of little or no value, because the solution was extremely dilute. It contained absolutely too little sugar to admit of a satisfactory examination. Nevertheless, it was evaporated to dryness, and treated with cold, strong alcohol. The portion soluble in alcohol gave quasi-$[\alpha]_D = 53{\cdot}34°$.

* *Bulletin of the Bussey Institution*, 1900, vol. ii., Part 9.

The second half of the filtrate, obtained after soaking in strong hydrochloric acid, and subsequently boiling in this acid diluted to 3 per cent, was boiled three hours longer, but so little sugar was contained in the liquid that no tests could be made. It is noticeable that hydrochloric acid of 35 per cent has no such power to break up the cellulose in wood as is exhibited constantly by strong sulphuric acid.

The residual wood left after the treatment with strong hydrochloric acid, and subsequent boiling with the 3 per cent acid, was mixed thoroughly with 10 c.c. of strong sulphuric acid (90 per cent H_2SO_4), and left at rest for twenty-four hours. The black, pasty mass was poured into enough boiling water to reduce the strength of the acid to 3·5 per cent, and the mixture was boiled for three hours. The filtered solution was neutralised with calcium carbonate and tested. It did not need to be decolorised. It gave quasi-$[\alpha]_D = 92°9'$, and 23·72 per cent of sugar, calculated as dextrose on the dry residue—or 18·83 per cent calculated on the dry wood. When this solution was evaporated and treated with cold, strong alcohol, the matter left undissolved gave quasi-$[\alpha]_D = 71°60'$, and the portion soluble in alcohol gave quasi-$[\alpha]_D = 54°93'$. On again evaporating the aqueous solution of the matter not dissolved by alcohol, and treating the new residue with cold, strong alcohol—in order to dissolve out as much dextrose as might be possible—there was obtained a new fraction insoluble in alcohol which, on being dissolved in water, gave quasi-$[\alpha]_D = 85°88'$. There was not enough matter dissolved by the alcohol to admit of any critical examination, but the solution was set aside to evaporate, and after six months it was noticed that the solid residue had segregated in the form of isolated tufts or balls (presumably of dextrose), rising from the centres of thin, star-like radiations of crystals.

The second half of the filtrate from the hydrolysis with sulphuric acid of 3 per cent (after the action of strong sulphuric acid) was boiled three hours longer, and examined as before. It did not need to be decolorised. That it had suffered considerable alteration was shown by the fact that it now gave quasi-$[\alpha]_D = 64°49'$, and 28·27 per cent of dextrose calculated on the dry residue, or 22·45 per cent calculated on the dry wood. After evaporating to dryness, and treating with cold, strong alcohol, the matter not readily dissolved in this liquid gave quasi-$[\alpha]_D = 58°66'$, while the portion soluble in alcohol gave quasi-$[\alpha]_D = 49°85'$, both calculated as dextrose.

It should be said that most of these experiments with birch wood were made before those upon maple wood, as reported above. It is evident enough that beside xylose and dextrose some other substance of higher rotatory power than dextrose is produced when birch wood is boiled with acids under the conditions here described.

(To be continued).

A NEW COLOUR REACTION FOR AMYGDALIN.

By E. R. DEACON.

During some experiments I was conducting recently on amygdalin I found that on treating the substance with a few drops of concentrated sulphuric acid a bright carmine colour was developed, which was discharged on pouring into water.

I cannot find this reaction mentioned in the books, and the above colour reaction may interest your readers.

Two samples of amygdalin from presumably different sources gave the same characteristic colour.

Chemical Laboratory,
Technical College, Finsbury, E.C.
June 5th, 1901.

Royal Institution.—A General Monthly Meeting of the Members of the Royal Institution was held on the 3rd inst., Sir James Crichton-Browne, Treasurer and Vice-President, in the Chair. Mr. Henry J. Wood and Mr. John T. Middlemore, M.P., were elected Members.

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Extraordinary General Meeting, May 15th, 1901.

Prof. Emerson Reynolds, Sc.D., F.R.S., President, in the Chair.

The President stated that this Meeting had been convened in accordance with a requisition, signed by sixty-six Fellows of the Society, to consider the decision of the Council to hold the Ordinary Meetings of the Society during the ensuing session on Wednesdays at 5.30 p.m.

After a discussion in which, amongst others, the following Fellows took part, Dr. Lewkowitsch, Dr. Moody, Mr. A. G. Bloxam, Mr. Cassal, Dr. Armstrong, Mr. Hehner, Mr. Tyrer, Mr. Fakes, Prof. Tilden, Prof. Ramsay, Dr. Crossley, Dr. Forster, Prof. Dewar, and Mr. F. J. Lloyd,

Dr. Armstrong moved and Mr. Hehner seconded the following resolution :—

"That in the opinion of this Meeting the change proposed in the day and hour of meeting will prevent the attendance of a large proportion of the junior and other Fellows who have hitherto been regular attendants; that the said change is contrary to the best interests of the Society, and that it is desirable that the question be reconsidered by the Council."

The resolution was declared by the President to be carried. The numbers being asked for, a division was taken, with the following result :—For the resolution, 92; against, 3. A certain number of Fellows abstained from voting.

Ordinary Meeting, May 16th, 1901.

Prof. Emerson Reynolds, Sc.D., F.R.S., President, in the Chair.

Messrs. McKenzie, Ferguson, Woodbridge, Robertson, Jennings, Dodd, Neil, Mees, Wayland, and Dixon were formally admitted Fellows of the Society.

The following certificates were read for the first time:—Hubert Haigh Barker, 3, Waverley Place, St. John's Wood, N.W.; George Dean, 2, Scriven Grove, Knaresborough; Thomas Henry James Eling, 32, Hill Top Avenue, Shepherd's Lane, Leeds; Edward Kenneth Hanson, Hadley Wood, N.; Frederick Thomas Harry, 106, Sandmere Road, Clapham, S.W.; Edward Horton, 8, Orford Street, Chelsea, S.W.; Christopher George Kiddell, 24, Queen's Gardens, Muswell Hill, N.; Robert Tabor Lattey, Trinity College, Oxford; F. G. Macdonald, Government Laboratory, Durban; Frank Oram, Market Place, Romsey; John Edward Purvis, University Chemical Laboratory, Cambridge; Gerald Theodore Sylvester Sichel, R.N. Hospital, Haslar, Gosport; Duncan Randolph Wilson, Magdalen College, Oxford.

The President read the resolution passed at the Extraordinary General Meeting, which, he stated, had been that afternoon brought before the Council, by whom it was being carefully considered.

Dr. Armstrong, referring to the ruling given by the President at the previous meeting, that a paper read in the absence of the author could not be discussed, drew attention to By-law XIV., and contended that this By-law expressly provided that every paper communicated to the Society should be open to discussion. He stated that during the whole course of his experience, extending over thirty years, it had always been the practice of the Society, when the occasion arose, to discuss papers read in the absence of their authors.

Dr. PERKIN, in reply to a question by Dr. Armstrong, said that in the past papers had often been discussed in the absence of their authors.

Dr. DIVERS said that having been resident in Japan when most of his papers were sent to the Society, he had always been willing that they should be discussed.

Prof. DUNSTAN pointed out that By-law XIV. evidently supposed that authors would be present to read their papers, and its directions could not be literally followed at the present time. In these matters, however, the By-law gave large discretion to the Chairman.

Mr. W. P. BLOXAM asked whether it was within the power of the President to closure or prevent discussion on any paper read to the Society.

The PRESIDENT replied that, as a general rule, he should not think of doing so.

Mr. BLOXAM remarked that probably Dr. Armstrong would recollect when he read a paper on ammonium sulphides, Dr. Armstrong, as President, had prevented any discussion whatever on that paper.

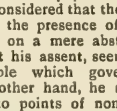
The PRESIDENT considered that the By-law read by Dr. Armstrong assumed the presence of the author at the meeting. Criticism on a mere abstract in the author's absence, and without his assent, seemed contrary to the fair general principle which governed most public meetings. On the other hand, he saw no objection to questions relating to points of nomenclature or detail which could be elucidated by reference to the original paper, should the latter be available at the time.

Dr. ARMSTRONG said that such being the President's opinion, and as he could not accept the ruling as correct, it would be necessary for him to raise the question again elsewhere.

Of the following papers, those marked * were read:—

*78. "*Derivatives of Methylfurfural.*" By H. J. H. FENTON and Miss M. GOSTLING.

The authors have already (*Trans.*, 1898, lxxiii., 554; 1899, lxxv., 423; 1901, lxxix., 361) described the isolation, properties, and constitution of bromomethylfurfural,—



a well-defined crystalline substance, melting at 60°, which gives rise to remarkable colour reactions. Because of the interest which attaches to this compound, owing to its relations with the carbohydrates and the bearing of its formation on questions in plant physiology, it was considered desirable to make a further study of the compound and its derivatives. The following new compounds were described:—

Chloromethylfurfural, m. p. 36—37°; *acetoxy*-derivative, m. p. 55°; *benzoxy*-derivative, m. p. 56—57°; *difurfurylethane-dialdehyde*, m. p. 119—120°; with its corresponding *dihydrazone*, m. p. 179—181°; *dicarboxylic acid*, m. p. 267—269°; and *dioxime*, m. p. 182°. A very simple method of obtaining pure methylfurfural was also described.

DISCUSSION.

Mr. W. J. POPE asked whether bromomethylfurfural, which contains a bromine atom and an ethereal oxygen atom attached to adjacent carbon atoms, was capable of condensing with alkyl sulphides or tertiary amines to yield sulphonium or quaternary ammonium derivatives.

Mr. FENTON, in reply, said that both the chloro- and the bromo-derivatives of methylfurfural readily interacted with various amines.

*79. "*Optically Active Nitrogen Compounds and their Bearing on the Valency of Nitrogen; Dextro- and Lævo-α-benzylphenylallylmethylammonium Salts.*" By W. J. POPE and A. W. HARVEY.

The authors have prepared in a state of purity a number of substances owing their optical activity to the presence of an asymmetric pentad nitrogen atom.

The externally compensated α-benzylphenylallylmethylammonium iodide of Wedekind, when treated with silver *d*-camphorsulphonate, yields *d*-benzylphenylallylmethylammonium *d*-camphorsulphonate, which melts at 171—173° and has the molecular rotation $[M]_D = +218{\cdot}1°$ in an aqueous solution containing one-fifth of a grm.-molecule per litre; whence the value for the *d*-benzylphenylallylmethylammonium ion is $[M]_D = +166{\cdot}4°$. The residue from the preparation of this salt, when treated in aqueous solution with potassium iodide, yields crude *l*-benzylphenylallylmethylammonium iodide, which, on treatment with silver *l*-camphorsulphonate, gives the new salt *l*-*benzylphenylallylmethylammonium l-camphorsulphonate*. This melts at 171—173°, and has the molecular rotation $[M]_D = -210{\cdot}6°$ in an aqueous solution containing one-fourth of a grm.-molecule per litre; the molecular rotation $[M]_D = -159{\cdot}0°$, is thence deduced for the ion of the *l*-base.

These salts, when treated with potassium iodide in aqueous solution, give crystalline precipitates of the corresponding iodides which may be crystallised from alcohol without undergoing inversion; they are soluble in cold chloroform, and in this solvent have the specific rotations $[\alpha]_D = +55{\cdot}2°$ and $[\alpha]_D = -53{\cdot}4°$ respectively. On warming the chloroform solutions, the rotation rapidly vanishes, and a similar result is attained on allowing the cold chloroform solutions to stand for three days; the solutions on evaporation yield the externally compensated iodide in a state of purity, so that the inversion may be attributed to a dissociation into tertiary base and benzyl iodide.

The bromides are prepared in a similar manner and have the specific rotations $[\alpha]_D = +64{\cdot}1°$ and $[\alpha]_D = -65{\cdot}0°$ respectively in cold chloroform; the salts undergo inversion in chloroform, just as the iodides do, although appreciably less rapidly.

d-*Benzylphenylallylmethylammonium nitrate*,—

$$C_7H_7{\cdot}N(C_6H_5)(C_3H_5)(CH_3)NO_3,$$

is a colourless crystalline substance melting at 164—165°, and in aqueous solution has the molecular rotation $[M]_D = +165{\cdot}3°$, a value comparing well with that of the ion of the *d*-base deduced from the examination of the *d*-camphorsulphonate.

d-*Benzylphenylallylmethylammonium mercuri-iodide*, $C_7H_7{\cdot}N(C_6H_5)(C_3H_5)(CH_3)I,HgI_2$, is obtained as a bright yellow crystalline compound by heating the pure *d*-iodide with one equivalent of mercuric iodide in ethyl acetate solution; it melts at 125—127°, and has the specific rotation $[\alpha]_D = +24{\cdot}4°$ in ethyl acetate solution. The enantiomorphously related salt also melts at 125—127°, and has the specific rotation $[\alpha]_D = -23{\cdot}0°$ in ethyl acetate. It is concluded that these mercuri-iodides contain quinquevalent nitrogen.

Attention was drawn to the persistency of the optical activity of these asymmetric nitrogen compounds except under the specific conditions which cause inversion. It should be noted that these substances are fundamentally distinguished from asymmetric carbon compounds in that they are electrolytes which, in aqueous solution, must be supposed to undergo electrolytic dissociation, giving an optically active ion of which the disrupted valency is one of those attached to the asymmetric atom; yet even under these conditions no inversion takes place.

DISCUSSION.

Dr. ARMSTRONG said that when Messrs. Pope and Peachey first stated that they had succeeded in obtaining optically active nitrogen compounds, he had pointed out that the discovery was of special importance, because it seemed at last to afford a means of deciding the long standing dispute as to the valency of nitrogen in the ammonium compounds. The discovery was not in itself sufficient to disprove the molecular hypothesis advocated by Kekulé, as it was possible to formulate the ammonium

salts as molecular compounds, which it was conceivable might have a tetrahedral configuration. But the subsequent discovery of optically active sulphur compounds by Messrs. Pope and Peachey might be regarded as complete disproof of the molecular compound hypothesis, and it was consequently legitimate to argue that nitrogen acted as a pentad in the ammonium compounds. Nevertheless, there could be little doubt that the "superior" valency assumed by nitrogen in the ammonium compounds and by sulphur in the sulphonium compounds was in some way different in character from the lower or ordinary valency of these elements: that it was a "conditional" valency, as nitrogen became pentad, and sulphur tetrad only under special conditions, and in a very limited number of cases. There could be little doubt that the direction in which valency could act was of importance, and the inquiry into this must play an important part in the future. Reference was made to the behaviour of sulphur in thiophen as affording proof that the superior valency in some way became masked by the inclusion of the sulphur in the ring. The use made by the authors of the behaviour of double mercuric and platinic compounds as arguments against a change in valency was of a most ingenious character, as was also the reference to the evidence afforded by the stability of the active salts against the ionic dissociation hypothesis: the suggestion that a free affinity could not well act "materially," and serve to condition optical activity, was particularly worthy of note.

Dr. Hewitt referred to Mr. Pope's remarks on the fact that the addition of mercuric iodide to optically active quaternary ammonium iodides gives rise to double salts in which the optical activity is preserved, and the conclusion drawn that the valency of nitrogen remains unchanged, and the extension of this argument to the valency of sulphur in the compounds of sulphonium iodides with metallic iodides. He considered it possible that the two active forms of a sulphonium iodide might add on mercuric iodide, the sulphur atom becoming hexavalent, and nevertheless the two resulting octahedral formulæ be related to one another as an object is to its image.

Dr. Forster suggested that the numerical difference between the rotation constants of *d*A*d*B and *l*A*l*B might disappear if *l*A*l*B were separated first, by adding *l*-camphorsulphonate to the racemic mixture, and inquired whether *l*-bromocamphorsulphonic acid would not be a useful substitute for *l*-camphorsulphonic acid. He questioned whether racemisation of the active ammonium iodide is due to dissociation on the lines indicated by Mr. Pope, pointing out that addition of ammonia should accelerate the change. Referring to the principle that a change of valency involves an alteration in the original valency directions, he wished to know why, if divalent sulphur forming part of a ring is prevented from becoming tetravalent on account of this principle, nitrogen does not lie under the same disability.

Dr. H. McKenzie asked whether Mr. Pope had had occasion to confirm Le Bel's resolution of inactive methylethylpropylisobutylammonium chloride by means of *Penicillium glaucum*; and, further, whether he had attempted to resolve Le Bel's substance by aid of an optically active acid, such as α-bromocamphorsulphonic acid.

Dr. Morgan, in supporting the view that the nitrogen in the ring systems of the pyridine and acridine types is generally capable of assuming the quinquevalent condition, recalled the fact that naphthacridine readily combines with alkyl iodides, yielding quaternary iodides so stable that they can be crystallised from hot aniline without decomposition, indicating thereby that the cyclic nitrogen is able to maintain its quinquevalency, even in the presence of an amine containing a nitrogen atom free from constraint as regards the direction of its linkings.

Mr. W. J. Pope, in reply, observed that the new principle brought forward, namely, that during change of valency of an atom the valency directions might also change, appeared to be applicable when a bi- or quadrivalent sulphur atom became quadri- or sexa-valent respectively, or when a quinquevalent nitrogen atom became septavalent; it is not necessarily applicable to the case of a tervalent nitrogen becoming quinquevalent because such a change might be effected by the two fresh groups attaching themselves to the nitrogen atom along a direction perpendicular to the plane containing the original three groups. The principle derived support from the fact that bivalent sulphur contained in a closed ring, and consequently restrained from altering its environment, cannot be caused to combine with alkyl iodides, and become quadrivalent; the *n*-alkyl derivatives of piperidine and tetrahydroquinoline, on the other hand, combine with alkyl iodides at least as readily as do tertiary bases in which the nitrogen atom is not contained in a closed ring. *d*-Benzylphenylallylmethylammonium iodide undergoes inversion in chloroform solution about twice as rapidly as the corresponding bromide, but no experiments have yet been made with other salts. It is not immediately apparent how the inversion of optically active stannomethyl derivatives can be caused by dissociation, but the inversion is possibly due to dissociation of the stannic compound into a stannous compound and an alkyl salt.

*80. "*Reactions of Hydroxyoxamides.*" By R. H. Pickard and W. Carter.

Hydroxyoxamide and its mono-phenyl, *p*-tolyl, α- and β-naphthyl-derivatives, $RNH{\cdot}CO{\cdot}CONHOH$, react as hydroxamic acids. The general reactions of hydroxamic acids (Thiele and Pickard, *Ann.*, 1899, cccix., 189), can be carried out with these compounds, giving quantitative yields of substituted biurets, carbonyl di-carbamids, and allophanates.

The monosubstituted phenyl-, *p*-tolyl-, α-, and β-naphthyl-biurets, analogously substituted ethyl allophanates, and the *sym*-disubstituted carbonyl di-carbamides, $CO(NHCONHR)_2$, were described.

The acetate of oxalodihydroxamic acid described by Hantzsch (*Ber.*, 1894, xxvii., 801), is apparently a diacetate; it is acid in properties, and dissolves in a solution of sodium carbonate, giving a solution which, after warming, contains small quantities of hydrazine.

*81. "*The* sym*-Trichlorobromoanilines; and Chloro- and Bromoamino-derivatives of Chlorobromoacetanilides.*" By F. D. Chattaway and K. J. P. Orton.

The authors called attention to the great resemblance existing between the two similarly constituted *sym*-chlorodibromoanilines and their acetyl derivatives respectively. There is a similar resemblance between the two *sym*-dichlorobromoanilines. The acetylchloroamino-derivatives, however, serve to distinguish the one isomeric aniline from the other, as they possess melting points lying several degrees apart.

The following compounds have been prepared:—*4-Chloro-2:6-dibromoaniline*, $C_6H_2ClBr_2{\cdot}NH_2$ (first prepared by Hofmann, *Ann.*, 1845, liii., 38), needles, melting at 97° (Hofmann does not record the melting point), and boiling at 301° under 760 m.m. pressure; *4-chloro-2:6-dibromoacetanilide*, $C_6H_2ClBr_2{\cdot}NHAc$, flattened prisms or needles, melting at 226—227°; *acetylchloroamino-4-chloro-2:6-dibromobenzene*, $C_6H_2ClBr_2{\cdot}NClAc$, short, four-sided prisms melting at 110—111°; *2-chloro-4:6-dibromoaniline*, $C_6H_2ClBr_2{\cdot}NH_2$ (first prepared by Langer, *Ann.*, 1882, ccxv., 115), needles, closely resembling the isomeric aniline, and melting at 95°; *2-chloro-4:6-dibromoacetanilide*, $C_6H_2ClBr_2{\cdot}NHAc$, flattened prisms or needles, melting at 227°; *acetylchloroamino-2-chloro-4:6-dibromobenzene*, $C_6H_2ClBr_2{\cdot}NClAc$, four-sided prisms, melting at 99—100°; *2:6-dichloro-4-bromoaniline*, $C_6H_2Cl_2Br{\cdot}NH_2$ (first prepared by Fittig and Büchner, *Ann.*, 1877, clxxxviii., 22), needles, melting at 92° (Fittig and Büchner give 93·5°); *2:6-dichloro-4-bromoacetanilide*, $C_6H_2Cl_2Br{\cdot}NHAc$, flattened prisms or needles, melting at 214°; *acetyl chloroamino-2:6-dichloro-4-bromobenzene*, $C_6H_2Cl_2Br{\cdot}NClAc$, prisms melting at 81°; *2:4-dichloro-6-bromoaniline*,

$C_6H_2Cl_2Br{\cdot}NH_2$, needles melting at 83·5°; 2 : 4-*dichloro*-6-*bromoacetanilide*, $C_6H_2Cl_2Br{\cdot}NHAc$, flattened prisms or needles melting at 218°; *acetylchloroamino*-2 : 4-*dichloro*-6-*bromobenzene*, $C_6H_2Cl_2Br{\cdot}NClAc$, four-sided prisms melting at 91—92°; 2 : 6 - *dibromoacetanilide*, $C_6H_3Br_2{\cdot}NHAc$, prisms melting at 208—209°; *acetylchloroamino*-2 : 6 *dibromobenzene*, $C_6H_3Br_2{\cdot}NClAc$, short prisms melting at 88°; *acetylbromoamino*-4-*chlorobenzene*, $C_6H_4Cl{\cdot}NBrAc$, yellow plates, melting at 91°; *acetylchloroamino*-4-*bromobenzene*, $C_6H_4Br{\cdot}NClAc$, rhombs, melting at 108—109°; *acetylbromoamino*-2 : 4-*dichlorobenzene*, $C_6H_3Cl_2{\cdot}NBrAc$, yellow plates or prisms, melting at 95—96°; *acetylchloroamino*-4-*chloro*-2 *bromobenzene*, $C_6H_3ClBr{\cdot}NClAc$, four-sided prisms, melting at 74—75°; *acetylbromoamino* - 4 - *chloro* - 2 - *bromobenzene*, $C_6H_3ClBr{\cdot}NBrAc$, yellow rhombs melting at 85—86°; *acetylchloroamino* - 2 - *chloro* - 4 - *bromobenzene*, $C_6H_3ClBr{\cdot}NClAc$, rhombs or prisms melting at 88—89°; *acetylbromoamino* - 2 - *chloro* - 4 - *bromobenzene*, $C_6H_3ClBr{\cdot}NBrAc$, yellow, four-sided prisms melting at 110—111°; *acetylchloroamino* - 2 : 4 - *dibromobenzene*, $C_6H_3Br_2{\cdot}NClAc$, plates or rhombs melting at 56—57°; *acetylchloroamino* - 2 : 4 : 6 - *tribromobenzene*, $C_6H_2Br_3{\cdot}NClAc$, prisms melting at 109—110°.

*82. "*Replacement of Bromine by Chlorine in Anilines.*" By F. D. Chattaway and K. J. P. Orton.

When tribromoaniline (NH_2 : Br : Br : Br = 1 : 2 : 4 : 6) reacts with acetylchloroamino-2 : 4-dichloroacetanilide in chloroform solution, bromine is evolved, and in addition to an azo-derivative and another coloured substance, a chlorodibromoaniline can be isolated. This aniline proves to be 4-chloro-2 : 6-dibromoaniline. With *sym*-chlorobromoaniline (2 chloro-4 : 6-dibromoaniline, 4-chloro-2 : 6-dibromoanilines, 2 : 4-dichloro-6-bromoaniline, and 2 : 6-dichloro-4-bromoaniline), it was observed that bromine was given off to a far greater extent from those anilines which possessed a bromine atom in the para-position relatively to the amino-group. Again, an aniline in which bromine had been replaced by chlorine could only be isolated in the case of those anilines where bromine originally occupied the para-position. Thus, 2 : 4-dichloro-6-bromoaniline could be obtained from 2-chloro-4 : 6-dibromoaniline, but not from 4-chloro-2 : 6-dibromoaniline.

Acetylchloroamino-2 : 4 : 6-tribromobenzene (and similar derivatives of chlorobromobenzenes) gives off bromine when heated in a sealed tube with acetic acid. No pure chlorobromoacetanilide has been isolated.

*83. "*The Absorption Spectra of Cyanogen Compounds.*" By W. N. Hartley, F.R.S., J. J. Dobbie, D.Sc., M.A., and A. Lauder, B.Sc.

The authors described the results of an examination of the absorption spectra of cyanogen compounds, more particularly of cyanuric acid, melamine, and their respective esters.

Cyanuric acid and methyl cyanurate (m. p. 135°) are commonly represented as closed chain compounds in which the chain is formed of alternate atoms of carbon and nitrogen alternately doubly and singly linked, while methyl *iso*cyanurate (m. p. 175°) is represented as a derivative of *iso*cyanuric acid containing three keto-groups and having the carbon and nitrogen atoms only singly linked. From the circumstance that pyridine, dimethylpyrazine, and other similar substances, in which the carbon and nitrogen atoms are united by alternate double and single linkings, exhibit strong absorption bands, it was expected that cyanuric acid and its esters would likewise exhibit marked selective absorption. On the other hand, it was anticipated that the esters of *iso*cyanuric acid would behave like piperidine and other substances composed of a closed chain of singly linked carbon and nitrogen atoms. The authors found, however, no trace of selective absorption in any of the substances examined, and pointed out that in the absence of more satisfactory chemical evidence it is questionable whether the constitution of cyanuric acid ought to be represented by a structural formula so closely analogous to that of pyridine and of dimethylpyrazine.

The spectrographic examination confirms the view generally accepted on the evidence of chemical reactions, that cyanuric acid and methyl cyanurate (m. p. 135°) are similarly constituted, and that the relations between melamine and triethylmelamine (m. p. 74°) are correctly represented by the commonly accepted formulæ.

84. "*The Nutrition of Yeast.*" Part III. By A. L. Stern, D.Sc.

The author has determined the effect of varying the concentration of the sugar, the temperature of fermentation, the amount of seed-yeast and the time, on the nutrition of yeast.

The experiments were made in exactly the same manner as those previously described (*Trans.*, 1899, lxxv., 202); the sugar used was dextrose, the nitrogenous nutriment, asparagine; and the inorganic nutriment, potassium phosphate, magnesium sulphate, and calcium sulphate; and the yeast a pure culture from a Burton pitching yeast.

The conclusions drawn are:—

(1). Any increase of nitrogenous or inorganic nutriment beyond a definite limit will not increase either the amount of nitrogen assimilated by the yeast, or the weight of the yeast. This limit is but little greater than the largest amount which the yeast is able to assimilate under the conditions of the experiment.

(2). Any increase of the sugar is accompanied by an increase of the weight of nitrogen assimilated, and of the weight of the yeast. This increase goes on up to the strongest concentrations which can be completely fermented. The rate of increase is greatest at the lowest concentrations, and falls off gradually as the concentration rises.

(3). Temperatures between 12° and 25° have but little influence on the weight of nitrogen assimilated and the weight of the yeast crop. At higher temperatures reproduction is weakened.

(4). The weight of the nitrogen assimilated and of the yeast crop is composed of two quantities: the weight of the seeding plus a quantity dependent on the composition of the solution.

(5). The growth of the yeast is during a portion of the fermentation proportional to the amount of sugar fermented, and proceeds as long as any sugar remains unfermented.

From a consideration of these deductions, and of the work of others, the author concludes that there is an essential difference between the functions of the inorganic and nitrogenous nutriment on the one hand, and of the sugar on the other; that the former supply only material to the yeast, whilst the latter supplies both material and energy. Whether fermentation is caused by an enzyme or not, the author does not yet consider definitely determined; whilst there is certain amount of evidence to support this supposition, there is none to negative it.

85. "*On the Colloid Form of Piperine, with especial reference to its Optical Refraction and Dispersion.*" By H. G. Madan.

The author has examined the conditions under which crystalloid piperine is converted into the colloidal allotropic form of the substance. He finds that while crystallised piperine when heated to its melting point, 135°, solidifies on cooling into a transparent resin-like substance, the latter, when thus prepared, is not permanent, but reverts spontaneously in the course of a few months into the crystalloid form. The same change takes place quickly and completely when the substance is heated to 100°. If, however, piperine is kept for an hour at a temperature of 180°, the resulting product is much more stable if not absolutely permanent as a colloid. It does not become crystalline when heated to 100° or above, nor has the lapse of two and a half years had any effect in changing it back into the crystalloid condition.

The results of a determination of the refractive indices of colloid piperine for some of the principal spectrum lines were given, from which it appears that, while its refraction is very high ($\mu_D = 1{\cdot}684$), its dispersion is quite extraordinary, the visual spectrum being nearly four times as long as that given by a prism of dense flint glass having the same refracting angle. The coefficient of dispersion ($\mu H_\gamma - \mu H_\alpha$) is 0·142, while that of carbon disulphide is only 0·057.

86. "*Note on Pyromucylhydroxamic Acid.*" By R. H. Pickard and A. Neville.

The reactions of pyromucylhydroxamic acid have been studied with a view of obtaining the furan carbamides and carbamates by the method of Thiele and Pickard. These are, however, uncrystallisable oils, which decompose on hydrolysis. *Pyromucylhydroxamic acid*, $C_4H_3O{\cdot}CONHOH$, obtained by hydrolysing ethyl pyromucate with hydroxylamine, melts at 124°, and forms a *benzoyl* derivative, which melts at 134°.

(To be continued).

PHYSICAL SOCIETY.

Ordinary Meeting, May 31st, 1901.

Prof. S. P. Thompson, President in the Chair.

A paper "*On the Resistance of Dielectrics and the Effect of an Alternating Electromotive Force on the Insulating Properties of India-rubber,*" by A. W. Ashton, was read by Prof. Fleming.

The author has obtained from his experiments formulæ for the charging and discharging currents of a condenser with rubber dielectric. The currents are exponential functions of the time. Curves for various potential differences have been plotted, and were exhibited. These curves show that the insulating properties of rubber are increased by the application of high alternating electromotive forces.

Prof. Fleming then read a note by Mr. Ashton "*On the Electrification of Dielectrics by Mechanical means.*"

A sheet of pure Para rubber was placed in a condenser, the plates of which were connected to a quadrant electrometer. A two-pound weight was then dropped on to the condenser from a height of three inches. The electrometer received two impulses of opposite sign, one quickly following the other. The rubber was then stretched while in position, and a potential difference of seven volts was shown between the plates, the top plate being negative. The condenser and electrometer were then discharged, the sheet reversed, and the experiment repeated. The same effect was produced, the top plate again being negative. It appears, therefore, that polarisation of a dielectric being thus produced by mechanical energy, some part of the mechanical energy expended on the india-rubber during manufacture would remain in the dielectric as electric energy.

A Model which Imitates the Behaviour of Dielectrics, by Prof. Fleming and Mr. Ashton, was exhibited by Prof. Fleming.

The behaviour of dielectrics with regard to their residual charge is analogous to that of wires subjected to mechanical stress. A simple twisted wire is not, however, able to imitate all dielectric effects, and the present paper describes a model which represents things more completely. Six pistons separated by springs are placed inside a vertical cylinder. The bottom piston fits fairly tightly in the cylinder. The second piston fits slacker than the first. The third piston has a small hole in it, and each succeeding piston has a greater area cut away, the top piston having just sufficient metal left to make the spring come to rest without vibration after being compressed. The cylinder is filled with machine-oil and vaseline. To the top piston is attached a rod by means of which pressures can be exerted on the pistons for any length of time. This represents the charging of the condenser. The motion of the rod after releasing the weights represents the discharge of the condenser. This is registered graphically by a revolving drum, and the curves obtained are very similar to those from condensers with dielectrics.

Prof. Ayrton said he would like to know in what respect the model shown was superior to a strained wire. He had noticed about ten years ago that alternating E.M.F.'s appeared to improve condensers. He was then working with comparatively small voltages, and he was interested to know that Mr. Ashton, working with high voltages, had established the improvement. The deflection obtained by stretching the india-rubber sheet might be due to changes in temperature, the dielectric having a high thermoelectric power.

Mr. Price was glad that the question as to what actually might be called the resistance of a dielectric had been raised. There are two theories of residual charge; one due to Maxwell and the other to Heaviside. The model exhibited represents Maxwell's theory. He considered that the electrometer experiment with the rubber dielectric favoured Heaviside's theory; that is that the dielectric is composed of small charged bodies similar to the small magnets conceived to constitute a magnet. He expressed his interest in the fact that the top plate of the condenser was always negative.

Mr. Blakesley suggested putting a small hole in the bottom piston of the model so that it might represent a condenser passing a small steady current. With regard to the stretched rubber experiment, he said it would be interesting to make observations with the plates of the condenser vertical.

Mr. Campbell said he had made experiments, and found that the change in capacity of the rubber condenser affects the voltage sufficiently to mask the real effect.

Mr. Appleyard said it was important to have perfect contact between the dielectric and the metal plates.

It was pointed out by a visitor engaged in the cable industry that manufacturers are aware that pressure affects the insulating properties of gutta-percha. Rubber is a mixture, and different rubbers behave differently under the action of alternating potential differences.

The Chairman said that if the quantity of electricity taken in on charging was equal to the quantity given out on discharge then there could be no dielectric hysteresis.

The Society then adjourned until June 14th.

CORRESPONDENCE.

FIRES AT CHEMICAL WORKS.

To the Editor of the Chemical News.

Sir,—It is satisfactory to learn that, although several explosions occurred at the recent fire at Runcorn, no person was injured. But, in view of the possible loss of life of which fires at chemical works are liable to be the cause, it is important, in the interests of common humanity, that no expense should be spared to fit such premises with absolutely the best fire-extinguishing and life-saving apparatus.

I have been gratified to notice that several of the leading firms in the trade take an interested view of the question—such as Messrs. Brunner, Mond, and Co., the United Alkali Co., and Messrs. Lever Bros., at Port Sunlight—and are provided with portable steam fire-engines by the Merryweather firm; besides which, they possess private fire brigades, thereby ensuring the efficient use of the apparatus in case of fire. These arrangements must be advantageous, even from the economical point of view; and the subject is worthy of increased attention by the proprietors of chemical works in its humanitarian aspect.—I am, &c.,

The Editor of *The Fireman.*

CHEMICAL NOTICES FROM FOREIGN SOURCES.

NOTE.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. cxxxii., No. 19, May 13, 1901.

Aromatic Organo-magnesium Compounds.—MM. Tissier and Guignard.—The halogen derivatives of benzene and its homologues react easily on magnesium, with formation of organo-metallic compounds analogous to those of the fatty series. The method employed is the same for both. Monobromobenzene and monobromotoluene are made to drop slowly on to magnesium, and, after the addition of some anhydrous ether, the corresponding organo-metallic derivative is produced: C_6H_5—Mg—Br and $C_6H_4(CH_3)$—Mg—Br. A portion of this compound crystallises from the ether at ordinary temperatures, and on cooling down to freezing-point the whole becomes solid. At the beginning of the operation, the vessel in which the preparation takes place should be slightly heated, or a small particle of iodine added to start the reaction; after this it proceeds regularly. An investigation of the various reactions shows that the halogen ethers of the aromatic series react on magnesium in an exactly similar manner to the ethers of the fatty series, but the velocity of the reaction diminishes with the complication of the radicle.

The Phosphoric Acid of the Soil.—Th. Schlœsing, jun.—The author extracts all the phosphoric acid in the form of phosphates which are soluble in water from the soil at Boulogne, Joinville, and Neauphle, and examines these. He also uses, on the same soils, very dilute nitric acid, and obtains different quantities of soluble phosphates.

MEETINGS FOR THE WEEK.

THURSDAY, 13th.—Royal Society, 4.30. (The Bakerian Lecture). "The Nadir of Temperature, and Allied Problems—(1) Physical Properties of Liquid and Solid Hydrogen; (2) Separation of Free Hydrogen and other Gases from Air; (3) Electric Resistance, Thermometry, and the Boiling-point of Hydrogen; (4) Experiments on the Liquefaction of Helium at the Melting-point of Hydrogen; (5) Pyro-electricity, Phosphorescence, &c.," by James Dewar, M.A., LL.D., F.R.S.

THE
DAVY FARADAY RESEARCH LABORATORY
OF
THE ROYAL INSTITUTION.

Directors:
The Right Hon. LORD RAYLEIGH, M.A., D.C.L., LL.D., F.R.S.
Professor DEWAR, M.A., LL.D., F.R.S.

Superintendent of the Laboratory:
Dr. ALEXANDER SCOTT, M.A., D.Sc., F.R.S.

This Laboratory was founded by Dr. LUDWIG MOND, F.R.S., as a Memorial of Davy and Faraday for the purpose of promoting, by original research, the development and extension of Chemical and Physical Science.

The Laboratory is open free of charge to Workers of either sex, and any nationality, prosecuting individual investigations; and the extensive collection of Physico-Chemical Apparatus presented by the Founder is available for their use, together with such materials, chemicals, electricity, &c., as the Directors may authorise.

Assistants and a trained mechanician are attached to the Laboratory to aid Workers in the prosecution of their researches.

All persons desiring to be admitted as Workers must send evidence of scientific training, qualification, and previous experience in original research, along with a statement of the nature of the investigation they propose to undertake.

MICHAELMAS TERM.—Monday, October 7, to Saturday, December 14.
LENT TERM.—Monday, January 6, to Saturday, March 22.
EASTER TERM.—Monday, April 14, to Saturday, July 26.

Forms of application can be had from the Assistant Secretary, Royal Institution, Albemarle Street, W.

MACMILLAN & CO.'S BOOKS
FOR
CHEMICAL STUDENTS.

JUST PUBLISHED.

PRACTICAL ORGANIC CHEMISTRY
for ADVANCED STUDENTS.
By JULIUS B. COHEN, Ph.D.
Globe 8vo, 3s. 6d.

NATURE:—"The best elementary book, in the English language, on practical organic chemistry."

Second Edition Now Ready.

INTRODUCTION TO PHYSICAL CHEMISTRY.
By JAMES WALKER, D.Sc., Ph.D.,
Professor of Chemistry in University College, Dundee.
8vo, 10s. net.

JOURNAL OF EDUCATION:—"The author has succeeded admirably in his task, and the work should be gratefully received by those for whom it is intended."

Second Edition Now Ready.

THE SCIENTIFIC FOUNDATIONS of ANALYTICAL CHEMISTRY
Treated in an Elementary Manner.
By Professor WILHELM OSTWALD, Ph.D. Translated with the Author's sanction by GEORGE M'GOWAN, Ph.D.

THE CHEMICAL NEWS.

Vol. LXXXIII., No. 2168.

CONCERNING THE INFLUENCE OF SELENIUM ON CERTAIN TESTS FOR ARSENIC.

By OTTO ROSENHEIM, Ph.D., F.C.S.,
Research Scholar in Pharmacological Chemistry, King's College.

In view of the fact that the presence of selenium compounds has recently been demonstrated in brewing-sugar and in two samples of beer implicated in the beer-poisoning epidemic in Manchester, the chemistry of this substance becomes invested with greater practical interest than heretofore. This is more especially the case since the highly poisonous nature of selenium compounds has been placed beyond any doubt (Tunnicliffe and Rosenheim, *Lancet*, Feb. 2, 9, and March 30, 1901).

The fact that selenium, as far as the products in question are concerned, was accompanied by arsenic, introduces a complication. From the point of view of the analyst, the question becomes not merely one of the detection of selenium or arsenic alone, but of the detection of selenium in the presence of arsenic and *vice versâ*.

Since selenium has been brought into the region of practical hygiene, much has been said and written concerning its chemical behaviour. Many, apparently contradictory, statements have been recorded, owing no doubt to the scarcity and inaccessibility of the literature. Under these circumstances, the following observations, although in some part consisting of a critical repetition of the work of former investigators, would seem to be of some interest.

1. *Behaviour of Selenium in Marsh's Test.*

If selenium compounds be submitted to the Marsh test (the apparatus being provided with a small wash-bottle containing about 50 c.c. of a 5 per cent lead acetate solution), as for the exact estimation of arsenic,* it will be observed that no deposit is produced in the heated glass tube, even when quantities of 100 m.grms. selenious acid are treated for two hours. The zinc in the generating vessel, however, assumes an unusual appearance, becoming covered with a brick-red deposit of amorphous selenium. The small quantities of hydrogen selenide, evading reduction by the zinc, are completely retained by the lead solution, lead selenide being formed and deposited. If, however, the lead acetate wash-bottle be omitted, a deposit of selenium is obtained in the glass tube at some distance from the heated part.† This deposit varies in colour from dark brick-red to reddish yellow, according to the quantities used (and the relative freedom from sulphur and carbon compounds of the zinc employed). It is possible, by using a tube of very small diameter (1 m.m.), to obtain a distinct deposit from one-tenth m.grm. selenious acid (=0·06 m.grm. Se). The actual amount of selenium thus deposited is, however, very small, owing to the ease with which hydrogen selenide is decomposed, even in aqueous solution, and reduced to selenium in the generating vessel. By a quantitative estimation, it was shown that 96 per cent of the selenium introduced as selenious acid was retained by the zinc.*

The systematic study of the influence of selenium compounds on the formation of the arsenical mirror in the absence of a lead acetate wash-bottle brings out clearly two facts which do not seem to have been sufficiently emphasised in recent publications (compare Willcox, *Lancet*, March 16, 1901; Berry, *Journ. Soc. Chem. Ind.*, vol. xx., 322 and Discussion). It may be pointed out at once that both these facts have been observed already by L. Dawydow (*Farmazeft*, 1895, iii., 1; abstracted in *Chem. Zeit., Analyst, Chem. Soc. Journ.*, &c.), and have since, according to private information, been confirmed by several other observers in this country, apparently without the knowledge of Dawydow's experiments.

The first fact is important with regard to the detection of arsenic; and is, that selenium compounds have a very distinct inhibitory influence on the formation of the arsenical mirror, and under certain conditions completely prevent its formation.† *Ceteris paribus*, the influence is proportional to the amount of selenium present; this is best shown by the accompanying figure (Fig. 1), which is an exact reproduction of the results actually obtained.

The tests were made under exactly identical conditions —the same quantity of zinc from one stock and a generating vessel of the same size (250 c.c.) being used for each experiment. The zinc was relatively free from sulphur.‡ In order to control the evolution of hydrogen more exactly than by the size of the flame, and thus to obtain comparable results, a small wash-bottle was used at the end of the apparatus, and the acid supply regulated by means of a stopcock in the sulphuric acid funnel. The time for each experiment was one hour, the tube being heated a quarter of an hour previously, to make sure of the absence of arsenic in the materials used. The quantity of arsenic was 1 m.grm. in all experiments, whilst the quantity of selenious acid varied from 0·3 to 20 m.grms. The deposit formed on the zinc in the generating vessel in the presence of arsenic and selenium was of a dark reddish brown colour. In the case of Experiment 9, the evolution of hydrogen was kept very slow, with the result that only the faintest deposit was obtained. For the sake of comparison, one experiment was made under identical conditions with 20 m.grms. selenious acid alone. From this the usual selenium deposit was obtained.

The second fact to be observed is of importance with regard to the detection of selenium, and consists in the total absence of any brick-red colour in the deposits obtained from admixtures of arsenic and selenium in Marsh's apparatus. Just as in the formation of the ordinary arsenical mirror, so in this case, a slight anterior brownish portion, followed by a metallic black portion, may be observed in the first half-hour of the experiment. After one hour, however, the two mirrors are united into one black

* Compare Polenske, *Arbeiten a. d. k. Gesundheitsamte*, v., 357; Kuhn u. Sager, *Ber. d. Deut. Chem. Ges.*, xviii., 1758; Langmuir, Chemical News, 1899, vol. lxxix., p. 121 (from *Journ. Am. Chem. Soc.*). The use of this wash-bottle is indispensable for arsenic estimations, and its value has been clearly brought out by the experience of recent investigators. The statements in the *Lancet*, Feb. 2, 1901, refer to experiments made under these conditions.

† The temperature at which the deposit of selenium from the hydrogen and hydrogen selenide current appeared was found to be 350°. When once started, the reaction proceeds even at a lower temperature through catalytic action (compare M. Bodenstein, *Zeit. Physikal. Chem.*, xxix., 429). No selenium deposit is obtained on porcelain from the flame under the above conditions.

* The estimation was made by weighing the part of the tube with the deposit obtained from 20 m.grms. selenious acid after one and a half hours, dissolving out the selenium by cyanide of potassium solution and weighing back. It is interesting to note that no difference was observed in the size of the selenium deposit when, for the generation of the hydrogen, HCl was used instead of H_2SO_4. Selenic acid and its salts, although necessitating a long time for their reduction, seemed to give rise to a slightly larger deposit in the tube.

† It is possible that the non-formation of an arsenical mirror in the Manchester beers examined by Estcourt (Chemical News, 1900, lxxxii., 287, 295) was due rather to the presence of selenium than to the interference of sulphur compounds; more especially as the latter, in conjunction with arsenic, produces yellow mirrors (J. F. Smith, Chemical News, 1900, lxxxii., 315; 1901, lxxxiii., 2).

‡ Only once a sample of "pure zinc," free from sulphur, was obtained; all samples examined since contained sulphur. From 500 grms. of a certain sample of "pure zinc," which gave no reaction for arsenic in Marsh's test and was not very sensitive to arsenic, selenium was isolated in traces. Schlagdenhauffen and Pagel (*Comptes Rendus*, 1899, cxxviii., 1170) obtained a considerable deposit of selenium from 2 kilogrms. of "pure zinc." It is possible that this fact explains the different sensitiveness of various samples of zinc with regard to arsenic (see also O. Hehner, *Journ. Soc. Chem. Ind.*, xx., 195).

typical arsenical mirror.* It seems, *à priori*, probable that when selenium is in large excess of the arsenic, a red deposit would be obtained, especially if the hydrogen evolution be very rapid. Working under the above conditions, however, this was never observed, even when the quantity of selenious acid was 100 times that of arsenic.

If, for the purpose of these experiments, instead of using solutions of these substances in water, we take solutions of them in liquids containing organic and sulphur compounds (such, for instance, as beer), it will be observed that selenious acid alone (1 grain per gallon), in the absence of a lead acetate wash-bottle, produces no brick-red deposit in the tube. After one and a half hours a very faint whitish deposit of sulphur was obtained. Evidently the hydrogen selenide is reduced completely by the organic matter. In the presence of arsenic and selenious acid the arsenical mirror, in the absence of lead acetate, is usually deposited in the early stage of the experiment as described above, namely, in two portions, an anterior reddish brown and a posterior black one. If the quantity of arsenic be very small, the mirror formation is arrested at this stage. The relative

Influence of Selenious Acid on the Formation of the Arsenical Mirror.

distinctness of the brown portion is due to the formation of the solid hydrogen arsenide and to the amount of sulphur and organic compounds present, and is not dependent in any way on the presence of selenium. This can easily be shown by adding to a beer, free from arsenic, known quantities of selenious and arsenious acid, and to another sample of the same beer the same quantity of arsenic alone. Experiments were made with beer mixed with 1 grain of arsenic and 0·3 grain of selenious acid per gallon (and, in another case, one-tenth grain of arsenic and one-twentieth grain selenious acid per gallon), and absolutely identical arsenical mirrors were obtained from the arsenic beer and the arsenic+selenium beer. In both cases the mirror consisted of two portions; the one nearer to the heated part being of a brownish tint, whilst the posterior part was of a pure black colour. When the organic matter was destroyed in these two beers, they still gave identical mirrors—the brown portion, however, not being so well marked. It is evident from the above results that, when selenium is present in beer together with arsenic, no conclusion can be drawn concerning the presence or the absence of the former substance from the colour of the mirror.

Since, so far as we are aware, this anomalous behaviour of arsenic and selenium in the presence of each other has received no explanation supported by analytical facts, we thought it of interest to investigate more closely the reddish-brown deposit formed in the generating vessel. For this purpose a somewhat larger amount was prepared, filtered, and dried *in vacuo*. The product, mechanically contaminated with small particles of zinc, was partly soluble in potassium cyanide, and easily soluble in sodium hydrate. Both solutions gave a brick-red deposit of selenium upon the addition of hydrochloric acid. The solution in sodium hydrate, after the removal of the selenium from it, was found to contain arsenious acid. These facts afford an explanation of the point in question. The deposit in the generating vessel consists of a mixture of selenium and arsenium selenide (probably As_2Se_3), and its formation is evidently due to the interaction of the small quantity of hydrogen selenide (evading complete reduction to selenium), and the arsenious acid. The following equation expresses the reaction:—

$$As_4O_6+6H_2Se=2As_2Se_3+6H_2O.$$

The reaction was studied separately. Dry hydrogen selenide mixed with hydrogen (prepared by heating selenium in a dry hydrogen current), was passed through a slightly acidified arsenious acid solution. The formation of a reddish-brown deposit began at once. After filtering and drying, it was found on examination to be identical with the compound prepared and analysed by Uelsmann (*Lieb. Annalen*, vol. cxvi., p. 122), corresponding to the formula As_2Se_3.

In addition to the chemical explanation just given there are also mechanical reasons for the non-formation of hydrogen arsenide in the presence of selenium in the Marsh generating-flask. The zinc becomes completely covered with the selenium compound in question, and thus the evolution of hydrogen is prevented. If hydrogen be passed through the liquid from an outside source a small arsenical mirror is formed.

The influence of selenium on the formation of the antimony mirror was found to be analogous to that exerted on the arsenical mirror in every respect.

* The formation of two portions in the arsenical mirror is well known (compare, for instance, A. W. Blyth, "Poisons, their Effects and Detection," p. 526). J. W. Retgers (*Zeit. f. Anorg. Chem.*, 1893, 439) showed that the brown portion consists of a solid modification of hydrogen arsenide (AsH), distinguishable from the black arsenium deposit by its solubility in boiling xylol, methylene iodide, and potassium hydrate. Probably impurities of the zinc (sulphur, carbon compounds, &c.) also influence the colour of the deposit.

2. *Behaviour of Selenium in Reinsch's Test.*

It has already been pointed out by Reinsch himself that selenious acid forms a black coating on pure copper-foil, resembling that produced by arsenic (*Neues Jahrbuch. f. Pharm.*, 1866, 202). Later, Drinkwater (*Analyst*, vol. viii., p. 241), made the same observation independently, and also drew attention to its importance in toxicology. This latter observer states that the distinctly crystalline sublimate obtained from the copper does not resemble arsenic, and dissolves in sulphuric acid with a green colour.*

According to our own observations selenic acid as well (in distinction from arsenic acid), is easily reduced and precipitated on copper-foil in the presence of hydrochloric acid. This fact is explained by the previous reduction of selenic to selenious acid by boiling with hydrochloric acid alone. On long-continued boiling selenium as such is deposited, not only on the copper-foil, but in the liquid as well, producing a red colouration of the latter.

On subjecting the blackened copper-foil to sublimation in a glass tube, a small amount of a crystalline sublimate of selenium dioxide is obtained. The greater part of the selenium is retained on the foil as copper selenide. Owing to its highly hygroscopic properties it is somewhat difficult to observe the crystals under the microscope, as they immediately absorb moisture, becoming transformed into selenious acid (H_2SeO_3). If no special precautions be taken the formation of this sublimate may easily be overlooked. If the tube, containing apparently only droplets of water, be left in the desiccator over sulphuric acid for a few hours, fern shaped crystals of selenious acid are formed, and may easily be identified by micro-chemical reactions. (Reaction with iodide of potassium, reduction by zinc or stannous chloride and HCl, &c.; compare Behrens, "Microchem-Analyse"). The selenium remaining on the copper may be dissolved by means of a weak potassium cyanide solution, from which it is re-precipitated by hydrochloric acid, and may then easily be identified by the usual reactions.

By a simple modification the whole of the selenium deposited on the copper may be obtained as a sublimate. For this purpose a current of dry oxygen is passed through the tube during the sublimation, and a white ring of beautiful transparent prismatic crystals is formed. The copper-foil must be heated for some time. The same effect is obtained by a slow current of dry air, but the process must be continued for some hours. If one wishes to preserve these crystals of selenium dioxide for future observation, it is necessary to introduce some chloride of calcium, wrapped in filter-paper, into the upper part of the tube, before closing it up, sufficient moisture being present even in the closed tube to destroy the shape of the crystals.

Modification of Reinsch's Test.—If a liquid containing small amounts of selenious acid be treated in the way indicated by Reinsch, replacing, however, the copper-foil by polished silver-foil, suspended by means of a silver wire, it will be noticed that the silver quickly assumes a reddish and afterwards a bluish-black tint. No selenium is deposited in the liquid. This behaviour affords a convenient test for selenium in the presence of arsenic. The latter is under these conditions either not deposited at all, or only to an infinitesimal extent. On subjecting the dry blackened silver-foil to sublimation in a glass tube over a spirit-burner a sublimate is easily obtained, the silver reassuming its usual appearance. The sublimate consists in this case partly of selenium (producing a red tinge), and selenium dioxide. It it be desired to preserve the sublimate in its crystalline form the same precautions have to be taken as described above. Microscopically the sublimate consists of separate prismatic crystals. In that part of the sublimate in which selenium, as such, is present the crystals are arranged in fern-shaped masses. The crystals vary in length from 0·07 to 0·9 m.m., and are further characterised and distinguishable from arsenic by being doubly refractive when viewed in polarised light.

By this method a copious sublimate is obtained from 100 c.c. of a solution containing 1 : 1,000,000 selenious acid. If arsenic and selenium are present together in solution the former may be precipitated on copper-foil, after the removal of the selenium by repeated treatment with silver-foil. This method in suitable modification gives quantitative results in the absence of organic substances. Sulphur compounds blacken silver-foil, but no sublimate is obtained from it.

3. *Behaviour of Selenium in Gutzeit's Test.*

Hydrogen arsenide evolved by the action of zinc and hydrochloric acid on arsenicated material produces characteristic stains on filter-paper moistened with silver nitrate or mercuric chloride solution. Pure hydrogen selenide gives rise to similar stains. The above test, especially the silver one, is extremely sensitive when certain precautions are taken (1/1000 m.grm. being distinctly shown). The absence of hydrogen sulphide must, however, be ensured, and is best obtained by the use of acetate of lead. Under these circumstances selenium compounds have no influence on the test, being completely retained, except that when present in large quantities they keep back the arsenic as explained above under Marsh's test.

4. *Behaviour of Selenium in Bettendorf's Test.*

This test, which has been adopted by the German Pharmacopœia for the detection of arsenic in glycerin, consists in the action of stannous chloride dissolved in strong hydrochloric acid on arsenic. It has already been pointed out by Dawydow (*loc. cit.*), that selenium interferes in this test by masking the presence of arsenic. Selenium, in distinction from arsenic, is already precipitated immediately in the cold, whilst the reaction with arsenic proceeds slowly, and is only complete at higher temperatures. The drawback of this very sensitive test is that colourless solutions are necessary, and that stannous chloride is apt to contain impurities (such as sulphates, bismuth, iron, &c.), interfering with its use for the detection of arsenic (compare Dietze, *Zeit. Anal. Chem.*, 1900, 44).

Behaviour of Selenium in the Electrolytic Test.

If a solution of arsenious acid be decomposed electrolytically a part of the arsenic is deposited in the metallic state, the remainder escaping as hydrogen arsenide. In the presence of hydrochloric acid the greater part of the arsenic is transformed into the hydrogen compound, and may be identified by the usual methods (Bloxam's electrolytic test). The reaction, however, is not quantitative (Moore, CHEMICAL NEWS, liii., 209).

A few experiments showed that selenium is easily deposited as such from its solutions, acid as well as alkaline. Some hydrogen selenide, however, is produced, and subsequently partly decomposed (compare also Schucht, *Zeit. f. Anal. Chem.*, xxii., 495). The deposition of selenium from alkaline solution indicates a qualitative (and perhaps quantitative) method for its separation from arsenic, as the latter when present as arsenic acid is not electrolytically decomposed in alkaline solutions. The character of the selenium deposit (if flocculent or adhering to the platinum vessel), depends, however, very much upon the current density, temperature, &c., conditions which have not yet been worked out sufficiently to permit of this behaviour of selenium being made use of analytically.

The chief results of the above observations may be summarised as follows:—

* It may be noted here that from the green solution obtained by dissolving Se in H_2SO_4 at about 100°, selenium separates upon the addition of water as a red precipitate. On heating the solution, however, or on prolonged exposure to air, a colourless or reddish solution is produced from which no selenium is precipitated upon the addition of water. The Se is oxidised with evolution of sulphurous acid, to selenious and selenic acid, and it is probably in this state chiefly that selenium occurs in commercial sulphuric acids. (Compare Hilger, *Lieb. Ann.*, clxxi., p. 211).

1. Marsh's test gives no indication of the presence of selenium if it be accompanied by arsenic.
2. The magnitude of the arsenical mirror is influenced by the presence of selenium. Under certain conditions its formation is completely inhibited.
3. Reinsch's test, as ordinarily performed, is applicable for the detection of selenium, and can be used for its separation from arsenic if silver-foil be substituted for copper-foil.
4. None of the above methods are applicable for the quantitative estimation of small amounts of selenium together with arsenic in complex organic liquids, such as solutions of brewing sugar or beer.

Having demonstrated the presence of selenium in sugar and beer, implicated in the recent epidemic, Dr. Tunnicliffe and myself naturally turned our attention to its quantitative estimation. We therefore proceeded to work out a special method for this purpose, into which we shall enter fully elsewhere in a detailed communication on this subject.

A COMPARATIVE CRYSTALLOGRAPHICAL STUDY OF THE DOUBLE SELENATES OF THE SERIES $R_2M(SeO_4)_2.6H_2O$—SALTS IN WHICH M IS MAGNESIUM.*

By A. E. TUTTON, B.Sc., F.R.S.

This memoir on the magnesium group of double selenates, in which R is represented by potassium, rubidium, and cæsium, is analogous to that which was presented to the Society in March, 1900, concerning the zinc group.

The conclusions derived from the study of the morphological and physical properties of the crystals of the three salts are generally similar to those arrived at from the study of the zinc group. There is observed an uniform progression with regard to every property in accordance with the order of progression of the atomic weights of the three alkali metals present. That is to say, the constants of the rubidium salt are generally intermediate between those of the potassium and cæsium salts.

The magnesium group has, however, proved particularly interesting, inasmuch as the progressive diminution of double refraction, according to the rule which has now been established for this series of double sulphates and selenates, leads in the case of cæsium magnesium selenate to such close approximation of the three refractive indices that the crystals of this salt exhibit exceptional optical phenomena. This includes dispersion of the optic axes in crossed axial planes at the ordinary temperature, the uniaxial figure being produced for wave-length 466 in the blue; and the formation of the uniaxial figure for every wave length of light in turn as the temperature is raised, the attainment of uniaxiality for red lithium light occurring at the temperature of 94°. As the life-history of the salt terminates at 100°, owing to the presence of water of crystallisation, this substance exhibits the property of simulating uniaxial properties at some temperature within its own life-range for every wave-length of light, while still retaining the general characters of monoclinic symmetry, including slight dispersion of the median lines. In this respect it resembles to a truly remarkable extent the analogous sulphate, which the author has shown to possess like peculiarities, but it is even more striking than the sulphate, as the dispersion is much larger. It is interesting to observe that these optical properties of cæsium magnesium selenate could have been predicted, given the constants of the potassium salt, and the rules of progression established for the double sulphate, and for the zinc group of double selenates. For the double selenates resemble the double sulphates so closely that in general it may be said that their properties are precisely parallel, the constants and curves being merely moved on to a slight extent by the replacement of sulphur by selenium without disturbing their relationships.

* Abstract of a Paper read before the Royal Society, May 23rd, 1901.

THE LITERATURE OF ALCHEMY.*

By HENRY CARRINGTON BOLTON.

(Concluded from p. 270).

Another feature of certain writers on alchemy was an attempt to give a hermetic interpretation to the fables and mythology of ancient Greece and Rome; Glauber cites from an earlier author the following ingenious way of explaining the Story of the Argonautic Expedition.

"When ancient Philosophers by poetical parables described the laborious navigation of Jason to the Island Colchos where resided an huge dragon vomiting fire, which with eyes never closed diligently watched the Golden Fleece, they added this, viz.: that Jason was taught by his wife Medea to cast to this waking dragon an edible medicine to be swallowed whereby he should be killed and burst; and that Jason should presently take the dragon thus slain, and totally submerge him in the Stygian Lake.

"Jason, in this ingenious fable, hieroglyphically represents the Philosophers; Medea, accurate meditations; the laborious and perilous navigation signifies manifold chemical labours; the watching dragon vomiting fire denotes saltpeter and sulfur; and the Golden Fleece is the tincture or soul of Saturn, by the help of which Jason restored health to his aged father and acquired to himself great riches. By the pills of Medea is understood the preparation of sulfur and Sal Mirabile. By the total submersion of the dragon in the Stygian Lake is intimated the fixation of sulfur by Stygian water, *i.e.*, *aqua fortis*.

"Whence it is sufficiently clear how obscurely the ancient Philosophers did describe their fixation of sulfur by nitre, and how secretly they hid it from the eyes of the unworthy."

So far Glauber, whose discovery of the well-known medicine still called "Glauber's salts" is herein alluded to.

This association of mythology and alchemy was a favourite subject with many authors, and has been exhaustively discussed by the French Abbé Pernety in his "Mytho-Hermetic Dictionary" and in his "Egyptian and Greek Fables Unveiled." (Paris, 1758).

Plain prose has been found by a number of authors far too commonplace for recording their golden inspirations, and they have resorted to versification; this was early done by the Arabians, whose lines glow with the warmth and brilliancy of Oriental imagery. Spanish poets followed in the same vein.

Several notable poems in French have been often reprinted; one of the earliest was the "Roman de la Rose" composed by Guillaume de Loris, and extending to 1800 stanzas. In 1320 a portion of this was adapted by Jean de Clopinell, also known as Jean de Meung, whose new verses were entitled: "Les remonstrances de la nature a l'alchimiste errant." In 1413 Jean de la Fontaine, of Valenciennes, composed: "La Fontaine des amoureux de la Science." These, with others of like topics, were printed in a tiny little volume by Pierre Rigaud, at Lyons in 1618.

Their sturdy neighbours across the Channel were not long behind the lively French; among the celebrated poems of John Gower and of Chaucer were clever exposures of the chicanery of swindling alchemists, both dating from the 14th century. In 1471, Sir George Ripley, Canon of Bridlington, Yorkshire, dedicated to King Edward IV.

* From the *Pharmaceutical Review*, vol. xix., Nos. 4 and 5.

a poem of over 300 stanzas entitled: "The Twelve Gates of Alchemy"; these gates were Calcination, Solution, Separation, Conjunction, Putrefaction, Coagulation, Cibation, Sublimation, Fermentation, Exaltation, Multiplication, and Projection.

The quaint style of this poem may be observed by citing a single stanza, the last one.

> "Thus here the Tract of Alchemy doth end,
> Which Tract was by George Ripley, Canon, penn'd.
> It was composed, writ, and signed his own,
> In Anno twice seven hundred, seventy-one.
> Reader! assist him, make it thy desire,
> That after life he may have gentle fire!"

The hermetic poems written in English were collected by Elias Ashmole, the British antiquary, and printed in a volume having the title: "Theatrum Chemicum Britannicum," London, 1652. This book, which is illustrated with curious engravings, is much prized by bibliophiles. One of the fragments by an anonymous author is worth reproducing.

> "I asked Philosophy how I should
> Have of her the thing I would.
> She answered me, when I was able
> To make the water malleable:
> Or else the way, if I could find,
> To measure out a yard of wind;
> Then shalt thou have thine own desire,
> When thou canst weigh an ounce of fire.
> Unless that thou canst do these three
> Content thyself, thou get'st not me."

The Latin hexameters on the "Art of making Gold," written by Aurelius Augurelli in 1514, and dedicated by him to Pope Leo X., gave rise to an amusing incident; the Pontiff accepted the manuscript and rewarded the poverty-stricken author by the gift of an empty wallet, remarking that one who knew so well how to create the precious metal would have no difficulty in filling his purse.

The hermetic authors who produced books in the 16th to the 18th centuries, clothed their magnificent promises of immeasurable riches in very shabby attire; with few exceptions the insignificant volumes are printed with worn-out or badly cut type, on paper of poor quality, which is now stained yellow with age and damaged by careless handling. Some are injured by exposure to the acid fumes of laboratories, others are scorched by contact with furnaces, and many are disfigured by students who had the reprehensible habits of underscoring in ink lines on the printed pages, or of scribbling on the margins, thus spoiling the beauty that the books never had; moreover they were rarely bound in any material better than coarse boards or pigskin, so that alchemical literature does not appeal to lovers of works of art.

On the other hand, the unattractive looking volumes are often illustrated with curious engravings representing in strange hieroglyphics the secrets of the Philosophers' Stone; no verbal description can do these mystical pictures justice. The "Liber Mutus," as its name suggests, has no text, but fifteen plates purport to depict the mysteries of transmutation; these were drawn by Jacques Saulat Demarets and first published in 1677; they are intelligible only to the initiated.

The "Chemical Pleasure-Garden" (Viridarium Chemicum), composed by Daniel Stolz von Stolzenberg, a Bohemian physician, and printed at Frankfurt in 1624, consists of 106 emblematic plates accompanied by as many stanzas.

The earliest papyri as well as the latest products of the nineteenth century abound in arbitrary signs and characters representing substances, apparatuses, and processes, first used as a kind of shorthand; these make the books utterly unintelligible without a key. The "Alchemical Oracle," published at Ulm in 1772, contains a key to more than 2000 of these signs; some common substances had many synonymous characters, mercury was denoted by 39, alum by 26, borax by 35, distillation by 13, and a pound weight had four distinct symbols. To further mystify readers a given sign was used to designate several different articles.

The literature of alchemy reflects on its pages the intellectual environment of the pseudo-scientists producing it; the very earliest treatises show the influence of magic, astrology, and Gnosticism; then followed works in which Christian piety intrudes itself upon rhapsodies extolling the "Great Work"; somewhat later the writings exhibited a more practical phase, with attempts to adapt chemical knowledge to the healing art, which was the special honour of Paracelsus. A few decades later the literature became imbued with the fantastic tenets of theosophy, and with the transcendental vagaries of Rosicrucianism, whose advocates adopted as much of alchemical theory as suited their purposes. In proportion as the truths of scientific chemistry became known, the absurdity of the claims of the alchemists became more apparent, their writings acquired a more sober hue, and they finally made serious efforts to reconcile the two philosophies; at the close of the eighteenth century vain attempts to bolster up the sick patient were printed under the specious title "Higher Chemistry." "Higher," or esoteric chemistry, was chiefly cultivated in Germany, where appeared books with such titles as: "The Sign-Post of Alchemy" (Wegweiser, 1773), "The Pocket-Book" (Taschenbuch, 1790), and the "Magazine for Higher Natural Science and Chemistry" (1784).

Like many other superstitions, belief in alchemy took such deep root in the popular mind that it has been hard to eradicate the noxious growth, and even to-day men write and publishers print books proclaiming views quite as preposterous as those of the palmy days of the pseudo-science. It is truly extraordinary that in France, of all countries, an apparently earnest effort is being made to perpetuate the grossest follies of hermetism; there is in Paris an Alchemical Association now publishing a monthly journal advocating transmutation, hermetic medicines, and magic (L'Hyperchimie), and a "University of Higher Studies" in which Magic, the Kabbala, Occultism, and Spiritism are taught by Professors claiming for themselves esoteric knowledge of supernatural origin. A member of this unique faculty published in 1897 a text-book with the title: "How to become an Alchemist," which reads like a modernised Greco-Egyptian Papyrus.

This reference to nineteenth century books on alchemy published in France prompts brief notice of those in the English language during the same period; these are usually reprints of valued works or new translations, and their existence is probably one result of the recent revival in Astrology, Chiromancy, and Occult Science that has taken place on both sides of the Atlantic.

About fifty years ago, Ethan Allen Hitchcock, of St. Louis, wrote three works of a serious character; in "Remarks on Alchemy" (Boston, 1857), he argues that the alchemists were reformers, and he endeavours to "rescue from undeserved opprobrium the reputation of a class of extraordinary thinkers;" in "Remarks on the Sonnets of Shakespeare," Mr. Hitchcock attempts to give them hermetic significance: and the title of the third volume, "Swedenborg, an Hermetic Philosopher" (New York, 1858), explains itself.

More recently, unscrupulous men have published documents in which they claim to have found scientific processes for transmutation, and offer shares for sale in companies to exploit the same; but advertisement of dishonest enterprises do not form a legitimate part of the literature of alchemy.

During the last decade Mr. Arthur Edward Waite, in England, has shown himself to be a most industrious devotee of hermetic literature by issuing new translations of Latin works to the extent of eleven volumes, two of which are in small folio. Mr. Waite had the eccentricity to print only six copies of one of his books before distributing the type; at several guineas a copy they were taken chiefly by British libraries and collectors of rare books.

I am sometimes asked whether in my study of the writings of the alchemists I have found anything new or

of practical value to chemists; I am obliged to answer, emphatically No. The followers of Hermes made valuable contributions to the growing science of chemistry by increasing the number of acids, salts, metals, and compounds, but a false philosophy prevented them from appreciating the real significance of their discoveries; moreover, the writers chose to clothe their incoherent thoughts in a stilted, meaningless phraseology, they made wild assertions bordering on insanity, and the only redeeming feature of their sophistries was their sublime faith.

Washington, D.C.

ON THE RESULTS OF A SEARCH FOR OTHER SUGARS THAN XYLOSE AND DEXTROSE IN THE PRODUCTS OF THE HYDROLYSIS OF WOOD FROM THE TRUNKS OF TREES.*

By F. H. STORER,
Professor of Agricultural Chemistry, Harvard University.

(Continued from p. 271).

D. *Experiments on the Acid Hydrolysis of Cotton.*—In a preliminary trial a quantity of worn-out cotton cloth was boiled in several successive fresh portions of sulphuric acid of 2·8 per cent H_2SO_4, and the residual cotton left after this treatment was soaked in sulphuric acid of 86·3 per cent H_2SO_4 for twenty-four hours. Subsequently, water enough was added to reduce the acid to the strength of 2·8 per cent, and the mixture was heated during 5·5 hours on a boiling water-bath. On neutralising with calcium carbonate, evaporating to the consistence of a thick syrup, and mixing this syrup with strong alcohol, a considerable quantity of sticky, gummy matter was left undissolved.

In another trial 50 grms. of the cotton cloth were treated directly with 100 c.c. of sulphuric acid of 90 per cent H_2SO_4, and the mixture was left to stand during twenty-four hours, with occasional stirring. It was then poured into enough boiling water to reduce the acid to the strength of 6 per cent, and the boiling was maintained over a free flame for three hours. The filtered liquid was neutralised with calcium carbonate, evaporated, decolorised with bone-black, and tested with Fehling's liquor and in the polariscope. A rotation of quasi-$[\alpha]_D = 75{\cdot}88°$ was noted. The solution was evaporated to dryness, and the residue was treated with cold, strong alcohol, in which the larger part of it dissolved, the matter insoluble in alcohol being manifestly less in this case than in the preceding instance. On testing this insoluble matter after it had been taken up with water and decolorised with bone-black, a rotation of quasi-$[\alpha]_D = 81{\cdot}58°$ was noted, and "sugar" enough to amount to 0·5 per cent of the dry cloth. The matter soluble in alcohol, after having been decolorised with bone-black, gave quasi-$[\alpha]_D = 66{\cdot}62°$, and "dextrose" to the amount of 15·83 per cent of the dry cloth.

On again evaporating to dryness the solution of the matter soluble in alcohol, and treating this new residue with cold, strong alcohol, a portion of it was left undissolved, though the undissolved matter was small in proportion to that which went into solution. This matter undissolved by alcohol was taken up with water, decolorised with bone-black, and tested with Fehling's liquor and in the polariscope. Taking the sugar found as "dextrose," the rotatory power was quasi-$[\alpha]_D = 63{\cdot}66°$, while the matter that dissolved in the alcohol gave quasi-$[\alpha]_D = 63{\cdot}69°$ when similarly tested.

Subsequent trials, made after the study of birch and maple woods as above described, gave the results which here follow:—Sixty grms. of the cotton cloth were left to soak during twenty-four hours with 70 c.c. of sulphuric acid of 90 per cent of H_2SO_4, the mixture was poured into enough boiling water to reduce the acid to the strength of 3·5 per cent, and the boiling was continued during three hours over a free flame. The filtrate was neutralised with barium hydroxide, and evaporated to a syrup which was treated with successive portions of strong alcohol, as long as the alcohol became coloured. The matter insoluble in alcohol gave quasi-$[\alpha]_D = 71{\cdot}76°$.

Attempts to obtain crystals from the matter insoluble in alcohol, by operating in the manner described on page 257, failed, though an abundance of inorganic matter was encountered. After expelling alcohol, by warming upon a water-bath the matter insoluble in alcohol, a small quantity of water was added to a portion of it, the mixture was heated to a temperature somewhat higher than 50°, and set aside in an exsiccator over sulphuric acid. The mass hardened somewhat, although no crystals appeared. Another portion was tested for mucic acid by treating it with nitric acid after it had been dried for a short time at about 100°, and left over-night in an exsiccator, but the precipitate formed by the action of nitric acid was found to consist wholly of inorganic matter. When ignited on platinum foil it did not blacken, but remained white and unchanged.

In the hope or removing this inorganic contamination, a part of the matter insoluble in alcohol was dissolved in water, a current of carbonic acid was passed through the solution during several hours, and the whole was boiled thoroughly. No precipitate of barium carbonate formed, not even when these processes were repeated a second time. The solution was then evaporated, and the residue was heated to 100°, after which it was taken up with water, and treated with dilute sulphuric acid added in slight excess. The precipitate of barium sulphate that formed was removed by filtration, and lead carbonate was added to the filtrate to get rid of the sulphuric acid. After filtration the solution had an acid reaction when tested with litmus paper, but it gave no precipitate when tested with barium nitrate. Sulphuretted hydrogen gas was passed to remove lead, the filtrate from the lead sulphide was evaporated to dryness, and the residue was treated with successive portions of strong alcohol of 93 per cent. The matter insoluble in alcohol gave a slight acid reaction on being dissolved in water, and a rotation of quasi-$[\alpha]_D = 111°$. The solution was again evaporated to dryness, and tested for crystals as before (see page 257), but none appeared. The dark brown syrupy mass, on being treated with successive small portions of pure methyl alcohol, dissolved completely. This methyl alcohol solution set aside in a cold room, in mid-winter dried down to a syrup of the same appearance as before; it was now washed with ethyl alcohol of 93 per cent until all traces of acidity had been removed from it. On being dissolved in water it tasted somewhat bitter, with a suggestion of sweetness. A portion of it was tested for mucic acid, with nitric acid, and none was found—a result which coincides with that of a similar trial made by Braconnot.

Yet another portion of the matter insoluble in alcohol (see above), was dissolved in water and filtered, dilute sulphuric acid was added, to precipitate barium, if possible, and subsequently lead carbonate to remove sulphuric acid. Sulphuretted hydrogen was passed to remove lead, and, since the solution gave an acid reaction after the removal of the lead sulphide, a new quantity of lead carbonate was added, and afterwards sulphuretted hydrogen. It appeared however, that the acidity could not be annulled by this method of procedure. It was only by evaporating the filtrate from the lead sulphide to the consistence of a syrup, and washing this syrup with strong alcohol, that the last traces of free acid were removed. The syrup thus washed, when freed from alcohol and dissolved in water, had a peculiar, disagreeable odour, and a sweetish though somewhat bitter taste.

After complete removal of the acidity the syrup was dried carefully at a temperature of 70° to 80° C., and finally weighed after it had been heated for a short time to 100°. The rotatory power of this matter, based on the

* *Bulletin of the Bussey Institution*, 1900, vol. ii., Part 9.

actual weight of the solution examined, was found to be $[\alpha]_D = 63{\cdot}22°$; and on testing the solution with Fehling's liquor it appeared that the reducing power was 0·2163, that of pure dextrose being regarded as equal to 1—that is to say, the reducing power was about one-fifth that of pure dextrose anhydride. It is noteworthy that on calculating the rotatory power from the quantity of "dextrose"—that is, reducing matter—shown by Fehling's liquor to be present in a measured volume of the solution, the extraordinary figures quasi-$[\alpha]_D = 330{\cdot}9°$, were obtained.

For the sake of testing more explicitly than had been done in any of the foregoing experiments, some current statements as to the large percentage of dextrose that may be obtained on hydrolysing cotton, after treatment with strong sulphuric acid, the following trials were made:—

I. After Flechsig (*Zeit. fur Phys. Chem.*, vii., 528), 250 grms. of air-dried, well-worn cotton cloth, that had been cut into small fragments, were put, little by little, into a cooled mixture of 1250 grms. commercial sulphuric acid of 92·5 per cent H_2SO_4 and 420 grms. of water. After the lapse of one hour the mixture of cotton and acid was diluted with two-thirds its volume of water, and the whole was left to stand for one day. According to Flechsig, the mixture should now have been filtered; but it was so thick and adhesive that filtration was simply impossible. Instead, therefore, of filtering and making up the volume of the filtrate to 2·5 litres, enough water (some 700 c.c.) was added to the mixture of acid and cotton to bring its volume up to 2·5 litres, and it was found to be practicable to filter this mixture slowly with the aid of a suction pump. From the filtrate thus obtained, 50 c.c. were taken and mixed with water enough to bring the volume up to 900 c.c.; and the solution thus diluted was boiled over a free flame for six hours, in a flask with a reflux condenser, and then neutralised with a hot solution of barium hydroxide. Finally, a small quantity of barium carbonate was added to complete the neutralisation. After filtration the neutralised liquor was evaporated to the volume of 97 c.c. It gave quasi-$[\alpha]_D = 54{\cdot}64°$, and Fehling's liquor indicated dextrose enough to amount 30·26 per cent of the cotton taken (regarded as dried at 100°).

Returning now to the soft, pasty mass which remained undissolved when the mixture of strong acid and cotton was diluted with water, efforts were made to wash and collect this material in order that its weight might be subtracted from that of the cotton taken. To this end it was stirred up repeatedly with fresh portions of water, and re-filtered many times. Although it still retained an acid taste, the greyish mass was dried somewhat on a water-bath, where it turned brown and eventually black. As soon as the pasty particles had begun to ball together on stirring a new attempt was made to wash the material, but it became pasty again on the addition of water. Finally, the matter was dried at 100° in a current of air and weighed. It amounted to 27·82 per cent of the original cotton dried at 100°. From the nature of the case, the subtraction of this highly impure material from the weight of the cotton can be regarded as affording only a rough approximation to the quantity of cotton that escaped solution; but it is noteworthy that, after the subtraction of this insoluble matter, the percentage of dextrose yielded by the cotton cloth, minus the insoluble matter, amounted to no more than 41·92 per cent of the dry cotton.

A quantity of the clear neutralised filtrate, resulting from the hydrolysis of the dissolved cotton, was evaporated to dryness on a water-bath, and the residue was treated with several successive portions of cold, strong alcohol. Apparently, less than half of the residue dissolved; and, from evidence presented on previous pages, it is to be presumed that some part of this substance insoluble in alcohol must have been inorganic matter. After expelling the alcohol and dissolving in water, the matter insoluble in alcohol gave quasi-$[\alpha]_D = 55{\cdot}25°$, and Fehling's liquor indicated enough dextrose to amount to 17·38 per cent of the original cotton (dried at 100°), or to 24·07 per cent of the cotton, after subtraction of that portion of the cotton which was left undissolved by the sulphuric acid.

Although the percentage of dextrose obtained in this particular instance is very much less than the quantity reported by Flechsig in the experiment made by him, of which the trial here reported is a repetition, it is noteworthy that the rotation observed (quasi-$[\alpha]_D = 54{\cdot}64°$) is decidedly nearer that of pure dextrose than had ordinarily been detected in any of the very large number of tests made in this laboratory on products of the hydrolysis of cotton and woods of various kinds. Moreover, the rotation here exhibited by the matter insoluble in alcohol (quasi-$[\alpha]_D = 55{\cdot}25°$), is much nearer that of pure dextrose than had been observed in this laboratory in any previous instance where analogous materials were tested. But in the previous trials, the condition under which the hydrolysis of the cotton had been carried out were less closely akin to those commended by Flechsig than in the present instance, where his method of procedure was copied as closely as possible.

It would appear, therefore, that Flechsig's method of hydrolysing cotton, by means of acid of special strength, has real merit, although the conversion of cellulose to dextrose may perhaps never be so nearly complete as he was led to believe.

II. The following trial was meant at first to be in precise imitation of the work of Winterstein (*Die Landwirthschaftlichen Versuchs-Stationen*, 1892, xiv., 383), though the method finally adopted differs from his in that lead carbonate was here used to neutralise the acid product of the hydrolysis:—

0·9302 grm. of worn cotton cloth, dried at 100°, were rubbed up with 5 grms. of sulphuric acid of 92·5 per cent H_2SO_4, and allowed to stand during twelve hours. After diluting with water, the brown solution was thrown upon a tared filter, which retained nothing. The solution was made up to 200 c.c., and boiled during two hours. A sediment formed which, on being collected, washed, dried, and weighed, was found to amount to 0·043 grm. The clear filtrate was neutralised with lead carbonate. After filtration sulphuretted hydrogen gas was passed to remove any dissolved lead, and the solution was filtered and boiled to remove the excess of sulphuretted hydrogen. On being tested with Fehling's liquor sugar enough was found to amount to 52·34 per cent of the dry cotton taken, or to 54·87 per cent of that cotton, if we subtract from the weight thereof the weight of the small quantity of insoluble matter that was deposited during the hydrolysis. These last figures correspond to 49·4 per cent of the theoretically possible dextrose (111·1), which might be obtained from 100 parts of cellulose if it were practicable to change the whole of it to dextrose. The rotatory power of the solution was found to be quasi-$[\alpha]_D = 125{\cdot}2°$.

The larger part of the solution was evaporated to the consistence of syrup, which was treated with cold, strong alcohol, in which some of it dissolved; hot alcohol dissolved little more of it than cold alcohol did. The dextrin-like residue insoluble in strong alcohol was dried at 70° C. until it ceased to lose weight. There was 0·299 grm. of it, which was dissolved in 50 c.c. water. The reducing power of this solution was tested carefully with Fehling's liquor in comparison with that of a solution of pure dextrose. It appeared that while the reducing power of dextrose anhydride was 1, that of the matter insoluble in alcohol was 0·4122. In a previous trial, where the dextrin-like material had been prepared by a more circumstantial process, a reducing power of 0·2163 was observed, as has been said.

It must be observed, however, that neither of these tests of the reducing power of the "matter insoluble in alcohol" was wholly satisfactory. I am inclined to believe, indeed, that the use of lead carbonate for neutralising the acid products of hydrolysis is inadmissible. The extremely high and manifestly abnormal rotatory power of several of the "dextrins" observed after the use of the lead

carbonate make it evident that the results obtained after neutralising with this agent are not directly comparable with those got by means of barium and calcium compounds. Several chemists have called attention to the fact that by the action of one or another lead compound on sugar the rotatory power and other properties of the sugar may be changed, and it would seem that this remark must be true also of the case where lead carbonate is used for purposes of neutralisation. It was very noticeable withal in my experiments that the syrups obtained by evaporation after the use of the lead carbonate were of decidedly darker colour than those got by neutralisation with calcium carbonate or barium carbonate or hydroxide; they were, in fact, very dark, and of unpleasant, molasses-like appearance.

A satisfactory method of separating quantitatively the dextrose and "dextrins" obtained on hydrolysing cellulose from the acid and other matters with which they are admixed is still to be desired.

(To be continued).

(Concluded from p. 275).

87. "*The Condensation of Ethylphenylketone with Benzaldehyde.*" By R. D. ABELL, B.Sc.

Under the influence of a 20 per cent solution of sodium ethylate, ethylphenylketone reacts with benzaldehyde to form:—(1) 1 : 3-diphenyl-2 methyl-trimethylene glycol, colourless needles, m. p. 98—99°; (2) impure benzal-propiophenone, as a yellow oil, boiling at 210—213° (23 m.m.); (3) 1 : 3-dimethyl-1 : 3-dibenzoyl-2-phenylpropane, $C_{25}H_{24}O_2$, plates, m. p. 162—163°.

If sodium methylate be similarly employed, only the first two are obtained, whilst a solution of potassium hydroxide in aqueous alcohol gives only benzalpropiophenone, which may be more satisfactorily prepared by using hydrochloric acid gas as the condensing agent.

If the first substance (the glycol) be oxidised by means of chromic acid, methyldibenzoylmethane is produced, and this, by the action of hydrazine hydrate, gives 3 : 5-*diphenyl-4-methylpyrazol*, which melts at 222—223°.

Benzalpropiophenone readily unites with bromine to form *benzalpropiophenone dibromide*, which is obtained as a viscid green oil by adding a solution of bromine in chloroform to one of benzalpropiophenone in the same solvent. Benzalpropiophenone with phenylhydrazine gives a *hydrazone*, $C_{22}H_{20}N_2$, yellow needles, m. p. 127—128°.

As it seemed probable that for the preparation of the third substance the previous formation of benzalpropiophenone was necessary, a mixture of equimolecular quantities of benzalpropiophenone and ethylphenylketone was treated with sodium ethylate, when a compact crystalline mass was obtained which by re-crystallisation from alcohol was separated into two isomeric compounds having the formula $C_{25}H_{24}O_2$, one in the form of plates, m. p. 162—163°, identical with the 1 : 3-dimethyl-1 : 3-dibenzoyl-2-phenylpropane mentioned above, and the other as needles, m. p. 121—122°.

Sodium methylate cannot be used instead of the ethylate in this reaction.

When the isomeride, m. p. 162—163°, was heated with alcoholic ammonia, much resinous matter was formed together with a small quantity of a substance crystallising in needles, m. p. 155—156°, which from the percentage of nitrogen found may be either triphenyldimethyl dihydropyridine, $C_{25}H_{23}N$, or triphenyldimethyl pyridine, $C_{25}H_{21}N$.

This substance was also obtained by the action of hydroxylamine hydrochloride on both isomerides.

88. "*A New Method for the Determination of Hydrolytic Dissociation.*" By R. C. FARMER, B.Sc., Ph.D.

The usual method for the determination of hydrolytic dissociation by the velocity of saponification of an ester is not applicable in certain cases, particularly those in which the acid or base under investigation is difficultly soluble in water, and is precipitated during the reaction. The author has therefore devised a new method, in which the free acid or base is determined by distribution between two solvents.

An aqueous solution of the salt of a weak acid or base is shaken with a known amount of benzene or some other suitable solvent, which extracts only one of the dissociation products. From the amount extracted, the degree of hydrolysis of the salt can be calculated, the coefficient of distribution for the substance between the two solvents having been previously determined. The method was tested with a salt of hydroxyazobenzene. The values obtained at different dilutions agreed with those required by the law of dilution given by Arrhenius. The mean values found for the hydrolytic dissociation of a salt of hydroxyazobenzene at 25° were as follows:—

Dilution in litres	32	50	64	80	100
Percentage hydrolysis ..	0·91	1·09	1·24	1·32	1·60

Owing to the intense colour of the hydroxyazobenzene, the estimations had to be carried out gravimetrically. In most cases, volumetric methods could be used with advantage, both as regards rapidity and accuracy. Similar experiments with weak bases have not yet been attempted.

89. "*The Production of some New Metallic Borides.*" By S. A. TUCKER, Ph.B., and H. R. MOODY, B.S., M.A.

The authors describe the formation and properties of four new borides, those of zirconium, chromium, tungsten, and molybdenum. These compounds were prepared by bringing an intimate mixture of the metal with boron under the influence of a temperature produced by a current of from 200 to 275 ampères, and 60 to 75 volts in the electric furnace.

Combination takes place in a few minutes with the formation of compounds which are crystalline, hard, of a high specific gravity, not easily attacked by acids, and having very high melting points. The compounds thus prepared have the following formulæ:—ZrB_4, CrB, WB_2, and Mo_3B_4.

The authors were unable to produce the borides of copper and of bismuth in a like manner, and it seems therefore as if boron had no affinity for the members of the copper group, but that it combines readily with the members of the iron group.

90. "*The Action of Lead Thiocyanate on the Chlorocarbonates.* Part II. *Carboxymethyl- and Carboxyamyl-thiocarbimides and their Derivatives.*" By R. E. DORAN.

The author has already described (*Trans.*, 1896, lxix., 324), the preparation and properties of carboxyethyl-thiocarbimide and its derivatives, and this continuation of his work deals chiefly with the thiocarbamides, thioureas, and thiocarbamates obtained from its methyl and amyl homologues. No attempt was made in this case to isolate the parent substances, but the following compounds were prepared, identified, and are described in detail:—

ab-*Carboxymethylphenylthiocarbamide*,—

$CH_3O{\cdot}CO{\cdot}NH{\cdot}CS{\cdot}NH{\cdot}C_6H_5$,

white needles, m. p. 158°; ab-*carboxymethylbenzylthiocarbamide*, $CH_3O{\cdot}CO{\cdot}NH{\cdot}CS{\cdot}NH{\cdot}CH_2{\cdot}C_6H_5$, needles, m. p. 134°; ab-*carboxymethyl-o-tolylthiocarbamide*, $CH_3O{\cdot}CO{\cdot}NH{\cdot}CS{\cdot}NH{\cdot}C_6H_4{\cdot}CH_3$, needles, m. p. 172°; ab-*carboxymethyl-p-tolylthiocarbamide*,—

$CH_3O{\cdot}CO{\cdot}NH{\cdot}CS{\cdot}NH{\cdot}C_6H_4{\cdot}CH_3$,

short prisms, m. p. 158°; ab-*carboxymethyl-α-naphthylthiocarbamide*, $CH_3O{\cdot}CO{\cdot}NH{\cdot}CS{\cdot}NH{\cdot}C_{10}H_7$, needles, m. p. 193°; ab-*carboxymethyl-β-naphthylthiocarbamide*, $CH_3O{\cdot}CO{\cdot}NH{\cdot}CS{\cdot}NH{\cdot}C_{10}H_7$, minute needles, m. p. 184°; ab-*carboxymethylmethylthiocarbamide*, $CH_3{\cdot}O{\cdot}CO{\cdot}NH{\cdot}CS{\cdot}NH{\cdot}CH_3$, needles, m. p. 146°; ab-*carboxymethylethylthiocarbamide*, $CH_3O{\cdot}CO{\cdot}NH{\cdot}CS{\cdot}NH{\cdot}C_2H_5$, needles, m. p. 86°; ab-*carboxymethylisobutylthiocarbamide*, $CH_3O{\cdot}CO{\cdot}NH{\cdot}CS{\cdot}NH{\cdot}C_4H_9$, long prisms, m. p. 83°; *carboxymethylthiourea*, $CH_3O{\cdot}CO{\cdot}N{:}C(NH_2)SH$, short prisms, m. p. 166°; *carboxymethylpiperidylthiourea*, $CH_3O{\cdot}CO{\cdot}N{:}C(SH){\cdot}N{:}C_5H_{10}$, needles, m. p. 97°; *carboxymethylphenylsemithiocarbazide*, $CH_3O{\cdot}CO{\cdot}NH{\cdot}C(SH){:}N{\cdot}NH{\cdot}C_6H_5$, glistening plates, m. p. 180°; *methyl carboxymethylthiocarbamate*, $CH_3O{\cdot}CO{\cdot}NH{\cdot}CS{\cdot}OCH_3$, feathery needles, m. p. 45°; *ethyl carboxymethylthiocarbamate*, $CH_3O{\cdot}CO{\cdot}NH{\cdot}CS{\cdot}OC_2H_5$, needles, m. p. 83°; *benzyl carboxymethylthiocarbamate*, $CH_3O{\cdot}CO{\cdot}NH{\cdot}CS{\cdot}OCH_2{\cdot}C_6H_5$, cream-white needles, m. p. 103°.

Derivatives of carboxyamylthiocarbamide:—

ab-*Carboxyamylphenylthiocarbamide*,—

$$C_5H_{11}O{\cdot}CO{\cdot}NH{\cdot}CS{\cdot}NH{\cdot}C_6H_5,$$

white needles, m. p. 97—98°; ab-*carboxyamyl-o-tolylthiocarbamide*, $C_5H_{11}O{\cdot}CO{\cdot}NH{\cdot}CS{\cdot}NH{\cdot}C_6H_4{\cdot}CH_3$, white needles, m. p. 96—97°.

Carboxyamylthiourea was also obtained, but in too small a quantity to permit of its satisfactory identification.

91. "*The Chlorine Derivatives of Pyridine.* Part VII. *Some Condensation Products.*" By W. J. Sell, M.A., F.R.S., and F. W. Dootson, M.A.

A series of experiments having for their object the determination of the orientation of a compound, $C_{10}HCl_{11}N_2$, which has been obtained by the action of chlorine on pyridine hydrochloride, together with certain of its derivatives (*Trans.*, 1899, lxxv., 980) was described.

This substance, which is the principal product of the chlorination, may be crystallised unaltered from chloroform or acetone, but if the solvent contains the hydroxyl group the compound is decomposed. With benzoic and other acids it reacts, giving a theoretical yield of the acid chloride in accordance with the equation—

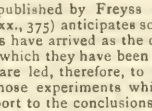
$$C_{10}HCl_{11}N_2 + C_6H_5CO_2H = C_6H_5COCl + C_{10}HCl_9N_2O + HCl.$$

The accompanying formulæ exhibit the relationship between the parent compound and certain of its derivatives.

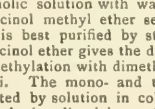
92. "*The Diazotisation of Dinitroanisidine and the Constitution of the Resulting Product.*" By R. Meldola, F.R.S., and J. V. Eyre.

A paper just published by Freyss (*Bull. Soc. Ind. de Mulhouse*, 1901, lxx., 375) anticipates some conclusions at which the authors have arrived as the outcome of an investigation upon which they have been engaged since last October. They are led, therefore, to place upon record the results of those experiments which appear to give independent support to the conclusions of the author just named. This work is an extension of that already published (Meldola and Wechsler, *Trans.*, 1900, lxxvii., 1172; *Proc.*, 1898, xiv., 226).

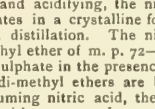
The crystalline diazo-compound, obtained by the action of a nitrite on dinitroanisidine in acetic acid solution, is a diazoxide of the formula—



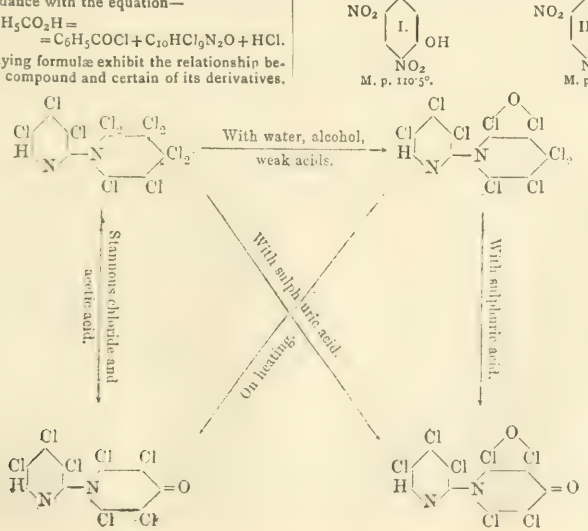
The proof of this constitution is given by several considerations, some of which appear from the experiments of Freyss, the most cogent, perhaps, being its ready convertibility into nitromethylresorcinol, $C_6H_3{\cdot}NO_2{\cdot}OH{\cdot}OCH_3 = 1:2:4$. The authors find the most convenient method for bringing about this conversion is to dissolve the diazoxide in alcoholic sodium hydroxide. The decomposition takes place at the ordinary temperature, with the evolution of nitrogen and the formation of aldehyde. On diluting the alkaline alcoholic solution with water and acidifying, the nitroresorcinol methyl ether separates in a crystalline form, and is best purified by steam distillation. The nitroresorcinol ether gives the dimethyl ether of m. p. 72—73° on methylation with dimethyl sulphate in the presence of alkali. The mono- and the di-methyl ethers are both nitrated by solution in cold fuming nitric acid, the dimethyl ether dissolving at first with a green colour. The corresponding dinitro-derivatives have the constitutions:—



M. p. 110·5°.



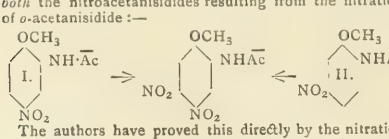
M. p. 154°.



The first of these crystallises from alcohol in large yellow plates. The second crystallises in small white needles from alcohol, and in very minute needles from boiling water; it is obtained also (mixed with colouring matters) by the direct nitration of resorcinol dimethyl ether in acetic acid with excess of fuming nitric acid, and its constitution as a derivative of resorcinol is thus confirmed. The nitroresorcinol monomethyl ether benzoylates very readily by the Schotten Baumann method. The benzoyl derivative, $C_6H_3{\cdot}NO_2{\cdot}OC_7H_5O{\cdot}OCH_3 = 1:2:4$, crystallises from alcohol in flat white needles melting at 95°. The nitro-derivative, when dissolved in acetic acid, gives an intense blue colour on the addition of zinc dust. If reduced with zinc dust and acetic acid in the presence of acetic anhydride, the acetamino-derivative, $C_6H_3{\cdot}NHAc{\cdot}OH{\cdot}OCH_3 = 1:2:4$, is obtained. This crystallises from water in lustrous flat white needles, which become brown on exposure to the air. The melting-point is 164—165°.

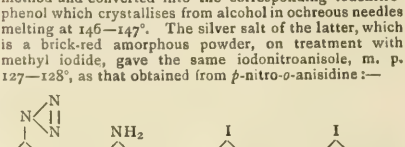
The diazoxide is remarkably stable towards acids; it can be boiled with dilute hydrochloric or sulphuric acid and can be crystallised from boiling glacial acetic acid or from acetic anhydride without undergoing decomposition. It is decomposed on boiling with hydriodic acid solution, and the product is iodonitroresorcinol methyl ether (Meldola and Wechsler, *loc. cit.*, 1173), $C_6H_2{\cdot}OCH_3{\cdot}OH{\cdot}NO_2{\cdot}I = 1:3:4:6$. The azo-β-naphthol derivative described in the former note (*loc. cit.*) has the formula $C_6H_4{\cdot}NO_2{\cdot}OCH_3{\cdot}OH{\cdot}N_2{\cdot}C_{10}H_6{\cdot}OH$. In addition to the properties already assigned to this compound, it may be added that it is distinctly phenolic in character, dissolving in cold aqueous alkali with a dull claret-red colour and being precipitated unchanged by acids. The phenolic character is due to the hydroxyl group in the para-position. An examination of the product of the action of ammonium sulphide on the azo-compound has shown that no aminoazo-compound is formed, and this is in accordance with the view that the nitro-group is not in the para-position with respect to the azo-group (Meldola, *Trans.*, 1883, xliii., 425).

The constitution of dinitroanisidine (m. p. 188°) first described (Meldola and Wechsler, *loc. cit.*) follows from the fact that it is obtainable by the further nitration of *both* the nitroacetanisidides resulting from the nitration of *o*-acetanisidide:—



The authors have proved this directly by the nitration of carefully purified specimens of the mononitroacetyl derivatives. No. I. was prepared by the reduction of dinitroanisole and acetylation of the nitroanisidine (Meldola, Woolcott, and Wray, *Trans.*, 1896, lxix., 1330). No. II was prepared from the corresponding nitroanisidine, the latter being obtained pure, by a modification of the method formerly described (*Proc.*, 1898, xiv., 226). The mixture of nitroacetyl derivatives resulting from the nitration of *o*-acetanisidide is boiled with dilute alkali till completely hydrolysed. The mixed nitroanisidines on being dissolved in hot dilute sulphuric acid deposit, on cooling, silvery scales of the sulphate of the *p*-nitro-compound, $C_6H_3{\cdot}NO_2{\cdot}NH_2{\cdot}OCH_3 = 1:4:5$, the sulphate of the isomeric compound remaining in solution. The crystalline sulphate gives pure *p*-nitro-*o*-anisidine on treatment with dilute alkali and crystallisation of the product from hot water. In order to characterise further the two nitroanisidines and the dinitroanisidine, the benzoyl derivatives have been prepared:—$C_6H_3{\cdot}NO_2{\cdot}NH(C_7H_5O){\cdot}OCH_3 = 1:4:5$, white silky needles from alcohol, m. p. 149—150°; $C_6H_3{\cdot}NO_2{\cdot}NH(C_7H_5O){\cdot}OCH_3 = 1:3:4$, slender ochreous needles from alcohol, m. p. 160—161°; $C_6H_2{\cdot}(NO_2)_2{\cdot}NH(C_7H_5O){\cdot}OCH_3 = 1:2:5:4$, ochreous scales from acetic acid, m. p. 185—186°.

The constitution of the *p*-nitro-*o*-anisidine was proved by two methods differing from those adopted by Freyss, as well as by conversion into the *p*-nitro-guaiacol of m. p. 104°. The latter compound, of which the discovery is assigned to Rupe (*Ber.*, 1897, xxx., 2446), was first described by one of the authors (Meldola, *Proc.*, 1896, xii., p. 125). The *p*-nitro-*o*-anisidine when diazotised and the amino-group replaced by iodine in the usual way, gave an iodonitroanisole which crystallised in straw-coloured needles melting at 127—128°. The constitution of this compound might have been expected to correspond with that of the nitro-aminophenol, m. p. 201—202°, obtained by Friedländer and Zeitlin (*Ber.*, 1894, xxvii., 196) by heating *p*-nitrobenzenediazimide with sulphuric acid. Some of the nitroaminophenol was prepared by this method and converted into the corresponding iodonitrophenol which crystallises from alcohol in ochreous needles melting at 146—147°. The silver salt of the latter, which is a brick-red amorphous powder, on treatment with methyl iodide, gave the same iodonitroanisole, m. p. 127—128°, as that obtained from *p*-nitro-*o*-anisidine:—



The other method consisted in combining the diazotised nitroanisidine with β-naphthol in the usual way and reducing the nitroazo-compound to an aminoazo-compound by ammonium sulphide. The nitroazo-compound is obtained as a scarlet precipitate on mixing solutions of the diazonium salt and β-naphthol dissolved in sodium hydroxide. It crystallises from glacial acetic acid, in which it dissolves with difficulty, in filamentous needles of a dull red colour with a slight metallic reflex. Its melting-point is 269°. It dissolves in alcoholic soda with a violet colour and with a similar colour in strong sulphuric acid, the latter solution becoming redder on dilution with water. The solution in alcoholic soda becomes red on heating with ammonium sulphide, and on dilution with water the aminoazo-compound, $NH_2{\cdot}C_6H_3{\cdot}OCH_3{\cdot}N_2{\cdot}C_{10}H_6{\cdot}OH$, separates out in bronzy scales. The melting-point of this compound is above 300°. It dissolves in alcohol with a Bordeaux-red colour, which becomes orange on adding hydrochloric acid. It dissolves in hot aqueous hydrochloric acid with a dull red and in strong sulphuric acid with a magenta-red colour, becoming more orange on dilution. The reducibility of the nitro-group without the separation of the nitrogen atoms of the azo-group may be taken as proof that the two groups are in the para-position with respect to one another.

The constitution of the nitroanisidine of Cahours (Meldola, Woolcott, and Wray, *loc. cit.*) was further proved by converting it into the corresponding iodonitroanisole by replacing the amino-group by iodine by the diazo-method. The iodonitroanisole, $C_6H_3{\cdot}NO_2{\cdot}I{\cdot}OCH_3 = 1:3:4$, melts at 95—96°, and is identical with that described by Reverdin (*Ber.*, 1896, xxix., 998).

Experiments were in progress to obtain direct evidence of the constitution of the dinitroanisidine at the time of appearance of the paper by Freyss. The triaminoanisole obtained by reducing the dinitroanisidine with tin and hydrochloric acid forms a crystalline hydrochloride, but it is very unstable, passing readily into a deep violet colouring-matter on exposure to the air. The dinitroacetanisidide does not give an anhydro-base on reduction, an observation which is in harmony with the view that the acetamino-group is not in the ortho-position with respect to a nitro-group. On the other hand, that the triaminoanisole contains two amino-groups in the ortho-position is proved by the formation of an azine with phenanthrene-

quinone. On heating together equimolecular weights of the triamine and the quinone in glacial acetic acid, the aminoazine is gradually formed, and on adding hydrochloric acid the hydrochloride is completely thrown out on cooling as a dull red precipitate. The free base is an ochreous powder which dissolves in alcohol with a magnificent green fluorescence. It does not readily crystallise, but separates from boiling toluene in the form of brown nodules having a melting-point of about 237°, but softening before this temperature. The base thus obtained contains one molecule of toluene and has the formulæ—

$$CH_3O\cdot NH_2\cdot C_6H_2\begin{cases}N\cdot C\cdot C_5H_4\\ |\quad |\\ N\cdot C_6H_4\end{cases} + C_7H_8.$$

The result of this investigation thus confirms the conclusion that on diazotising 3 : 4-dinitro-*o*-anisidine in acetic acid, it is the 4-nitro-group which is eliminated, probably in accordance with the scheme :—

$$CH_3O\cdot NO_2\cdot C_6H_2<\begin{matrix}N_2\cdot O\cdot H\\ NO_2\end{matrix} =$$

$$= CH_3O\cdot NO_2\cdot C_6H_2\begin{cases}N_2\\ |\\ O\end{cases} + HNO_2.$$

The more exact nature of the mechanism of the change will be made the subject of further investigation.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Note.—All degrees of temperature are Centigrade unless otherwise expressed.

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. Vol. cxxxii., No. 20, May 20, 1901.

Researches on the amount of Aluminium present in Vegetable Earths.—Th. Schloesing.—The greater number of specimens of earths from Madagascar which the author carefully examined in the course of his research, contain, often in considerable quantity, free alumina. This metal is also present as the silicate; the latter being very easily acted upon by a dilute solution of soda. The alumina and the silicate are present for the most part in a sandy condition, and do not form the agents of tenacity in the earths. Finally, the author finds that their presence appears to present no obstacle to vegetation.

Lowering of the Temperature of Maximum Density of Water produced by the Solution of Chlorides, Bromides, and Iodides of Potassium, Sodium, Rubidium, Lithium, and Ammonium; Ratio of these Lowerings amongst themselves.—L. C. de Coppet.—As in the case of the salts already examined, the lowering of the temperature of maximum density of water is proportional to the quantity of the substance dissolved. The molecular lowering is almost constant, the differences observed being attributable to experimental errors. The lithium salts, however, form an exception; their molecular lowering increases with the concentration of the solution, and this lowering is more accentuated for having been attributed to experimental errors. The author gives a table of the results obtained.

Alcohols and Carbide of Calcium.—Pierre Lefebvre.—In a previous paper, the author gave an account of the results obtained by passing the vapour of amyl chloride over calcium carbide heated to redness. This investigation is correlative to that which he now undertakes on the decomposition of the alcohols when passed over calcium carbide at a temperature of 500°. He examines the composition of the gases obtained when amyl alcohol, isobutylic alcohol, ethyl alcohol, and methyl alcohol are used. The gases in all cases consist of acetylene, ethylene, carbonic oxide, ethylenic carbides, ethane, hydrogen, and carbonic anhydride in varying proportions.

Condensation of the True Acetylenic Carbides with Formic Aldehyde. Synthesis of Primary Acetylenic Alcohols.—Ch. Moureu and H. Desmots.—By the condensation of the true acetylenic carbides, R—C≡CH, with formic aldehyde, CH_2O, the authors deduce a very simple method of synthesis of the primary acetylenic alcohols, R—C≡C—CH_2OH. After a number of fruitless attempts with an ordinary solution of formol and carbides in a free state in presence of various condensation agents, they were led to try to effect a reaction between the sodium carbides and the solid polymer, $(CH_2O)_n$, known under the name of trioxymethylene. The experiment succeeded excellently.

Action of Acid Chlorides on the Ether-oxides in presence of Zinc.—P. Freundler.—M. Freund has shown that when zinc acts on a solution of butyryl in ethyl oxide, a mixture of ethyl butyrate, ethyl chloride, and a compound corresponding to the formula of dibutyryl is produced, whilst, at the same time, zinc chloride is formed as a by-product. The action can be represented by the equation—

$$4C_3H_7.COCl + Zn + 2(C_2H_5)_2O = 2C_3H_7.CO_2C_2H_5 + 2C_2H_5Cl + ZnCl_2 + C_3H_7.CO.CO.C_3H_7.$$

The author's research confirms these conclusions. He acts with the zinc-copper couple on the chlorides of the acids, and finds his results coincident with the above, at least in so far as the formation of the ether salt and alcoholic chloride is concerned.

Oxidation of the Primary Alcohols by the Action of Contact.—J. A. Trillat.—The author's experiments show—(1) That all the primary alcohols of the fatty series are oxidisable under the influence of the platinum spiral; (2) that the oxidation of the aldehyde corresponding to the alcohol can be limited; (3) that the presence of water is not an obstacle to oxidation, but rather favours it; (4) that porous bodies and platinum black, under the experimental conditions employed by the author, give by oxidation the corresponding acids rather than the aldehydes; (5) the formation of the acetals under catalytic influence is constant at least for the first terms of the fatty series, besides which the action is reversible.

The Substitution of Zinc-white for White-lead in Oil-paints.—Ach. Livache.—Ever since 1782, efforts have been made to effect a substitution of zinc-white for white-lead in oil paints; these have in all cases proved unsuccessful. The author undertakes a methodical study of the subject. He obtained the various products employed in oil-painting, both with the base zinc oxide and the base white-lead; then, taking these as types, he examined the causes which render zinc-white inferior to white-lead. These causes once determined, he established formulæ which, if zinc-white is employed by the painter, would give results identical with the products obtained when white-lead is used as a base.

MISCELLANEOUS.

Decomposition of Albumenoids or Protoplasmides.—A. Etard.—The author finds that decalcified bones can be separated by simple hydrolysis into three groups of substances :—(1) Glycocoll, leucine, and a little tyrosine; (2) a syrupy substance which is very soluble in concentrated methyl alcohol; (3) a substance which is quite insoluble in concentrated methyl alcohol. A study of the two latter groups proves that bodies derived from albumenoids or protoplasmides should be considered as nitrated saccharides, a simple example of these being chitosamine.—*Comptes Rendus*, cxxxii., No. 19.

Elimination of a "Sulpho" Group by means of Reducing Agents.—F. J. Moore. (Preliminary notice).—The author having obtained some *p*-sulphocinnamic acid, tried, by treating it with sodium amalgam, to prepare the hitherto unknown *p*-sulphohydrocinnamic acid, but he

obtained in its place hydrocinnamic acid which can be prepared much more easily with aluminium amalgam. For this purpose the sulphocinnamic acid is dissolved in 20 parts of water, and then aluminium filings impregnated with a solution of sublimate are added; this solution, which must be made alkaline, is left all night in a warm place, and then neutralised with HCl or H_2SO_4, and extracted with ether. The hydrocinnamic acid thus extracted crystallises in warm water in long, silky neeedles, fusible at 48°. If the experiment is interrupted after two or three hours there is no hydrocinnamic acid formed, but only cinnamic acid. The reaction probably takes place in two phases according to the equations:—

$$NaSO_3.C_6H_4.CH{=}CH.COONa+H_2=$$
$$=NaHSO_3+C_6H_5.CH{:}CH.COONa;$$

$$C_6H_5.CH{:}CH.COONa+H_2=C_6H_5.CH_2.CH_2COONa.$$

The elimination of the "sulpho" group from the benzenic radicle takes place, therefore, before hydrogenation. Qualitative experiments undertaken with the object of eliminating the sulpho group of benzene-sulphonic acid, or other sulphonic acids, by means of aluminium amalgam, were unsuccessful.—*Berichte*, vol. xxxiii., p. 2014.

Direct Nitration of the Primary Aromatic Amines.—E. Tauber and F. Walder.—During some work done on Bismarck-brown the authors found that *m*-phenylenediamine could be nitrated directly in spite of its two "amino" groups, giving a hitherto unknown mononitroso-*m*-phenylenediamine. The following is the method of procedure:—324 grms. of *m*-phenylenediamine are dissolved in 2·5 litres of water and 444 grms. of hydrochloric acid; 3 kilogrms. of ice are also added. When the temperature has fallen to 0°, a cold solution of 156 grms. of nitrite of soda in 600 c.c. of water is suddenly added all at once, and stirred vigorously for at least five minutes. After standing for a few hours the product of the reaction is brought to 50°, and the Bismarck-brown formed is precipitated with 800 grms. of sea-salt; this is filtered at 30°, and washed with 1 litre of salt water at 10 per cent. The filtrate is covered over with 3 litres of ether, after which 800 grms. of powdered soda crystals are gradually added; after a few hours the nitrated base is deposited in crystals at the zone of separation of the two liquids; then, after a further twelve hours, during which time the mass is frequently stirred, the crystals are filtered off, and washed with ether; the pure substance is obtained by crystallising it in 20 parts of boiling water. Nitroso-*m*-phenylenediamine occurs in the form of brilliant brownish-red flakes or needles belonging to the monoclinic system. It is easily soluble in ether and benzene, almost insoluble in cold water, and fuses at 210°. Its hydrochlorate occurs in long reddish-brown needles, or in brilliant, almost black, prisms. The authors intend to prepare derivatives of this nitrated base, and to examine the direct nitration of other amines.—*Berichte*, xxxiii., p. 2116.

MEETINGS FOR THE WEEK.

WEDNESDAY, 19th.—Institution of Mining and Metallurgy, 8. "Sulphide Ore Treatment (Phœnix Process)," by Edgar A. Ashcroft. "Mineral Features of Pahang, Malay Peninsula," by F. J. Stephens. Notes on Winding and Pumping Plant driven by an Oil Engine," by Ll. Parker. "Additional Notes on Mine Surveying'" by G. A. Troye. "Mining and Other Statistics of the Thirty Mexican States," by A. Cairn Hodge.

—— Microscopical, 8. "An Examination of the Abbe Diffraction Theory of the Microscope," by J. W. Gordon.

THURSDAY, 20th.—Chemical, 8. Ballot for the Election of Fellows. "The Direct Union of Carbon and Hydrogen" (Part II.), by W. A. Bone and D. S. Jerdan. "Ammonium and other Imidosulphites," by E. Divers and M. Ogawa. "Nitrilosulphates," by E. Divers and T. Haga. "The Decomposition of Hydrocarbons at High Temperatures," by W. A. Bone and D. S. Jerdan. "The Sugars from Cellulose," by H. J. H. Fenton. "On a Theory of Chemical Combination," by G. Martin. "On the Occurrence of Paraffins in the Leaf of Tobacco," by T. E. Thorpe, C.B., F.R.S., and John Holmes. "Studies in the Camphane Series" (Part IV.), by M. O. Forster. "On the Decomposition of Carbon Dioxide when submitted to Electric Discharge at Low Pressures," by J. N. Collie, Ph.D., F.R.S. "Two New Substances in Lemon Oil," by H. E. Burgess.

BIRKBECK INSTITUTION,

Breams Buildings, Chancery Lane, E.C.

DAY and EVENING LECTURES, with PRACTICAL WORK in—

CHEMISTRY .. J. E. MACKENZIE, Ph.D., D.Sc.
PHYSICS .. .. A. GRIFFITHS, D.Sc.
METALLURGY.. G. PATCHIN, A.R.S.M.

A Course of EIGHT LECTURES on the "HISTORY OF CHEMISTRY" will be given by Dr. J. E. MACKENZIE on FRIDAY EVENINGS, at 8.30, commencing on MAY 31.

Prospectuses on application to Secretary.

GENUINE WORKING RECIPES,
IN THE
OIL, GREASE, SOAP, PAINT, COLOUR, VARNISH, and ALLIED TRADES.
Latest Up-to-date Processes and Methods — English and Continental Household and Trade Specialities, in every line. (Many Unpatented).
Consultations—Correspondence by Letter.
Analysis—Samples Matched—Identicals Found—Samples and Articles Received for Testing and Analysis—Certificates Given—Contract Work Undertaken.
WRITE FOR FULL LIST, FREE.

ACETONE.
JOHS. OSWALDOWSKI,
ALTONA, near HAMBURG.

CHEMICALS, *Pure and Commercial.*
For Scientific and Technical Purposes.
Specialities: ETHERS, CHLOROFORM.
POLGLASE & CO., Tyne Vale Chemical Works, Skinnerburn-rd., NEWCASTLE-ON-TYNE.

COVERS FOR BINDING.
Cloth, Gilt-lettered Covers for Binding the Half-yearly Volumes of the
CHEMICAL NEWS
may now be obtained. *Price 1s. 6d. each.*
Volumes Bound in Cloth Cases, Lettered, and Numbered, at 2s. 6d. per volume.
6 & 7, CREED LANE, LUDGATE HILL, E.C.

ALUMINOUS EARTH, which has stood the test of time, is now the acknowledged best basis for Cement, Paint, Plasters, Boiler-covering Composition, Polish and Polishing Powders, Metal Burnishing, &c., and is the best Filling for Brown and Coloured Papers, Corduroys, Tarpaulins, &c.—For samples and cheap quotation, apply to the MANAGER, at the Works, Frongoch, near Bala, North Wales.

THE CHEMICAL NEWS.

Vol. LXXXIII., No. 2169.

ON AN EXPLANATION OF THERMAL CENTRES OF STABILITY IN COMPOUNDS.

By GEOFFREY MARTIN.

In a paper "On the Existence of Thermal Centres of Stability" (Chemical News, 1900, lxxxi., 301), I gave six instances of bodies capable of existing at moderate and at very high temperatures, but incapable of existing at intermediate temperatures. To this list must now be added the case of nitrogen peroxide, which, although completely dissociated at moderate temperatures, seems to be able to exist at very high temperatures (*Nature*, May 16th, 1901, vol. lxiv., p. 67).

The following will, I think, give an intelligible explanation of the phenomenon :—

Let us imagine, as is now very probable, that an atom is not the hard indivisible unit of Dalton, but rather a very complicated system of particles in perpetual motion, and has a mobile constitution. Now the mere fact of bringing atoms into contact with each other does not necessarily lead to chemical action. Something more is required. This is well emphasised by Baker's recent experiments on the influence of impurity on chemical change. The necessary condition appears to be an "opening up" of the complex atoms so as to set free the internal forces—a process otherwise known as ionisation. A chemical atom is therefore analogous to a closed ring compound in organic chemistry. They can aggregate together by mutual attraction, but, before they can chemically combine, the atomic ring must be broken, so that the lines of force which before were contained in the circuit of the atom can now radiate into space. The atoms can then, and then only, unite chemically with other atoms. The greater the ease with which the ring opens out the more chemically active is the element concerned.

Consider, now, a gaseous system of molecules contained in a closed vessel. Each of the atoms composing the molecule has a certain internal time rate of vibration. As previously explained, these atoms are composed of particles grouped into a closed ring like that of a benzene nucleus, and are chemically inactive until the ring is broken, when the atoms become ionised. The ring may be ruptured by setting one or more of the particles composing it into such rapid oscillatory motion as to sever its connection with neighbouring particles. This may be effected if periodic impulses act on the particle, their frequency being either equal to its natural time rate of vibration or some multiple of it.

Now, as a given molecule flies through space, there is a continual flux of other molecules past it in every direction. These fluxing molecules will cause a continual variation in the intensity of the force acting on a given molecule—the ether strain increasing with the approach of a molecule and diminishing as it recedes. If many such molecules approach and recede in each second, the variations in ether strain will succeed each other with enormous rapidity. Suppose, now, this rate of variation of ether strain approaches in numerical value the natural time rate of vibration of some one particle of those composing the atomic ring, this particle will be set vibrating by a process analogous to resonance, and the rapid oscillatory motion thus produced may become so violent as to cause it to sever its connection with neighbouring particles. The ring will thus be ruptured, and the atoms will become "ionised," and therefore will react chemically on other atoms. No chemical reaction can take place until the atoms of the reacting molecules are thus ionised. Chemical combination will continue until the rate of variation of the ether strain no longer corresponds to the rate or rates of vibration of the atoms.

The bodies concerned will cease to act chemically on each other when this occurs.

But suppose now the temperature to be greatly increased, then a point will be reached when the rate of variation of ether strain will again correspond to twice, thrice, &c., the rate of vibration of the atom, and in this case again the atom will be so internally disturbed as to open out and allow chemical combination to take place once more. This then explains the recurrent nature of chemical action as instanced in the examples given in my former paper. It also explains phenomena like the phosphoresence of phosphorus which is dependent upon the narrow limits of temperature and pressure, for it is obvious that the rate of variation of ether strain due to rapidly passing atoms will vary with the temperature and pressure.

Merchant Venturers' College, Bristol,
May 25th, 1901.

A BIBLIOGRAPHY OF STEEL WORKS ANALYSIS.

Part IX.

By HARRY BREARLEY.

(Continued from p. 172).

PHOSPHORUS.

An enormous number of papers have been written on the estimation of phosphorus. Those relating exclusively to the analysis of agricultural material, except when dealing with the chemistry of the process, are not noticed. Amongst the papers dealing with metallurgical materials, there is so much repetition that a selection of those presenting new features, and a grouping together of papers on similar lines, was necessary in order to make this section of the compilation usable. The classification is :—

I. Separations from other Elements.
II. Gravimetric Estimations.
  a. Precipitating Finally with Mo.
  b. Precipitating Finally with Mg.
  c. Precipitating Finally in Various Ways.
III. Volumetric Estimations.
  a. Of the Molybdate Precipitate.
  b. In Various Ways.
IV. Miscellaneous.

I. Separations from other Elements.

Iron and Aluminium.—

1195. Schulze (*C. N.*, i., 49).—Add Sb_2Cl_3 to neutralised solution, boil the precipitate with NaHO, filter off Sb, &c., and precipitate P in the filtrate with Mg.

1196. Girard (*C. N.*, v., 281; vi., 99) and Antony and Mondolfo (*J. C. S.*, lxxvi., ii., 330).—Dissolve in HNO_3 along with Sn, dissolve SnO_2 in aqua regia, add Am_2S to precipitate traces of Fe, &c., and add Mg to the filtrate.

1197. Kessler (*C. N.*, xxiii., 76).—Dissolve Fe in HNO_3, evaporate, reduce with H_2S, precipitate with ferrocyanide, and add Mg to the filtrate. Mohr (*J. C. S.*, lii., 864).—Similarly. Titrate P with uranium solution.

1198. Chancel (*C. N.*, i., 72).—Precipitate from nitric solution with $AgNO_3$ and Ag_2CO_3; collect Ag_3PO_4, remove Ag as chloride, and precipitate P with Mg.

1199 Lyte (*C. N.*, iii., 131).—Pass H_2S to form FeO, and remove As, &c.; add $K\bar{A}$ and $Pb\bar{A}_2$, decompose

precipitate with Am_2S, and P from filtrate with Mg. Specially suited to separating P from Al and Cr.

1200. Mayer (*C. N.*, iv., 75).—Requisite proportions of reagents when P is precipitated from tartrate solutions in order to keep up tartrate of magnesia.

1201. Warington (*C. N.*, viii., 19).—Citric acid does not form insoluble Mg salts when used for holding up Fe and Al in AmHO solutions.

1202. Flight (*C. N.*, xxxi., 214).—Boil with hyposulphite. Fe and P in filtrate separated with Am_2S. Al and P in precipitate separated with NaHO and $BaCl_2$.

1203. Derome (*C. N.*, xl., 292).—Ignite with an excess Na_2SO_4, and precipitate Na_3PO_4, extracted with water, with Ur, Ag, or Mg.

Lime.—

1204. Smith (*C. N.*, vii., 212).—In the presence of tartaric acid, CaO can be precipitated as oxalate quite free from P.

1205. Williams (*C. N.*, xxi., 170).—As 1196; but dissolves the Sn-P compound in KHO, adds H_2S, &c.

1206. *SiO_2 and WO_3.*—Skey (*C. N.*, xvi., 187).—Both SiO_2 and WO_3 form insoluble compounds with P_2O_5, and on this account P estimations are frequently imperfect.

1207. *Vanadium.*—Holverscheit (*J. C. S.*, lviii., 1343).—Add SO_2 to form V_2O_4, expel excess, and precipitate P rapidly with Mo at 60° C.

1208. *Uranium.*—Reichardt (*C. N.*, xxviii., 315).—Dissolve in Na_2CO_3 and precipitate P with Mg.

1209. *Selenium.*—Same process as 942.

II. Gravimetric Estimations.

a. Precipitating Finally with Mo.—

1210. Eggertz (*C. N.*, ii., 227).—Precipitates from HNO_3-HCl solution of iron. The precipitate more soluble in 1 per cent HNO_3 than in water; tartaric acid prevents the precipitation (see 1279).

1211. Fresenius (*C. N.*, xii., 73).—The PMo* is not interfered with by HNO_3, H_2SO_4, Fe_2Cl_6, or Al_2Cl_6; it is by large amounts of HCl, AmCl, or dilution. The mixture is kept at 65° for six hours.

1212. Parry (*C. N.*, xxv., 229).—To solution of the metal add AmHO to complete precipitation, re-dissolve in HNO_3, and boil with a neutral solution of Am_2MoO_4.

1213. Holtoff (*C. N.*, xxxvi., 234).—PMo may be formed in the presence of HCl, but the temperature must be kept low. The precipitate is soluble in aqua regia, and MoO_3 is precipitated. The magnesia precipitate may contain Mo. The acetate-magnesia process gives low results.

1214. Deane (*C. N.*, liv., 174).—Usual process. The precipitate has a tendency to pass the filter when formed in very acid (nitric) solutions.

1215. Eggertz (*C. N.*, xlii., 87).—Deals with criticisms *re* the formation of the precipitate, its composition, reagents, estimation, and comparison with the Mo-Mg process.

1216. Hundeshagen (*C. N.*, lx., 169, 177, &c.).—The yellow precipitate is always $(NH_4)_3PO_4.12MoO_3$ when dried at 130—150° C. The influence of alkaline nitrates, concentration, temperature, and acidity. The formation of PMo from neutral solutions with HNO_3. The dissociation of PMo with HNO_3, and the limiting molecular proportions of its constituents for quantitative estimations. The solubility of PMo in various salts, acid, and water. P_2O_5 or MoO_3, may be estimated by titrating one against the other. Volumetric processes depending—(1) on the saturation of PMo with NaHO, and (2) on precipitating with HNO_3 from neutral solutions are outlined.

* Used throughout as a contraction for ammonium phosphomolybdate.

1217. Carnot (*C. N.*, lxvii., 101).—Preliminaries like 1241; but the PMo is dissolved and re-precipitated under well-defined conditions.

1218. Hanamann (*J. S. C. I.*, 1895, 598).—The P is precipitated and filtered at ordinary temperatures in order to assure a constant composition. Wash from the paper and ignite as 1239.

1219. Parry and Morgan (*C. N.*, lxvii., 161).—Dissolve in aqua regia and eliminate HCl. Any excess of nitric acid is corrected by AmHO after* the Am_2MoO_4 has been added.

1220. Villiers and Borg (*C. N.*, lxvii., 313).—The precipitation should be effected below 15°. In the presence of Fe and Al, a pure precipitate is not obtained.

1221. Johnson (*C. N.*, lxx., 157).—Above 50° the PMo is contaminated with Fe, Al, and Mn. The citrate method gives good results only by compensatory errors.

1222. Tauber (*J. I. S. I.*, 1883, 313).—The influence of $AmNO_3$. Mo in the $Mg_2P_2O_7$ precipitate can be eliminated at high temperatures.

1223. Huss (*J. C. S.*, I., 1073).—AmCl added to the $Fe_2(NO_3)_3$ solution in order to form Fe_2Cl_6 and $AmNO_3$. Vorwerk (*J. C. S.*, lii., 299).—The results are low on account of the undecomposed nitrated carbon compounds.

1224. Lucas (*J. C. S.*, lxxiv., ii., 482).—Chlorides prejudicial. Ratio of MoO_3 to Fe present should be 3 to 2, and temperature 80°.

1225. Handy and Lœffler (*J. I. S. I.*, 1894, i., 612).—P is not completely precipitated by five minutes' shaking at 25° (see 1253).

1226. Phillips and Carnahan (*J. I. S. I.*, 1814, i., 612).—Use a stream of gas or air for accelerating the precipitation of the P.

1227. Schmœger (*J. C. S.*, lxxii., ii., 230).—P is completely precipitated by Mo in the presence of citric acid.

1228. Tamm (*C. N.*, xlix., 208).—P may be imperfectly precipitated when organic acids due to combined carbon are not destroyed. Prescribes the best mode of decomposing the iron, &c. Ores must be fused in order to get all the P into solution.

1229. Wood (*C. N.*, lii., 279).—By dissolving Fe in HNO_3 and at once adding Mo, exactly two-thirds of the P is precipitated. After boiling with CrO_3, all the P is precipitated. SiO_2 need not be separated.

1230. Eggertz (*J. S. C. I.*, 1884, 179).—By merely dissolving and adding Mo as above, three-fourths of the P is precipitated. Deficiency due to existence of P other than as orthophosphate.

1231. Schneider (*J. I. S. I.*, 1893, i., 407).—The nitric acid solution is further oxidised in order to change all the P to orthophosphate, and not to destroy organic acids. $KMnO_4$ is better than CrO_3 or H_2O_2. The MnO_2 should be re-dissolved by $FeSO_4$ and not oxalic compounds.

1232. Hamilton (*J. S. C. I.*, 1891, 904).—Showing that incomplete precipitation from nitric acid solutions is not due to carbonaceous matter, but to incomplete oxidation of the P.

1233. Cheever (*J. I. S. I.*, 1884, 715; and 1885, 364).—Oxidise the iron solution with HNO_3+KClO_3, dissolve the MnO_2 in HCl, eliminate chlorine, and precipitate with Mo as usual.

1234. Reis (*J. I. S. I.*, 1887, ii., 365).—Oxidation with CrO_3 causes Cr to be occasionally precipitated with the P. Oxidise with $KMnO_4$, destroy excess with HCl, and proceed as usual. Or add $SnCl_2$ to the HCl solution of the yellow precipitate and titrate the excess with permanganate.

1235. McKenna (*J. I. S. I.*, 1894, i., 612).—Oxidation of

* AmHO added after the Am_2MoO_4 accelerates the formation of the PMo, but generally gives high results.—H. B.

chilled iron solutions with $KMnO_4$ gives lower results than evaporation to dryness.

1236. Ibbotson and Brearley (*C. N.*, lxxxii., 270)—SiO_2 removed by evaporation with acids contains some P (1206). Dissolve ferro-silicon in HNO_3+HF, and proceed as in 1348).

1237. Finkener (*C. N.*, xxxix., 42; and xlvii., 94).—Precipitate from solutions containing large amounts of $AmNO_3$, wash with very acid 20 per cent $AmNO_3$, dissolve from the paper, and expel $AmNO_3$ by gentle ignition.

1238. Troilius (*C. N.*, xliv., 299). — Dissolve in HNO_3+HCl. Expel HCl. PMo dried at 95—140°, or may be ignited so gently as to get rid of the paper without loss of weight.

1239. Meinecke (*C. N.*, liii., 53).—Add Mo at 50—60°, and allow to settle in the cold. Ignite at 400—500°; the paper separately. Residue contains 4·02 per cent P_2O_5, or, more accurately (*J. I. S. I.*, 1896, i., 540), 3·95 per cent P_2O_5.

1240. Vorwerk (*J. I. S. I.*, 1887, i., 465).—Oxidise nitric acid solution with CrO_3, and ignite PMo as 1239; ignited precipitate contains 1·754 per cent P. Si does not interfere with the precipitation of the P. Digestion with CrO_3 does not complete the oxidation of spiegels.

1241. Anon. (*C. N.*, lxii., 28).—Oxidise the nitro-sulphuric solution with CrO_3, and ignite PMo as 1239 to $P_2O_5Mo_{24}O_{68}$.

1242. Neumann (*J. C. S.*, lxxiv., ii., 454) and Sherman and Hyde (*J. C. S.*, lxxviii., ii., 757).—The PMo is ignited to $P_2O_5.24MoO_3$ by placing the platinum crucible within a porcelain one well into a Bunsen flame.

1243. Carnot (*C. N.*, xlix., 216).—All the P (in rocks, &c.) is precipitated along with some Al_2O_3 by boiling with hyposulphite and acetate. Ignite, dissolve in HNO_3, and add Mo.

1244. Lechartier (*C. N.*, xlix., 224).—Digest (soil) with aqua regia, precipitate Fe, &c., with CaO emulsion, ignite, digest with HNO_3, and precipitate solution (containing only a little iron) with Mo.

1245. Arnold (*C. N.*, xliii., 147, 186, &c.).—Fe_2Cl_6 and free HCl cause low results; in any case all the P is not precipitated unless part of the iron is removed. Recommends an acetate-Mo-Mg process.

1246. Mackintosh (*C. N.*, liii., 223).—On treating iron with HCl, all the P is not liberated as gas. Boil with SO_2, mix residue and the absorbing solution, and make acetate-Mo estimation (see 1338).

1247. Smith (*C. N.*, xlv., 195) and Macfarlane and Wilson (*J. I. S. I.*, 1893, i., 406).—Acetate-Mo, acetate-Mg, and direct precipitation with Mo processes described.

1248. Pattinson and Stead (*J. I. S. I.*, 1888, i., 181).—As, when present, may be removed by repeated evaporation with FeO in HCl, precipitation with H_2S, or adding Zn to form arsenic hydride.

1249. Benezat (*J. I. S. I.*, 1895, i., 505).—Eliminate As by evaporating ferric solution with HCl and Na_2SO_3. 0·1 per cent As does not interfere when the precipitation is made at 45° C. Compares results by direct weighing, ignition, $SnCl_2$ colour test, and $KMnO_4$ titration of the PMo.

1250. Campbell (*J. I. S. I.*, 1891, i., 436).—Oxalic acid added to HCl solution of the ore reduces As to As_2O_3, and HCl evaporation eliminates it.

1251. Pattinson (*J. C. C. I.*, 1893, 119).—Reduce solution of ore with $Na_2S_2O_3$, precipitate As with ZnS, and P from the filtrate (as ferric phosphate) with $BaCO_3$. Finish as usual.

1252. Schneider (*J. I. S. I.*, 1893, ii., 529).—As is precipitated with the P only when the solution is a nearly neutral one.

1253. Babbitt (*J. I. S. I.*, 1895, i., 134).—As is precipitated with the P beyond 25° C. At that temperature five minutes' shaking precipitates all the P, but the PMo is very finely divided.

1254. Schneider (*J. I. S. I.*, 1897, ii., 497).—A careful investigation of the best conditions for precipitating P. As comes down at ordinary temperatures; Mo in acid solutions is reduced by Zn to Mo_2O_3, but is readily re-oxidised by the air.

1255. Reis (*J. I. S. I.*, 1889, i., 396).—The rapid methods of estimating P allow very little As to contaminate the precipitate.

1256. Ridsdale (*J. I. S. I.*, 1895, i., 124).—Influence of varying amounts of As on the precipitation of PMo.

1257. Carnot and Goutal (*J. C. S.*, lxxii., ii., 520).—Treatment of the iron with neutral cupric-potassic chloride leaves all the P in the residue; As passes into solution.

1258. Jennings (*J. I. S. I.*, 1888, ii., 331).—Decompose ore with HCl, reduce with SO_2, and boil to precipitate Ti. Fuse the residue, add soluble portion to main filtrate, precipitate P along with a little Fe, and add Mo to the solution thereof as usual.

1259. Baskerville (*J. I. S. I.*, 1893, ii., 538).—Fuse titaniferous iron ore with Na_2CO_3+KNO_3, digest with water, add Fe_2Cl_6 to filtrate, and proceed as above.

1260. Pattinson (*J. S. C. I.*, 1895, 443 and 1022).—Ti interferes with precipitation of P. Add alum to FeO solution, precipitate $AlPO_4$, fuse, remove soda titanate, and precipitate P as usual. Hogg finds that Ti retards, but does not prevent, the precipitation of any P.

1261. Tamm (*J. I. S. I.*, 1887, ii., 365).—The P must be determined in the basic acetate of iron precipitated from the solution of the Fe-Mn alloy.

1262. Meinecke (*J. I. S. I.*, 1888, i., 378).—Manganese interferes in no way with the direct precipitation of P with Mo.

1263. Metz (*J. I. S. I.*, 1891, ii., 324) and Zimmermann (*J. S. C. I.*, 1893, 293).—The PMo is weighed in a specific gravity bottle; its actual weight being deduced from its known specific gravity (3·252).

1264. Ziegler (*C. N.*, lxvi., 298).—The ferro-chromium is fused with $NaNO_3$+KHO, dissolved in HCl+HNO_3, HCl eliminated, and P estimated as usual.

1265. Hempel (*J. S. C. I.*, 1890, 111).—Phosphor-tin is decomposed in a current of Cl, and P precipitated with Mo.

1266. Woodbridge (*J. I. S. I.*, 1889, ii., 476).—P exists in ores chiefly as apatite, and therefore merely boiling with nitric acid and adding Mo to the filtrate serves to estimate it.

1267. Mixer (*J. I. S. I.*, 1896, ii., 454; and 1897, ii., 509).—The P in the insoluble residue of an ore is estimated after the manner of 1270.

1268. Lychenheim (*J. I. S. I.*, 1894, i., 620).—The P of coal is all in the ash, and can be completely extracted with HCl.

1269. Campredon (*C. N.*, lxxv., 8).—The ash of the fuels must be fused with Na_2CO_3; treatment with HCl merely does not dissolve out all the P. Also Crobaugh (*J. S. C. I.*, 1893, 1061).

1270. Norris (*J. I. S. I.*, 1894, ii., 500).—Dissolve ash with HCl+HF, eliminate these with HNO_3, and precipitate with Mo.

1271. Gladding (*C. N.*, lxxvii., 32).—PMo of constant composition. Direct weighing on tared papers for large amounts; final washing with alcohol.

1272. Brunnemann (*C. N.*, lviii., 108).—Digest basic slag with mixture of acids, evaporate at 110° to remove SiO_2, take up in HNO_3, and precipitate with Mo.

1273. Loges (*J. I. S. I.*, 1887, ii., 371).—Digest basic slag with H_2SO_4 in order not to attack phosphides,

which have not the same agricultural value as phosphates. Also Kosmann (*J. C. S.*, l., 489).

1274. Klein (*J. I. S. I.*, 1886, 401 and 1024).—Decompose slag with $KNaCO_3 + KClO_3$, eliminate SiO_2, and add Mo. Boiling HCl does not attack iron phosphide.

1075. Spuller and Kalmann (*J. C. S.*, lxvi., ii., 29).—Formation of silico-molybdate is favoured by $AmNO_3$. Oxidise HNO_3 solution with $KMnO_4$, destroy excess with KNO_2, and add Mo.

1276. Crispo (*J. I. S. I.*, 1892, i., 489).—The amount of PMo formed depends on the proportion of P_2O_5, MoO_3, and N_2O_5 present. The simpler forms of the method are unreliable.

1277. Lipowitz (*C. N.*, i., 264).—Adds tartaric acid in making up the Mo reagent, so that MoO_3 may not be precipitated by an acid, by diluting, or by boiling (see 1210 and 1227).

1278. Juptner (*J. I. S. I.*, 1894, ii., 491).—As 1227. As much as 60 grms. tartaric acid per litre may be used.

1279. Veitch (*J. C. S.*, lxx., ii., 543).—The use of tartaric acid is permissible, but not advantageous.

(To be continued).

ON THE RESULTS OF A SEARCH FOR OTHER SUGARS THAN XYLOSE AND DEXTROSE IN THE PRODUCTS OF THE HYDROLYSIS OF WOOD FROM THE TRUNKS OF TREES.*

By F. H. STORER,
Professor of Agricultural Chemistry, Harvard University.

(Concluded from p. 284).
